The EEG patterns of propofol have been related to its neural circuit mechanisms. The brain states under propofol are readily visible in the unprocessed EEG and the spectrogram (Figs. 50-2, 50-6 and Fig. 50-7, *A*). Propofol acts primarily at $GABA_A$ receptors throughout the brain and spinal cord to enhance inhibition in neural circuits.[73,76] When patients are unconscious from propofol, the EEG shows a characteristic alpha (8 to 12 Hz) oscillation along with slow (0.1 to 1 Hz) oscillations (see Fig. 50-7, *A*).[38,43,77,78] Another phenomenon that is observed in patients who are unconscious from propofol and several other anesthetics is anteriorization, the increase in power in the alpha and beta frequency ranges during unconsciousness across the front of the scalp relative to other areas of the scalp (see Fig. 50-6, *C, D*).[38,41,43] During unconsciousness, the alpha oscillations are highly coherent across the front of the scalp, whereas the slow and gamma oscillations are not coherent.[38,43,78] Highly coherent alpha oscillations have also been identified in animal studies of inhaled anesthetics during unconsciousness.[79] The coherent structure in the alpha oscillations is most likely due to strong alpha oscillations between the thalamus and frontal cortex.[80] The slow oscillations are a marker of fragmented intracortical communication because in the presence of the slow oscillations, cortical neurons spike only in a limited phase dictated by their local slow oscillation.[78] As the slow oscillations are spatially incoherent and spiking is phase limited, communication among brain regions that are separated by more than 1 cm is greatly impeded. With return of consciousness, the alpha and slow oscillations dissipate (see Fig. 50-6, *B*). Understanding how the alpha and slow oscillations arise offers a neural circuit explanation of part of the mechanism through which propofol induces unconsciousness.

Similarly, the EEG patterns of ketamine (see Fig. 50-7, *B*)[25] and dexmedetomidine (see Fig. 50-8, *A, B*)[29,30] are distinctive and can be related to the mechanisms of actions of these drugs in the brain and central nervous system.[2,37] Ketamine acts principally by binding to *N*-methyl-D-aspartate (NMDA) receptors.[37,81] Thus, with small to moderate doses, ketamine has its primary effect by blocking excitatory glutamatergic inputs to inhibitory interneurons.[82,83] Impaired control over pyramidal neurons is why increases in cerebral metabolism, and the appearance of altered behavioral states including hallucinations, dissociative states, euphoria, and dysphoria are common with low-dose ketamine. Brain regions, such as the limbic system, cortex, and thalamus, continue to communicate but with much less regulatory control from the inhibitory interneurons; that is, information processing proceeds in the absence of proper coordination in time and space.[2,37] Increasing the dose of ketamine blocks the NMDA receptors on the excitatory glutamatergic neurons, and eventual loss of consciousness, as when ketamine is used to induce anesthesia.[84] The increased activity of pyramidal neurons throughout the brain is consistent with the high frequency (20 to 30 Hz) oscillations that are commonly observed in the EEG of patients receiving ketamine (see Fig. 50-7, *B*).[25,85] This high-frequency EEG activity helps explain why EEG-based indices often give high values in patients receiving ketamine.

Dexmedetomidine induces its sedative effects primarily by actions on presynaptic α2-adrenergic receptors on neurons that project from the locus ceruleus.[86-88] Binding of dexmedetomidine results in a decrease in the release

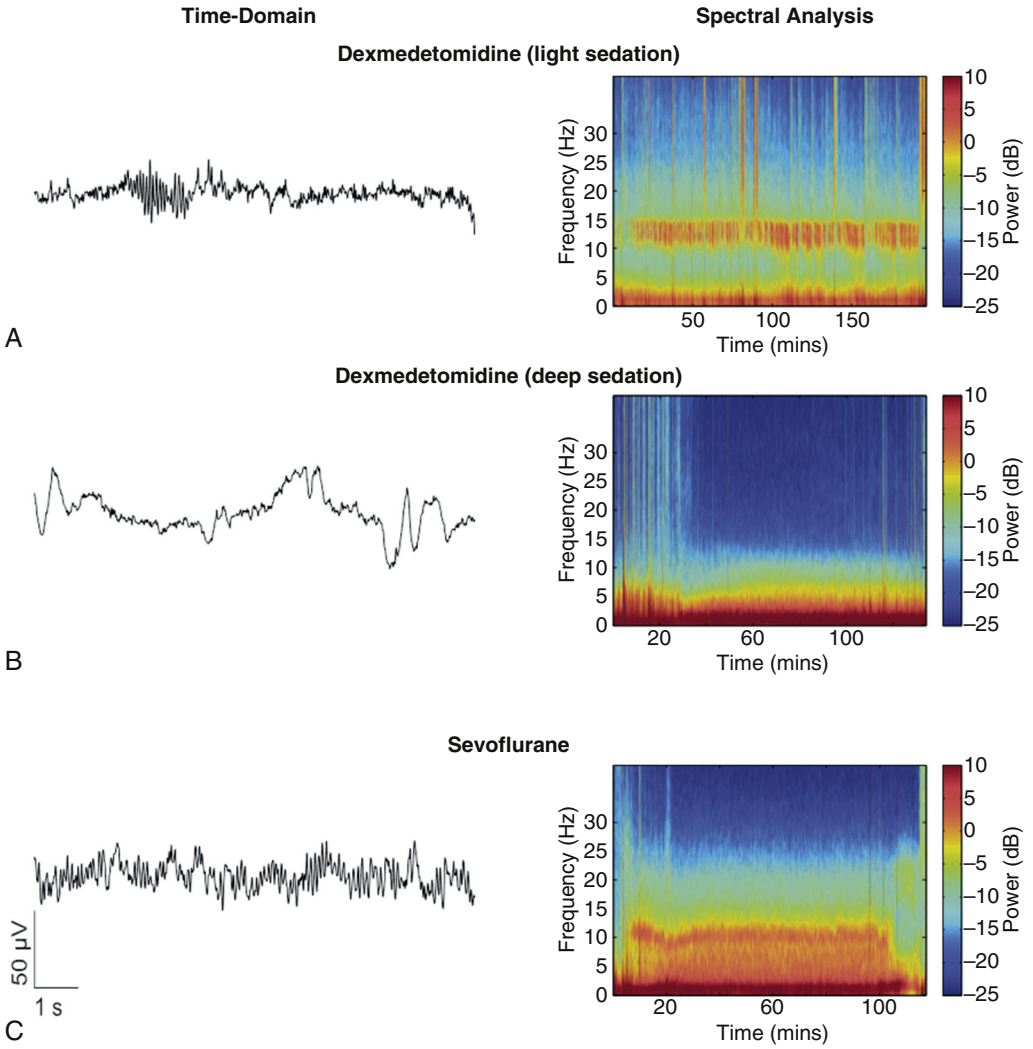

Figure 50-8. Time-domain and spectral electroencephalogram (EEG) signatures of common anesthetics. The *left column* shows a 10-second time-domain (unprocessed) segment of the EEG for each anesthetic. The *right column* shows several minutes of the spectrogram (density spectral array) computed from the EEG for each anesthetic. **A,** The dexmedetomidine spectrogram for light sedation shows spindle (9 to 15 Hz) oscillations and the slow oscillations similar to the EEG patterns observed in nonrapid eye movement (NREM) sleep stage 2. The spindle is apparent in the unprocessed EEG trace (red underscore). The spindles are intermittent and have less intensity than the alpha oscillations observed with propofol. **B,** The spectrogram for deep dexmedetomidine sedation is associated with an absence of spindles and a predominance of slow waves similar to the slow waves seen in NREM sleep stage 3, termed *slow-wave sleep*. **C,** The sevoflurane spectrogram is similar to propofol with the addition of oscillatory activity in the theta band from 4 to 8 Hz. *LOC,* Loss of consciousness; *ROC,* recovery of consciousness.

of norepinephrine from these neurons.[89-91] Loss of the norepinephrine-mediated inhibition to the preoptic area of the hypothalamus leads to activation of the preoptic area's GABAergic and galanergic inhibitory inputs to most of the principal arousal centers in the midbrain, pons, basal forebrain, and hypothalamus.[92] Activation of inhibitory inputs from the preoptic area is postulated to be an essential component of how nonrapid eye movement (NREM) sleep is initiated.[93,94] This explains why light sedation with dexmedetomidine shows spindle-intermittent bursts of 9 to 15 Hz oscillations and slow-wave patterns in the EEG that closely resemble NREM sleep stage 2 (see Fig. 50-8, *A*). In contrast, deep sedation with dexmedetomidine shows a slow-wave EEG pattern that closely resembles the patterns observed in NREM sleep stage 3 or slow-wave sleep (see Fig. 50-8, *B*).

Sevoflurane, like the other inhaled anesthetics, produces its physiologic and behavioral effects by binding at multiple targets in the brain and spinal cord. These include binding to $GABA_A$ receptors and enhancing GABAergic inhibition, and blocking glutamate release by binding to NMDA receptors, moreover, blocking two-pore potassium channels and hyperpolarization-activated cyclic nucleotide-gated channels.[73] Although debates still exist over the relative importance of these targets, sevoflurane and the other ether anesthetics have distinct EEG signatures. At doses of sevoflurane appropriate for general anesthesia, the EEG shows strong alpha and slow oscillations like propofol, in addition to a strong theta (4 to 8 Hz) oscillation (see Fig. 50-8, *C*). The presence of the theta oscillations creates a distinctive pattern of evenly distributed EEG power from the slow oscillation through the alpha oscillation range.

Although the unprocessed EEG recordings of the anesthetics can look similar, the spectrograms make clear that each anesthetic has a distinct EEG signature. These signatures can be related to the mechanisms through which the drugs act at specific receptors in specific neural circuits to alter arousal. Using the spectrogram to monitor brain function under general anesthesia and sedation is fundamentally different from using EEG-based indices that are predicated on the assumption that different anesthetics can create the same anesthetic state irrespective of mechanism. The differences in the spectral signatures between propofol (see Fig. 50-7, *A*) and ketamine (see Fig. 50-7, *B*) illustrate why the latter often gives a high index reading when clinically the patient is clearly sedated. Similarly, the predominance of the slow-wave oscillations observed during deep dexmedetomidine (see Fig. 50-8, *B*) sedation helps explain why this drug gives low index values consistent with profound unconsciousness yet the patient remains arousable.

These observations suggest that the unprocessed EEG and the spectrogram could be used to monitor the brain states of patients receiving anesthesia care (see Figs. 50-6 to 50-8). Although the spectrogram has been used on many occasions for studies of anesthetic state,[74,75,95] a strategy to use it in conjunction with the unprocessed EEG and the EEG-based indices for management of patients receiving anesthesia care has not been attempted. Furthermore, the spectrogram is easy to compute in real time. Many of the current EEG brain function monitors display both the unprocessed EEG and the spectrogram.[21,48,96] Training anesthesia providers to track brain states under general anesthesia and sedation by reading the unprocessed EEG and the spectrogram is a program being pursued currently in the Department of Critical Care and Pain Medicine of Massachusetts General Hospital (www.anesthesiaeeg.com). Use of the spectrogram to track brain states under general anesthesia and sedation can facilitate direct integration of clinical and research observations from EEG recordings into biophysically based modeling studies that can help to delineate specific, testable hypotheses about neural circuit mechanisms of anesthetic actions.[80,97-99]

NORMALIZED SYMBOLIC TRANSFER ENTROPY

A growing body of information suggests that a key marker or mechanism of unconsciousness under general anesthesia is loss of intracortical connectivity.* The loss of functional connectivity between the frontal and parietal areas is associated with unconsciousness.[84,100] By using the EEG recorded from a montage that includes both frontal and parietal electrodes, a mutual information technique termed normalized symbolic transfer entropy (NSTE) can be used to measure this loss of functional connectivity. When NSTE is used to assess functional connectivity from the parietal area to the frontal cortical area, it is termed feedforward functional connectivity, whereas when it is used to assess functional connectivity from the frontal area to the parietal area, it is termed feedback functional connectivity.

Unconsciousness induced by propofol, sevoflurane, or ketamine has been associated with loss of feedback functional connectivity (Fig. 50-9).[84,100] As a consequence, measuring NSTE to assess functional connectivity could provide a means of monitoring the level of consciousness in patients receiving general anesthesia. The loss of feedback functional connectivity is present for unconsciousness induced by all three anesthetics, suggesting that NSTE does not distinguish among the mechanisms of actions of these anesthetics.[100] Nevertheless, NSTE could still offer a way to track level of consciousness.

A partial answer regarding the mechanism of loss of the feedback functional connectivity for unconsciousness induced by propofol and the inhaled ether anesthetics may be related to anteriorization (see Fig. 50-7, *C*). The recent model by Vijayan and colleagues[99] shows that anteriorization can be explained by the differences in the electrophysiologic properties, such as the resting membrane potentials and ionic currents, in the frontal thalamocortical connections compared with the posterior thalamocortical connections. If the parietal circuits resemble their nearby occipital counterparts neurophysiologically, then the neurophysiologic dynamics that lead to anteriorization could also contribute to loss of feedback functional connectivity. Studies of functional connectivity changes during loss of consciousness due to general anesthesia using the Vijayan model may shed mechanistic light on the differences between changes in feedback connectivity and feedforward connectivity.

At present, the use of NSTE in the operating room is not tractable because it is not possible to compute these mutual information measures in real time.[84] Moreover, the use of NSTE in its current form requires an EEG montage with both frontal and parietal electrodes, unlike the montages used with most current brain function monitors, which use only frontal electrodes.

CLOSED-LOOP ANESTHETIC DELIVERY SYSTEMS

Several clinical studies have recently demonstrated the benefit of closed-loop anesthetic delivery (CLAD) systems as a means of simultaneously monitoring brain function and delivering anesthetic drugs. These studies have been summarized recently.[102,103] The CLAD systems work by using an EEG marker of anesthetic state to define a desired state for maintenance during surgery. The EEG is monitored, the marker is computed from the EEG, and a computer-controlled infusion delivering the anesthetic drug is automatically changed based on the difference between the targeted level of the EEG marker and the actual level of the marker computed from the EEG analysis. Although numerous EEG markers have been used to guide delivery of anesthetics in CLAD systems, the most widely used marker is the BIS index.[24,104] Use of the BIS requires a 20- to 30-second delay in computing updates.[23] Use of a CLAD system leads to maintenance of the desired anesthetic state while delivering significantly less anesthetic drug.[24,105-107] Although most CLAD systems have focused on maintenance of unconsciousness, a recently developed system can control maintenance of unconsciousness and antinociception.[108,109]

Recent simulation studies using rodent and human models, as well as recent experimental studies in rodents,

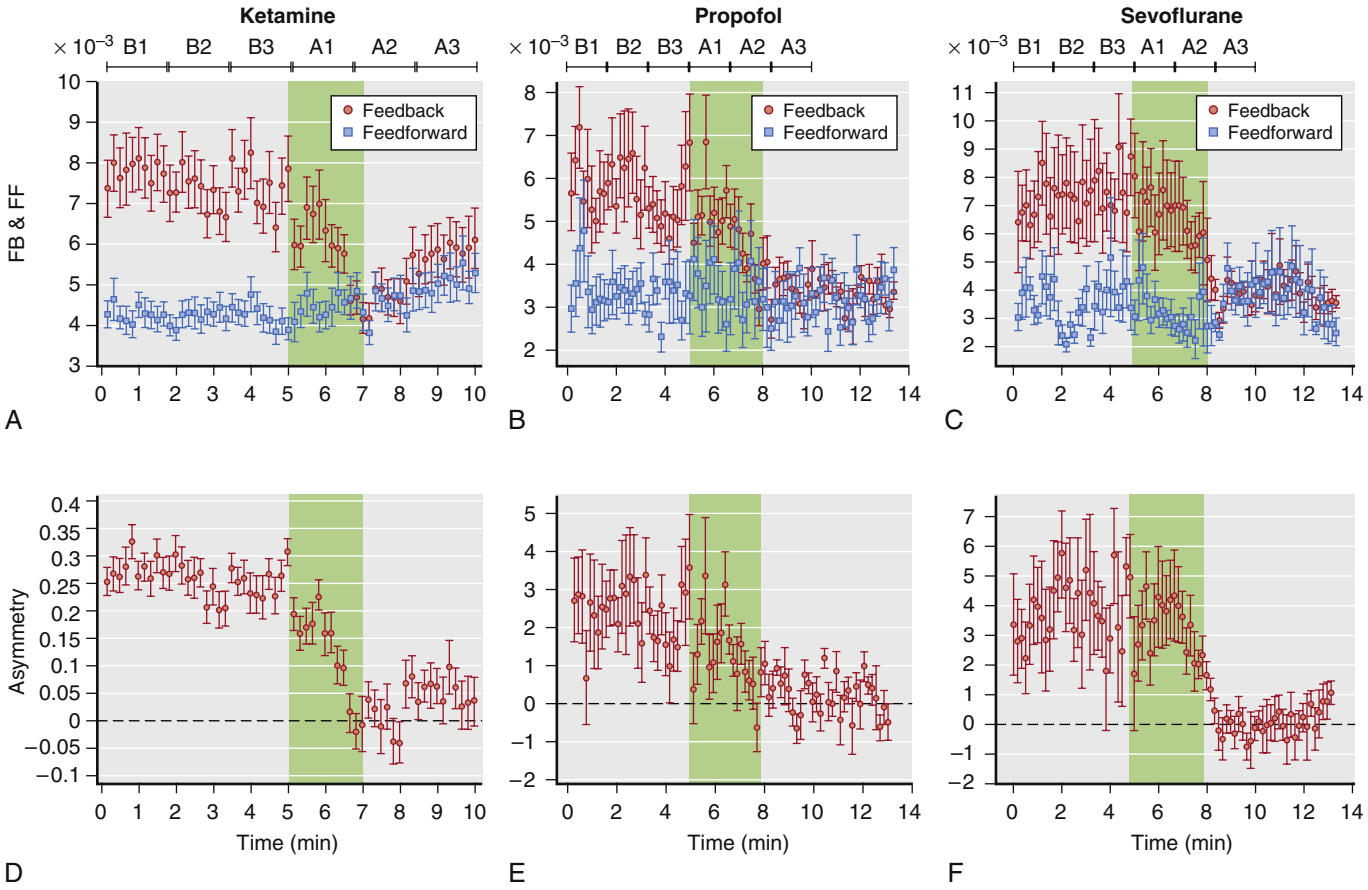

Figure 50-9. Normalized symbolic transfer entropy. An analysis of loss of consciousness induced by ketamine, propofol, and sevoflurane using normalized symbolic transfer entropy. Asymmetry in the change of feedforward (FF) and feedback (FB) connectivity is common to all three anesthetics. The FF (*blue*)/FB (*red*) connections (**A**-**C**) and their associated asymmetry (**D**-**F**) in the frontal–parietal network displayed for (**A** and **D**) ketamine, (**B** and **E**) propofol, and (**C** and **F**) sevoflurane. Green shading highlights induction of general anesthesia. *B1 to B3* define baseline substates. *A1 to A3* define anesthetized substates. There were 30, 9, and 9 subjects in the ketamine, propofol, and sevoflurane groups, respectively. All three anesthetics show a greater loss in FB frontal-parietal connectivity than FF connectivity at loss of consciousness. *(Redrawn from Lee U, Ku S, Noh G, et al: Disruption of frontal-parietal communication by ketamine, propofol, and sevoflurane,* Anesthesiology *118:1264-1275, 2013).*

have shown that highly reliable and accurate CLAD systems can be devised to maintain medical coma by using burst suppression (Fig. 50-2, F) as the control variable.[102,103] A CLAD system recently developed by Shanechi and colleagues[110] uses a stochastic control framework and, as the control variable, the burst suppression probability, which is the instantaneous probability that the brain is suppressed (Fig. 50-10).[110] The burst suppression probability is a more reliable way to track burst suppression than the suppression ratio.[111] The CLAD system precisely tracked the target level of burst suppression. If these results are successfully reproduced in human studies, the CLAD system could offer an automatic and highly efficient way to maintain medical coma in the many patients who require this therapy for multiple days to treat intractable status epilepticus or intracranial hypertension.

No CLAD system has been approved for administering general anesthesia. Many new findings and approaches will probably be reported in the near future because the study of CLAD systems is an active area of research by many investigators.

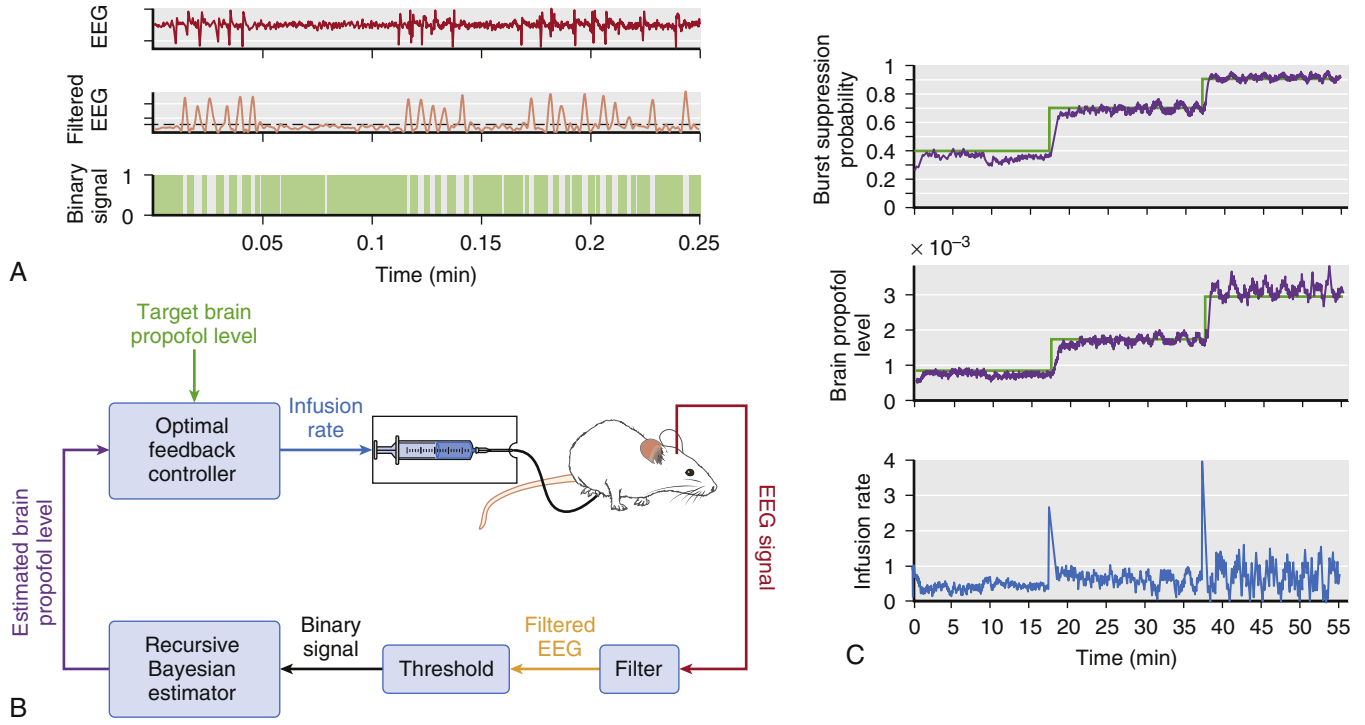

Figure 50-10. An experimental closed loop anesthetic delivery system for control of medical coma by controlling burst suppression. **A,** The electroencephalogram (EEG) of the rat in burst suppression is filtered, thresholded, and converted into binary observations (i.e., 0 for a burst and 1 for a suppression). **B,** A target brain level of propofol is set by specifying a burst suppression probability. The Bayesian estimator estimates the brain level of propofol from the EEG. The controller compares the estimated propofol level with the target level and adjusts the infusion rate every second to maintain the specified target burst suppression probability or, equivalently, the target brain propofol level. **C,** The *top panel* shows that the target burst suppression probability (*green line*) was maintained at 0.4 for 20 minutes, changed to 0.7 for 20 minutes, and then changed to 0.9 for 15 minutes. The estimated burst suppression probability (*purple curve*) tracks exactly the targeted level. The *middle panel* shows the equivalent close tracking of the target brain propofol level (*green curve*) by the estimated propofol level (*purple curve*). The *bottom panel* shows how the controller instantaneously changed the infusion rate to maintain the targeted level of burst suppression. This experimental study establishes the feasibility of real-time control of burst suppression and most likely other states of general anesthesia. *(Redrawn from Shanechi M, Chemali JJ, Liberman M, et al: A brain-machine interface for control of medically-induced coma,* PLoS Comput Biol *9:e1003284, 2013.)*

MONITORING NOCICEPTION

The discussion of monitoring brain states under general anesthesia and sedation has focused largely on monitoring the level of consciousness. Monitoring nociception (i.e., the flow of pain information in the body during surgery) and antinociception, the ability of anesthetics or analgesics to impede nociceptive transmission, are growing areas of investigation. At present, heart rate, arterial blood pressure, and perhaps respiratory rate analyzed in the context of the patient's clinical condition are the most commonly used markers of nociception. These markers are indirect and do not tap directly into nociceptive information processing in the central nervous system. Extensions are being considered. One investigation is using multiple physiologic parameters including heart rate, heart rate variability (0.15 to 0.4 Hz band power), plethysmograph wave amplitude, skin conductance, skin conductance fluctuations, and the derivatives of these signals.[114] A second study recently investigated a measure of surgical stress in comparison to skin conductance fluctuations.[115] A recent review of nociception monitoring noted that most systems currently being studied can rapidly detect nociceptive inputs, but they are not successful in predicting the somatic or autonomic output.[116] At present, there is no approach that provides reliable and reproducible information on nociception during anesthesia care.

Chapter 51

Respiratory Monitoring

HOVIG V. CHITILIAN • DAVID W. KACZKA • MARCOS F. VIDAL MELO

Acknowledgment: The editors and the publisher would like to thank Drs. Stephen M. Eskaros, Peter J. Papadakos, and Burkhard Lachmann, who were contributing authors to this topic in the prior edition of this work. It has served as the foundation for the current chapter.

Key Points

- Intraoperative respiratory monitoring is a fundamental component of standards for basic anesthetic monitoring (see also Chapter 44). Monitoring of oxygenation and ventilation is an absolute requirement for the safe conduct of an anesthetic regimen.
- A thorough understanding of the principles underlying respiratory monitoring is essential for appropriate clinical application.
- Most respiratory monitors in clinical use provide information at the systemic and whole-lung level from which clinical conclusions are attempted regarding the regional lung and tissue-level conditions.
- The degree of invasiveness of the monitors used should be determined by clinical requirements.
- Pulse oximetry is a noninvasive, reliable, and simple method for continuously monitoring the fractional arterial oxygen saturation and is an essential component of respiratory monitoring.
- Ventilation-perfusion mismatch, shunt, and hypoventilation are the most common causes of hypoxemia in the perioperative period. Monitoring of gas exchange can facilitate differentiation of these causes.
- Mixed venous oxygen saturation can be used to monitor the global balance between oxygen delivery and consumption, allowing for make inferences regarding gas exchange, cardiac output, and global oxygen consumption.
- Systems using infrared spectroscopy are used clinically to monitor regional tissue oxygenation. The utility of regional saturation-guided management is being established.
- Capnography is the primary quantitative method to assess ventilation in the perioperative period. Besides providing physiologic information on ventilation, pulmonary blood flow, and aerobic metabolism, capnography is important for verifying endotracheal tube positioning and determining the integrity of the breathing circuit (see also Chapter 55).
- End-tidal carbon dioxide (CO_2) is not always a reliable approximation of arterial CO_2 tension, especially in the presence of significant heterogeneity in the distribution of pulmonary ventilation and perfusion.
- Measurement of the pressures, flows, and volumes associated with ventilation is necessary to optimize mechanical ventilation, as well as to detect pathophysiologic mechanical derangements of the respiratory system (i.e., increased airway resistance or reduced lung compliance).
- Imaging techniques are emerging as important tools for respiratory monitoring. Lung ultrasonography allows for bedside assessment of pulmonary abnormalities, such as pneumothorax, edema, consolidation, and pleural effusions. Electrical impedance tomography provides information on lung aeration and recruitment.
- Current approaches to respiratory monitoring primarily assess pulmonary mechanical and global gas exchange processes. Monitoring of tissue and subcellular respiration remains a desirable goal for future innovation.

OVERVIEW OF RESPIRATORY MONITORING

Respiratory monitoring is a fundamental component of every anesthetic regimen. Its major relevance for maintenance of homeostasis and patients' safety is recognized in its position as a mandatory element in national and international standards for anesthetic monitoring.[1,2] Through the decades, advances in respiratory monitoring have reduced the incidence of anesthetic morbidity and mortality and have opened a new era of safe anesthetic practice.

Respiration is the transport of oxygen (O_2) from the environment to the body cells and the transport of carbon dioxide (CO_2) from those cells to the environment. The concept includes a component of cellular respiration, the process by which cells obtain energy in the form of adenosine triphosphate from the controlled reaction of hydrogen with O_2 to form water.[3] In its broadest sense, respiratory monitoring refers to the assessment of processes involved in the exchange of respiratory gases between the environment and the subcellular pathways where those gases are used and produced (Fig. 51-1).[3] Respiratory monitoring conceptually includes assessment of (1) convective and diffusive gas transport through the branching airway tree and alveoli, (2) equilibration of gases between alveoli and pulmonary capillary blood, (3) mass balance of the distinct regional ventilation and perfusion contributions to produce expired gases and arterial and mixed venous blood, (4) gas transport between the blood and body tissues through the microcirculation, (5) gas diffusion between tissues and mitochondria, and (6) cellular respiration with O_2 use and CO_2 production.

Significant developments in physiologic measurement have enhanced our understanding of these stages of respiratory function during anesthesia. This chapter provides an overview of current and emerging techniques of respiratory monitoring. Despite these technical advances, current instrumentation has limited ability to provide accurate and comprehensive information on respiratory function in patients. Clearly, advances in monitoring all components of respiration are needed.[4,5]

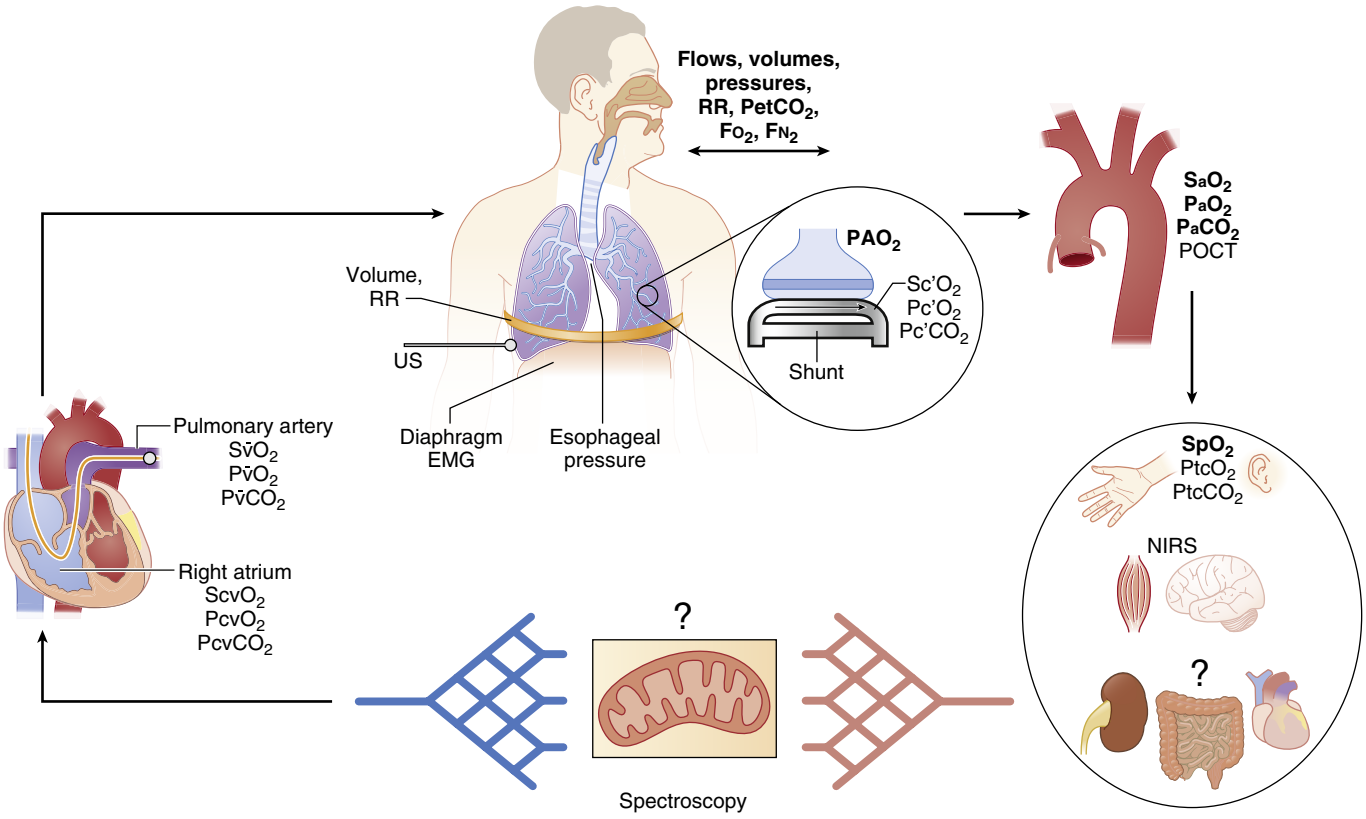

Figure 51-1. Respiratory processes and measurement sites for current respiratory monitoring techniques. Most monitored variables are derived from sites at the entrance of the airway and systemic blood (**bold**) and assess the elements of respiration related to pulmonary mechanics and gas exchange. Pulse oximetry represents a transition between systemic and local tissue oxygenation assessment. Methods for routine and reliable clinical monitoring of respiratory processes at the tissue, cellular, and subcellular levels are limited. *EMG,* Electromyography; F_{N_2}, nitrogen fraction; F_{O_2}, oxygen fraction; *NIRS,* near-infrared spectroscopy; Pa_{CO_2}, arterial partial pressure of carbon dioxide; Pa_{O_2}, arterial partial pressure of oxygen; PAO_2, alveolar partial pressure of oxygen; Pc'_{CO_2}, end-capillary partial pressure of carbon dioxide; Pc'_{O_2}, end-capillary partial pressure of oxygen; Pcv_{CO_2}, partial pressure of central venous carbon dioxide; Pcv_{O_2}, partial pressure of central venous oxygen; $PetCO_2$, partial pressure of end-tidal carbon dioxide; $P\bar{v}_{CO_2}$, partial pressure of mixed venous carbon dioxide; $P\bar{v}_{O_2}$, partial pressure of mixed venous oxygen; *POCT,* point of care testing; Pt_{CO_2}, transcutaneous partial pressure of carbon dioxide; Pt_{O_2}, transcutaneous partial pressure of oxygen; *RR,* respiratory rate; SaO_2, arterial oxygen saturation; Sc'_{O_2}, end-capillary oxygen saturation; Scv_{O_2}, central venous oxygen saturation; $S\bar{v}_{O_2}$, mixed venous oxygen saturation; SpO_2, peripheral oxygen saturation; *US,* ultrasound; *tc,* transcutaneous.

AMERICAN SOCIETY OF ANESTHESIOLOGISTS STANDARDS

The word *monitoring* is often associated with electronic instrumentation, and it is noteworthy that the current American Society of Anesthesiologists (ASA) Standards for Basic Anesthetic Monitoring states in Standard I that "Qualified anesthesia personnel shall be present in the room throughout the conduct of all general anesthetics, regional anesthetics, and monitored anesthesia care" (Box 51-1). This precedes reliance on any instrumentation (as implied in Standard II) and clearly indicates that the anesthesia provider brings essential expertise and interpretation to monitoring beyond information provided by equipment. Increased safety in our specialty lies primarily in high-quality training and environments that encourage continuing education, and not exclusively on new technology.[6] The ASA Standards for Basic Anesthetic Monitoring reflect monitoring principles during anesthesia established in the 1980s and should be systematically followed (see Box 51-1).[7] These standards represent a foundation to additional monitoring according to clinical requirements.

PHYSICAL EXAMINATION

The physical examination is still an essential component of perioperative respiratory monitoring. It provides critical information for diagnosis and treatment and may be the first indication of alterations in a patient's status that require intervention. Physical examination has limitations, but it routinely allows for detection of information relevant for a patient's management.

Respiratory monitoring starts with inspection of the patient, either when the patient is awake or during anesthesia. In elective cases, appropriate investigation of causes of abnormal presentations should be completed before surgery. In emergency situations, careful inspection may be the only source of information for timely and accurate anesthetic management. The perception of respiratory distress should be followed by a search for specific causes. Assessment of the respiratory rate provides a measure of the breathing pattern. For instance, during sepsis the respiratory rate is significantly correlated with disease severity.[8] Anatomic signs relevant to respiration include (but are not limited to) deformities of the chest wall and spine, goiter, tracheostomy scar, and tracheal deviation. Functional

BOX 51-1 ***American Society of Anesthesiologists Standards for Basic Anesthetic Monitoring Related to Respiratory Monitoring***

1. Standard I

Qualified anesthesia personnel shall be present in the room throughout the conduct of all general anesthetics, regional anesthetics, and monitored anesthesia care.

2. Standard II

During all anesthetics, the patient's oxygenation, ventilation, circulation, and temperature shall be continually evaluated.

2.1. Oxygenation

2.1.1 Objective: To ensure adequate oxygen concentration in the inspired gas and the blood during all anesthetics.

2.2. Methods

2.2.1 Inspired gas: During every administration of general anesthesia using an anesthesia machine, the concentration of oxygen in the patient breathing system shall be measured by an oxygen analyzer with a low oxygen concentration limit alarm in use.*

2.2.2 Blood oxygenation: During all anesthetics, a quantitative method of assessing oxygenation such as pulse oximetry shall be employed.* When the pulse oximeter is utilized, the variable pitch pulse tone and the low threshold alarm shall be audible to the anesthesiologist or the anesthesia care team personnel.* Adequate illumination and exposure of the patient are necessary to assess color.*

3. Ventilation

3.1. Objective

To ensure adequate ventilation of the patient during all anesthetics.

3.2. Methods

3.2.1 Every patient receiving general anesthesia shall have the adequacy of ventilation continually evaluated. Qualitative clinical signs such as chest excursion, observation of the reservoir breathing bag, and auscultation of breath sounds are useful. Continual monitoring for the presence of expired carbon dioxide shall be performed unless invalidated by the nature of the patient, procedure, or equipment. Quantitative monitoring of the volume of expired gas is strongly encouraged.*

3.2.2 When an endotracheal tube or laryngeal mask is inserted, its correct positioning must be verified by clinical assessment and by identification of carbon dioxide in the expired gas. Continual end-tidal carbon dioxide analysis, in use from the time of endotracheal tube/laryngeal mask placement, until extubation/removal or initiating transfer to a postoperative care location, shall be performed using a quantitative method such as capnography, capnometry or mass spectroscopy.* When capnography or capnometry is utilized, the end-tidal carbon dioxide alarm shall be audible to the anesthesiologist or the anesthesia care team personnel.*

3.2.3 When ventilation is controlled by a mechanical ventilator, there shall be in continuous† use a device that is capable of detecting disconnection of components of the breathing system. The device must give an audible signal when its alarm threshold is exceeded.

3.2.4 During regional anesthesia (with no sedation) or local anesthesia (with no sedation), the adequacy of ventilation shall be evaluated by continual observation of qualitative clinical signs. During moderate or deep sedation the adequacy of ventilation shall be evaluated by continual observation of qualitative clinical signs and monitoring for the presence of exhaled carbon dioxide unless precluded or invalidated by the nature of the patient, procedure, or equipment.

From American Society of Anesthesiologists: Standards for basic anesthetic monitoring, *2011.* <https://www.asahq.org/~/media/For%20Members/documents/Standards%20Guidelines%20Stmts/Basic%20Anesthetic%20Monitoring%202011.pdf>. *(Accessed 08.08.14.)*

*Under extenuating circumstances, the responsible anesthesiologist may waive the requirements marked with an asterisk (*); it is recommended that when this is done, it should be so stated (including the reasons) in a note in the patient's medical record.

†Note that "continual" is defined as "repeated regularly and frequently in steady rapid succession," whereas "continuous" means "prolonged without any interruption at any time."

elements to be noticed include the components of inspiration and expiration (diaphragmatic versus thoracic), duration and difficulty of inspiration and expiration, paradoxical chest wall motion, use of accessory muscles, central and peripheral cyanosis, pallor, wheezing, stridor, cough and sputum, aphonia, splinting, and clubbed fingers. Neck vein distention should be examined as an indicator of cardiac contribution to respiratory distress; this sign is a less reliable indicator of central venous pressure during significant dyspnea. Attention should be paid to painful respiration in trauma patients, as well as the possibility of flail chest, pericardial tamponade, hemothorax, pneumothorax, pulmonary contusion, and tension pneumothorax.

Characterization of breath sounds during anesthesia is another essential skill in physical diagnosis. Ambient noise, individual hearing limitations, and the acoustic properties of the stethoscope all influence the anesthesiologist's clinical judgment. A stethoscope of sufficient quality allows for identification of distinctive normal and abnormal breath sounds: vesicular sounds, rhonchi, wheezes, fine and coarse crackles, inspiratory stridor, and pleural friction. A clear understanding of the acoustic mechanisms of each of these sounds is essential for adequate clinical assessment.[9,10]

PULSE OXIMETRY

See also Chapter 44.

PHYSIOLOGIC FUNDAMENTALS

The primary roles of the cardiorespiratory system are the uptake and delivery of O_2 to the body. O_2 delivery (D_{O_2}) is quantified as the product of arterial O_2 content (CAO_2) and cardiac output (see Chapter 19). CAO_2 (in milliliters of O_2 per 100 mL of blood [hemoglobin—Hb], mL/100 mL) is calculated as:

$$CAO_2 = (1.34 \times SaO_2 \times Hb) + 0.0031 \times PaO_2 \qquad [1]$$

where 1.34 mL/g is the O_2 binding capacity of Hb (Hüfner constant, theoretically 1.39), which experimentally ranges between 1.31 and 1.37 mL/g, mostly because of the presence of small amounts of other Hb forms[11]; SaO_2 is the Hb O_2 saturation of the arterial blood (percent saturation/100); Hb is the concentration of Hb in the arterial blood (g/100 mL); 0.0031 is the solubility of O_2 in blood (mL O_2/100 mL blood/mm Hg); and PaO_2 is the arterial partial pressure of O_2 (mm Hg). As can be understood from the equation, SaO_2 is a major determinant of O_2 content and consequently D_{O_2}.

Four species of Hb are found in adult blood: oxygenated Hb (O_2Hb), deoxygenated Hb (deO_2Hb), carboxyhemoglobin (COHb), and methemoglobin (MetHb). Under normal circumstances, the concentrations of COHb and MetHb are small (1% to 3% and less than 1%, respectively). *Functional* O_2 saturation (SaO_2) refers to the amount of O_2Hb as a fraction of the total amount of O_2Hb and deO_2Hb and is expressed as:

$$\text{Functional } SaO_2 = \frac{O_2Hb}{O_2Hb + deO_2Hb} \times 100\% \qquad [2]$$

The O_2Hb fraction or *fractional* saturation is defined as the amount of O_2Hb as a fraction of the total amount of Hb[12]:

$$\text{Fractional } SaO_2 = \frac{O_2Hb}{O_2Hb + deO_2Hb + COHb + MetHb} \times 100\% \qquad [3]$$

SaO_2 is a function of PaO_2. The relationship between the two is described by the O_2Hb dissociation curve (Fig. 51-2). As can be appreciated by inspection of the curve, the relationship is not linear. This has important consequences. One is that a high SaO_2 cannot discriminate between normoxic and hyperoxic conditions; this can be relevant when attempting to limit O_2 exposure in neonates or in patients at risk for O_2 toxicity (see also Chapter 95). Another consequence is that a large numeric change in PaO_2 at the flat portion of the curve (PaO_2 approximately >70 mm Hg) has relatively small consequences in terms of blood O_2 content. Furthermore, changes in temperature, pH, partial pressure of CO_2 in arterial blood ($Paco_2$), and erythrocyte 2,3-diphosphoglycerate concentration can shift the curve such that the same SaO_2 can be present under a range of different O_2 partial pressures (PO_2). This is relevant given that diffusion from the microcirculation to tissue depends on PO_2 gradients.

MEASUREMENT PRINCIPLES

Oximetry

Oximetry is the measurement of the O_2 saturation of Hb. It is an application of the Beer-Lambert law (Equation 4), which relates the transmission of light through a solution

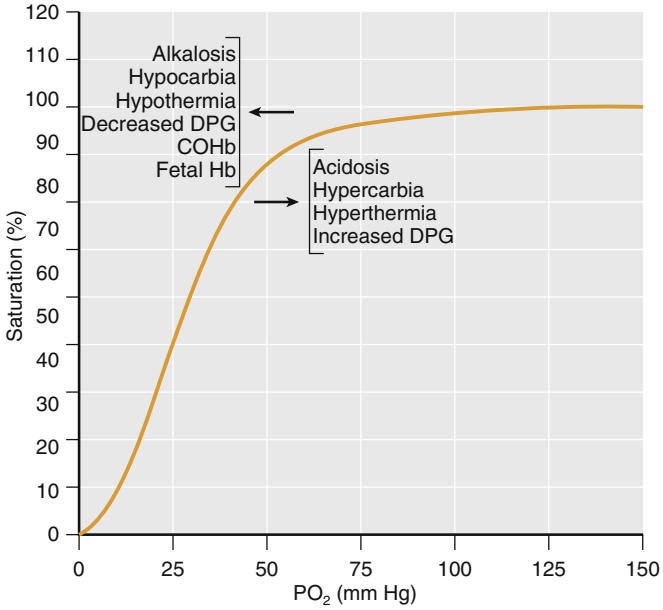

Figure 51-2. Oxyhemoglobin dissociation curve. The relationship between oxyhemoglobin saturation and the partial pressure of oxygen (PO_2) is nonlinear and affected by a number of different factors such as pH, partial pressure of carbon dioxide, and temperature. Given the nonlinear nature of the curve, it is difficult to determine the PO_2 at the higher range of oxygen saturations. *COHb,* Carboxyhemoglobin; *DPG,* 2,3-diphosphoglycerate; *Hb,* hemoglobin. *(Redrawn from Longnecker DE, Brown DL, Newman MF, Zapol WM, editors:* Anesthesiology, *ed 2, New York, 2012, McGraw-Hill.)*

to the concentration of the solute in the solution.[13] For each solute in a solution,

$$I_{trans} = I_{in} e^{-DC\varepsilon} \quad [4]$$

where I_{trans} is the intensity of transmitted light, I_{in} is the intensity of the incident light, e is base of the natural logarithm, D is the distance the light is transmitted through the solution, C is the concentration of the solute, and ε is the extinction coefficient of the solute.

The concentration of a single solute in solution can be calculated by measuring the amount of light transmitted through the solution as long as the other variables are known. For a solution containing multiple solutes, the calculation of the concentrations of the different solutes requires that light absorption be measured at a number of different wavelengths at least equal to the number of solutes. In a sample of blood in a cuvette, the absorption of a given wavelength of light passing through the blood depends on the concentrations of the four species of Hb. Figure 51-3 illustrates the extinction coefficients of the four species of Hb for wavelengths of light along the visible spectrum. To measure the concentrations of all four types of Hb in a sample of blood, light absorption of at least four different wavelengths must be measured. This measurement is typically conducted using a co-oximeter. A co-oximeter uses the principle of oximetry to measure the SaO_2 as well as the concentrations of other Hb species in a blood sample. Co-oximetry is considered the gold standard for SaO_2 measurements and is relied on when pulse oximetry readings are inaccurate or unobtainable.

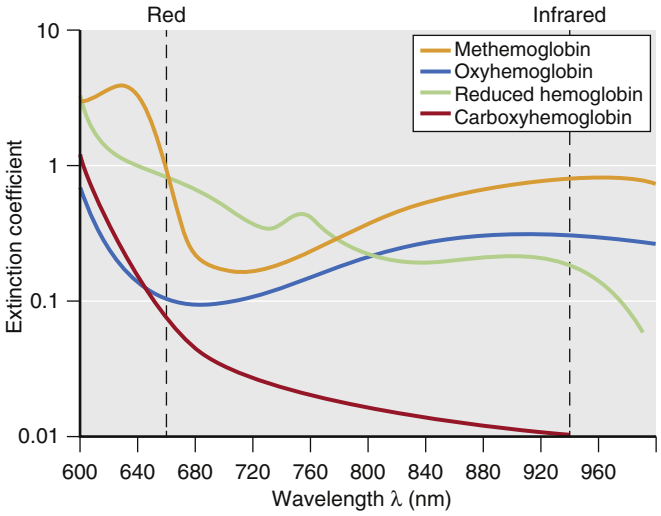

Figure 51-3. Extinction coefficients of the four species of hemoglobin for wavelengths of light across the visible spectrum. The *vertical lines* indicate the wavelengths for red and infrared light that are used in pulse oximeters. The differences in the extinction coefficients of oxyhemoglobin and reduced hemoglobin (deoxygenated hemoglobin) are pronounced at these wavelengths. The extinction coefficients of carboxyhemoglobin and methemoglobin are similar to those of oxyhemoglobin and reduced hemoglobin, respectively, at 660 nm. *(Redrawn from Tremper KK, Barker SJ: Pulse oximetry,* Anesthesiology *70:98-108, 1989.)*

Pulse Oximetry

Standard pulse oximetry aims to provide a noninvasive, in vivo, continuous assessment of functional SaO_2. Pulse oximeter readings are denoted as SpO_2. The history of the development of pulse oximetry is reviewed in detail in the literature.[14]

Pulse oximetry takes advantage of the pulsatility of arterial blood flow to provide an estimate of SaO_2 by differentiating light absorption by arterial blood from light absorption by other components. When compared with in vitro oximetry of an arterial blood sample, the challenges of obtaining SaO_2 in vivo are to ensure that the light is sampling arterial blood and to account for its absorption by other tissues. As illustrated in Figure 51-4, light absorption by tissue can be divided into a pulsatile component, historically referred to as AC, and a nonpulsatile component, referred to as DC. In a standard pulse oximeter, the ratio (R) of AC and DC light absorption at two different wavelengths is calculated. The wavelengths of light are selected to maximize the difference between the ratios of the absorbances of O_2Hb and deO_2Hb (see Fig. 51-3). Typically used wavelengths of light are 660 and 940 nm. At 660 nm, light absorption is greater by deO_2Hb than by O_2Hb. At 940 nm, light absorption is greater by O_2Hb than by deO_2Hb.

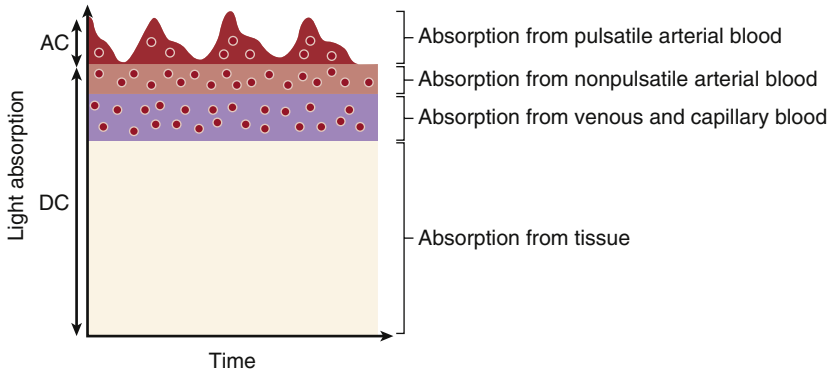

Figure 51-4. Schematic of the pulse principle. Absorption of light passing through tissue is characterized by a pulsatile component (AC) and a nonpulsatile component (DC). The pulsatile component of absorption is the result of arterial blood. The nonpulsatile component derives from arterial, venous, and capillary blood and the remainder of the tissues. *(Redrawn from Severinghaus JW: Nomenclature of oxygen saturation,* Adv Exp Med Biol *345:921-923, 1994.)*

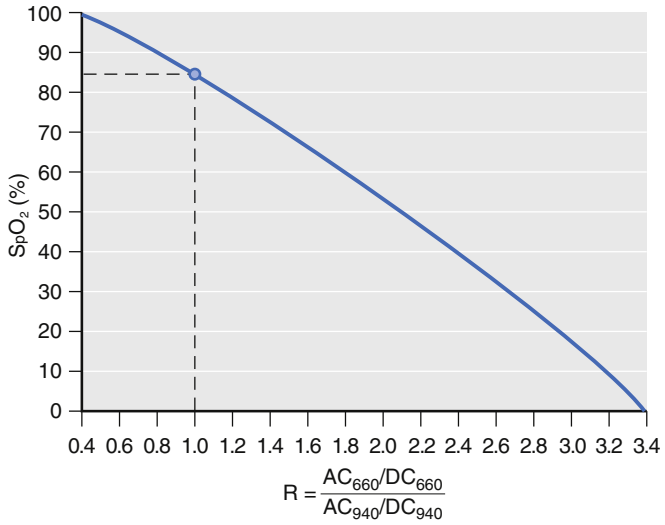

Figure 51-5. Typical pulse oximeter calibration curve relating oxygen saturation to the R value. These curves are developed using healthy volunteers and incorporated into the pulse oximeter. *SpO_2,* Peripheral oxygen saturation. See Figure 51-4 legend for explanation of AC and DC. *(Redrawn from Severinghaus JW: Nomenclature of oxygen saturation,* Adv Exp Med Biol *345:921-923, 1994.)*

$$R = \frac{AC_{660}/DC_{660}}{AC_{940}/DC_{940}} \quad [5]$$

where AC_{660}, AC_{940}, DC_{660}, and DC_{940} are the AC and DC components for the 640- and 940-nm wavelengths.

This ratio (R) is then empirically related to O_2 saturation based on a calibration curve internal to each pulse oximeter[13] (Fig. 51-5). Each manufacturer develops its own calibration curve by having volunteers breathe hypoxic gas mixtures to create a range of SaO_2 values between 70% and 100%. The international standard for pulse oximeter manufacture, ISO 80601-2-61-2011, requires an accuracy of up to a 4% error over a range of SaO_2 from 70% to 100%. Most manufacturing literature reports an accuracy of ± 2% to 3% SpO_2 over this range.[15]

A pulse oximeter probe is composed of a light emitter and a photodetector. Transmission pulse oximetry involves placement of the emitter and detector on opposite sides of the tissue being measured, usually a finger. Reflectance pulse oximetry probes have the emitters and detector arranged on the same side. They are typically placed on the forehead. In a typical pulse oximeter, two light-emitting diodes (LEDs) are used to emit light at the two wavelengths. During operation, each LED is turned on and off in sequence. The photodetector measures transmission of light from each LED. When both LEDs are turned off, the photodetector measures ambient light and subtracts it from the signals obtained throughout the remainder of the cycle.[16]

Multiwavelength pulse oximeters have been developed that use additional wavelengths of light to allow for the continuous noninvasive measurement of total Hb concentration (SpHb),[17] as well as concentrations of MetHb and COHb.[18] The accuracy of SpHb in operative and intensive care unit (ICU) settings is not clear as compared with laboratory measurements (see also Chapter 61).[19-21] However, few of the measurements reported were obtained in patients with Hb concentrations in the 6 to 10 mg/dL range used for transfusion decisions.[22] Another limitation is that SpHb readings may be absent or unreliable under conditions of low peripheral perfusion.[23] To date, noninvasive COHb measurements have not shown enough precision to replace laboratory measurements.[23,24] Pulse oximetry–based MetHb measurements with a newer device are accurate, even under conditions of hypoxia.[25]

Pulse oximetry has been an integral component of intraoperative anesthetic management since the first set of anesthetic monitoring standards was introduced in 1986.[7] It was adopted as a minimum monitoring standard by the ASA the same year and has subsequently been defined as a minimum standard for intraoperative monitoring by the World Federation of Societies of Anaesthesiologists (WFSA) and the World Health Organization (WHO).[26] The use of pulse oximetry is a part of the WHO safe surgery checklist.[27]

Universal pulse oximetry has been recommended by the U.S. Secretary of Health and Human Services to screen newborns for critical congenital heart disease.[28,29] Use of a clinical algorithm based on detection of SpO_2 lower than 95% in right upper or lower limbs or more than a 2% difference led to a sensitivity of 75% in suspected cases and 58% in cases that were not suspected. When this modality is combined with a routine anomaly scan and newborn physical examination screening, 92% of critical congenital heart disease lesions can be identified.[30,31]

Although a useful monitor for the early detection of hypoxemia, pulse oximetry has not reduced the incidence of postoperative complications.[32-34] In the largest randomized controlled trial investigating perioperative pulse oximetry (in 20,802 patients), a nineteenfold increase was noted in the incidence of diagnosed hypoxemia in the pulse oximetry group in both the operating room (OR) and the postanesthetic care unit.[33] Furthermore, the use of the oximeter was associated with a significant decrease in the rate of myocardial ischemia.[33] However, no significant difference was reported in the rate of complications, outcome, mean hospital stay, or in-hospital deaths between the two groups. Because this result was obtained in a population of primarily healthy patients, the sample size may have been insufficient to detect an effect.[35] In fact, one study indicated that early detection of deterioration of SpO_2 and heart rate with pulse oximetry led to fewer rescue events and a decreased need to escalate care (patient rescue and ICU transfers).[36]

Photoplethysmography. Along with measuring O_2 saturation, the pulse oximeter can also be used as a photoplethysmograph. Because the absorption of light is proportional to the amount of blood between the transmitter and photodetector, changes in the blood volume are reflected in the pulse oximeter trace (Fig. 51-6).[37] During anesthesia, the plethysmographic trace is affected by changes in blood volume pulsations, which depend on the distensibility of the vessel wall, as well as on the intravascular pulse pressure.[37] Variations in the amplitude of the pulse oximetry plethysmographic waveform (ΔPOP) have been shown to predict fluid responsiveness in mechanically ventilated patients.[38] An index derived from

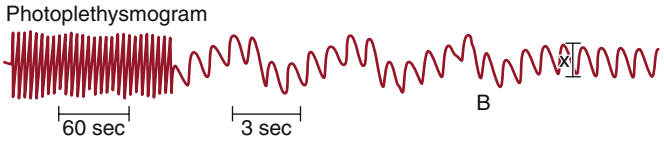

Figure 51-6. Photoplethysmograph recorded at two speeds demonstrating respiratory variation. At time point B, ventilation has been stopped, and no variation is observed. The plot illustrates the effect of intrathoracic blood volume in the pulse oximeter trace. The variation in the trace with respiration is associated with the fluid responsiveness of the patient. *(Redrawn from Dorlas JC: Photo-electric plethysmography as a monitoring device in anaesthesia,* Br J Anaesth *57:524, 1985.)*

the percentage of difference between the maximum and minimum amplitudes of the plethysmographic waveform during a respiratory cycle (PVI, Pleth Variability Index) has been incorporated into a commercially available pulse oximeter and used to quantify ΔPOP and predict fluid responsiveness.[39,40] Several small studies have shown it to be a reasonably reliable indicator of fluid responsiveness intraoperatively and in critically ill patients.[41] This index is more reliable in mechanically ventilated patients than in spontaneously breathing patients and is compromised by the presence of arrhythmias.[41] PVI-based goal-directed fluid management improves outcomes in major abdominal surgical procedures.[42]

LIMITATIONS AND SOURCES OF ERROR

SpO_2 is an estimate of SaO_2. As a consequence, it does not provide information about tissue oxygenation. SpO_2 is a measurement of functional and not fractional SaO_2, and the presence of other Hb species can significantly affect the accuracy of the measurements. Because of the nonlinearity of the Hb dissociation curve, at high saturations hyperoxia cannot be easily detected by SpO_2 measurements, whereas at low saturations such as at altitude, small changes in PaO_2 can produce large changes in SpO_2. Variability in the actual in vivo Hb dissociation curve is significant. A study in 10,079 samples showed that at a PaO_2 of 60 ± 4 mm Hg (8.0 ± 0.5 kPa), SaO_2 ranged between 69.7% and 99.4%, and at an SaO_2 of 90 ± 2%, the PaO_2 range was 29 to 137 mm Hg (3.8 to 18.3 kPa).[43] These measurements illustrate that knowledge of the individual Hb dissociation curve is important for correct interpretation of SaO_2 and PaO_2. Because of the manner in which calibration curves are obtained, SpO_2 accuracy is reduced at values lower than 70% to 75%. Changes in SpO_2 do not always reflect equal changes in SaO_2.[44,45] Pulse oximetry does not provide information about acid-base status.

Certain conditions can lead to inaccuracies in pulse oximeter readings (Table 51-1). These conditions include decreased perfusion, motion artifact, low SaO_2, variant Hb types, the presence of intravascular dyes, and the presence of nail polish.

The calibration of pulse oximeters is based on curves obtained in normal individuals under experimental conditions. As such, findings are limited in their accuracy at SaO_2 values greater than 70%. At SaO_2 levels lower than 70%, a positive or negative bias of the SpO_2 value can be observed, depending on the manufacturer of the pulse oximeter.[46] Manufacturers have developed pulse oximeters with increased accuracy at saturations as low as 60%. Preliminary data suggest that these probes may be useful in neonates with cyanotic congenital heart disease.[47]

Hypoperfusion leads to a reduction in the amplitude of the pulsatile component of the waveform, thus giving rise to lower readings. Significantly erroneous reductions in SpO_2 readings may be observed for systolic blood pressures lower than 80 mm Hg.[48] Motion artifact can produce considerable error in the pulse oximeter reading. Manufacturers have developed advanced proprietary signal processing algorithms that effectively filter out noise caused by motion.[49,50]

With continued clinical use, the performance of the LEDs in the probe may be degraded, leading to inaccuracy of the SpO_2 value outside of the range specified by the manufacturer. These inaccuracies are expected to be more pronounced at lower saturations (i.e., <90%).[15]

The presence of additional species of Hb can also generate erroneous pulse oximeter readings. As outlined earlier, the function of the pulse oximeter is predicated on the assumption that the only components present in the blood capable of absorbing light at the two wavelengths used are O_2Hb and deO_2Hb. Under normal circumstances, this assumption is valid, and the SpO_2 readings accurately reflect the SaO_2. However, the presence of significant concentrations of other Hb species or

TABLE 51-1 POTENTIAL SOURCES OF ARTIFACTS IN PULSE OXIMETRY AND THEIR EFFECTS ON MEASUREMENTS

Source of Error	Effect on SpO_2 relative to SaO_2

substances absorbing light at the used wavelengths will lead to erroneous SpO_2 readings. As illustrated in Figure 51-3, both COHb and MetHb absorb light at one or both of the wavelengths used by the pulse oximeter. Accordingly, the presence of these Hb species produces errors in SpO_2. The absorption of light at 660 nm by COHb is similar to that of O_2Hb. At 940 nm, COHb absorbs virtually no light. Thus, in a patient with carbon monoxide poisoning, the SpO_2 is falsely elevated.[51] MetHb absorbs a significant amount of light at both 660 and 940 nm. As a result, in its presence, the ratio of light absorption R (Equation 5) approaches unity. An R value of 1 represents the presence of equal concentrations of O_2Hb and deO_2Hb and corresponds to an SpO_2 of 85%. In a patient with methemoglobinemia, the SpO_2 is 80% to 85% irrespective of the SaO_2.[52]

With normal SaO_2, anemia has little effect on SpO_2.[53] However, in the presence of hypoxia, SpO_2 readings underestimate SaO_2 in anemic patients.[54] Pulse oximeters are sufficiently accurate in adult patients with sickle cell disease,[55] as well as in the presence of fetal Hb.[56] A relatively uncommon cause of reduced SpO_2 readings is the presence of congenital variants of Hb. Some variants, such as Hb Bassett, Hb Rothschild, and Hb Canabiere, have a reduced affinity for O_2, and changes in SpO_2 appropriately reflect changes in SaO_2.[57] Other variants, such as Hb Lansing, Hb Bonn, and Hb Hammersmith, have altered absorption spectra that result in low SpO_2 readings in the setting of normal SaO_2.[57]

The administration of intravenous dyes can result in inaccurate SpO_2 readings. Methylene blue leads to a transient, marked decrease in SpO_2 down to 65%. Indigo carmine and indocyanine green also artificially decrease SpO_2 measurements, although to a lesser extent than methylene blue.[58] Isosulfan blue can produce a prolonged reduction with larger doses.[58]

Although all colors of nail polish can reduce the SpO_2 reading, black, purple, and dark blue have the greatest effect. However, the error is generally within 2%.[59] Depending on the brand of pulse oximeter used, artificial acrylic nails may impair SpO_2 readings, although generally not to a clinically significant extent.[60] Under conditions of normal SaO_2, skin pigmentation has no effect on SpO_2 estimates.[61] However, increased skin pigmentation is associated with SpO_2 values that overestimate SaO_2 by as much as 8% for SaO_2 less than 80%.[46,62]

Although earlier case reports and small studies had suggested that ambient light may interfere with the accuracy of SpO_2 readings,[63,64] a larger prospective study found no significant effect on SpO_2 accuracy with exposure to five types of light sources: quartz-halogen, incandescent, fluorescent, infant bilirubin lamp, and infrared.[65] Infrared light pulses from image guidance systems used for navigational neurosurgery can interfere with pulse oximetry readings by causing decreased readings or disruptions in SpO_2 waveform detection.[66] Different pulse oximeters show variable susceptibility to such interference.[67] Shielding the probe with a single layer of aluminum foil can protect from this effect.[66,67] Misplacement of the probe can allow for direct detection of LED light by the photodetector. This optical shunt gives rise to an SpO_2 reading of 85%.[68]

In patients with intraaortic balloon pump support, SpO_2 accuracy depends on the brand of pulse oximeter used, as well as the support ratio. Accuracy is generally reduced in the setting of higher support ratios.[69] In patients with continuous-flow ventricular assist devices, pulse oximetry may not be possible because of the absence of pulsatile flow. In these cases, the use of cerebral oximetry as an adjunct is advocated.[70]

MIXED VENOUS OXYGEN SATURATION

PHYSIOLOGIC FUNDAMENTALS

Mixed venous O_2 saturation ($S\bar{v}O_2$) is the oxygen saturation of blood at the proximal pulmonary artery. It reflects the average O_2 saturation of the blood returning from the body to the right heart, weighted by the respective regional blood flows. As such, it is a measure of the balance between global DO_2 and global O_2 uptake ($\dot{V}O_2$). The factors that influence $S\bar{v}O_2$ can be illustrated through a derivation of the mixed venous O_2 content ($C\bar{v}O_2$) equation.

$\dot{V}O_2$ (mL/min) is defined as:

$$\dot{V}O_2 = 10 \times \dot{Q}_T \times (CAO_2 - C\bar{v}O_2) \quad [6]$$

where $\dot{Q}_T$ is cardiac output (L/min) and $C\bar{v}O_2$ is the O_2 content of the mixed venous blood (mL/100 mL).

Rearranging the equation to solve for $C\bar{v}O_2$ yields:

$$C\bar{v}O_2 = CAO_2 - (\dot{V}O_2/\dot{Q}_T) \quad [7]$$

The contribution of dissolved O_2 to the blood O_2 content is small. By expanding the definition of O_2 content (Equation 1) and ignoring the term for dissolved O_2, Equation 7 can be rewritten as:

$$S\bar{v}O_2 = SaO_2 - \dot{V}O_2/(1.34 \times Hb \times \dot{Q}_T) \quad [8]$$

Normal values of $S\bar{v}O_2$ range between 65% and 80%.[71,72] Values close to 40% are associated with tissue hypoxia, anaerobic metabolism, and lactate production. Although venous saturation reflects venous O_2 partial pressure ($P\bar{v}O_2$) based on the O_2Hb dissociation curve, $P\bar{v}O_2$ cannot be directly inferred from $S\bar{v}O_2$ values alone because the association is influenced by factors such as pH, PCO_2, and temperature (see Fig. 51-2). The normal value of $P\bar{v}O_2$ is 40 mm Hg.

DO_2 is defined as:

$$DO_2 = \dot{Q}_T \times CAO_2 \quad [9]$$

As is evident from Equation 8, a low $S\bar{v}O_2$ indicates a reduction in DO_2 secondary to low SaO_2, low Hb, or low $\dot{Q}_T$, or an increase in $\dot{V}O_2$. The association among $S\bar{v}O_2$, DO_2, and $\dot{V}O_2$ can be illustrated by expressing $S\bar{v}O_2$ as a function of the O_2 extraction ratio, ERO_2.

$$ERO_2 = \dot{V}O_2/DO_2 \quad [10]$$

Expanding the terms yields:

$$ERO_2 = 1 - C\bar{v}O_2/CAO_2 \quad [11]$$

which can be rewritten as follows by ignoring the dissolved O_2 term:

$$ERO_2 = 1 - S\bar{v}O_2/SaO_2 \quad [12]$$

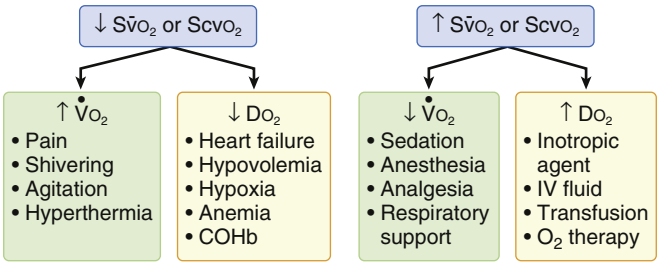

Figure 51-7. Mixed venous saturation $S\bar{v}O_2$ is a measure of the balance between global oxygen delivery and uptake. Conditions that increase oxygen uptake ($\dot{V}O_2$) or decrease oxygen delivery (DO_2) lead to a reduction in $S\bar{v}O_2$. Conversely, conditions that decrease $\dot{V}O_2$ or improve DO_2 lead to an increase in $S\bar{v}O_2$. *COHb,* Carboxyhemoglobin; *IV,* intravenous; *$ScvO_2$,* central venous oxygen saturation. *(Modified from Shepherd SJ, Pearse RM: Role of central and mixed venous oxygen saturation measurement in perioperative care,* Anesthesiology *111:649, 2009.)*

For conditions in which the arterial blood is fully saturated, the equation simplifies to:

$$ERO_2 = 1 - S\bar{v}O_2 \quad [13]$$

Solving for $S\bar{v}O_2$ yields:

$$S\bar{v}O_2 = 1 - ERO_2 \quad [14]$$

Thus, a reduction in $S\bar{v}O_2$ results from an increase in ERO_2, from either an increase in $\dot{V}O_2$ or a decrease in DO_2 (Fig. 51-7). A decrease in DO_2 occurs in conditions such as hemorrhagic or hypovolemic shock. An increase in $\dot{V}O_2$ may occur in conditions such as stress, pain, shivering, sepsis, and thyrotoxicosis. Conversely, an increase in $S\bar{v}O_2$ indicates either an elevation in O_2 supply (increased SaO_2, Hb, or $\dot{Q}_T$) or a reduction in $\dot{V}O_2$, as occurs during hypothermia.

Some subtle considerations are relevant in the interpretation of changes in $S\bar{v}O_2$. At PO_2 values typical of venous blood, small increases in the inspired fraction of O_2 (FiO_2) can cause significant increases in $S\bar{v}O_2$ because of the shape of the O_2Hb dissociation curve (see Fig. 51-2). Therefore, when $S\bar{v}O_2$ is being tracked as a measure of cardiac function, changes in FiO_2 must be taken into account when interpreting $S\bar{v}O_2$ measurements.[73] In the setting of septic shock, the impairment in O_2 extraction can produce normal $S\bar{v}O_2$ in the presence of tissue hypoxia.

The measurement of $S\bar{v}O_2$ requires the insertion of a pulmonary artery catheter, which actually increases morbidity risk. In the clinical setting, central venous catheterization is more commonly performed and has fewer risks. Thus, the use of central venous saturation can be a surrogate for mixed venous saturation. $ScvO_2$, which is the saturation of blood at the level of a central venous catheter placed in the superior vena cava, reflects the balance between O_2 supply and demand in the brain and upper extremities. Under normal physiologic conditions, $ScvO_2$ is typically 2% to 5% less than $S\bar{v}O_2$ primarily because of the higher O_2 content of splanchnic and renal venous blood.[74] However, during hemodynamic instability, as circulation is redistributed to the upper body, the relationship between $S\bar{v}O_2$ and $ScvO_2$ may reverse, and the difference between the two may increase significantly.[75-77] Although trends in $ScvO_2$ may reflect those in $S\bar{v}O_2$, the two measures cannot be used interchangeably.[77-85]

Mixed venous CO_2 has been used to compute the arteriovenous CO_2 difference ($\Delta PCO_2 = P\bar{v}CO_2 - PaCO_2$). In conditions of steady-state CO_2 production, ΔPCO_2 changes inversely and nonlinearly with cardiac output as a result of the Fick equation.[86] Accordingly, ΔPCO_2 is an indicator of the adequacy of cardiac output to provide adequate clearance of tissue CO_2. However, this measurement has not found widespread clinical use.[86]

MEASUREMENT PRINCIPLES

The measurement of venous O_2 saturation can be performed intermittently by co-oximetry of blood sampled from the distal tip of a pulmonary artery catheter ($S\bar{v}O_2$) or a central venous catheter ($ScvO_2$). Falsely increased values can occur in the presence of a wedged pulmonary artery catheter tip, mitral regurgitation, or left-to-right shunts.[87] Venous saturations can also be measured continuously by spectrophotometry using specialized fiberoptic catheters, which transmit infrared light and detect the amount of light reflected from red blood cells.[88,89] Specialized venous oximetry catheters are available for both pulmonary artery and central venous monitoring and have the advantage of providing continuous measurements of O_2 saturation. Their disadvantage is cost.

Although continuous venous oximetry catheters trend changes, their reported absolute values are not equivalent to concurrently obtained co-oximetry measurements.[90-92]

APPLICATIONS AND INTERPRETATION

In patients undergoing major abdominal as well as cardiac surgical procedures, intraoperative reductions in $S\bar{v}O_2$ and $ScvO_2$ have been associated with postoperative complications (see also Chapter 102).[93-97] Protocol-based interventions to target specific $S\bar{v}O_2$ or $ScvO_2$ values reduce the length of stay, organ dysfunction, and mortality in patients undergoing major surgical procedures and in patients presenting with sepsis.[98-100] $ScvO_2$-guided, protocol-based, goal-directed therapy is advocated for the management of sepsis, and the implementation of such protocols is associated with improvements in mortality.[101,102] The use of $ScvO_2$ as a therapeutic endpoint remains controversial for a number of reasons: $ScvO_2$ may be increased in sepsis because of impaired tissue O_2 extraction[103]; increased cost is associated with the use of $ScvO_2$-measuring catheters[104]; and other measures, such as lactate clearance, are less costly while leading to similar outcomes.[105] Furthermore, management of sepsis without an $ScvO_2$ endpoint can yield equally favorable results.[104]

TISSUE OXYGENATION

Arterial and venous O_2 saturations are measures of DO_2 and use by the whole body. Although useful, these global measures do not provide information regarding organ or tissue oxygenation, which reflects the important local balance between O_2 supply and demand. Regional O_2 balance can differ both among organs as well as within regions of the same organ. Current noninvasive methods for the assessment of microcirculatory oxygenation make

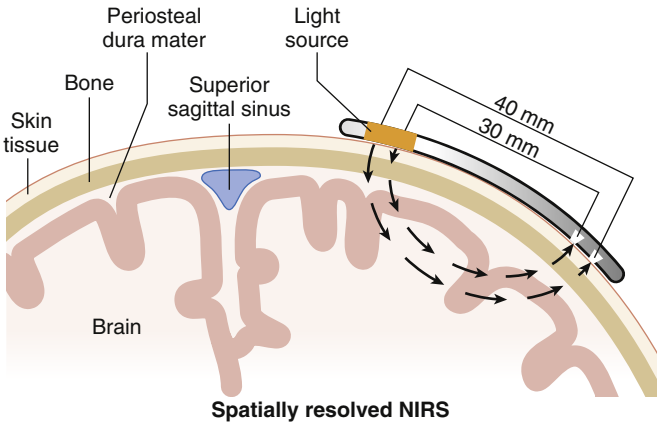

Figure 51-8. Near-infrared spectroscopy (NIRS) applied to cerebral oximetry. In this case, a reflectance oximeter is placed on the forehead. Near-infrared wavelength light is emitted from the light source and enters the underlying tissue. Light is scattered, reflected, and absorbed. Light that reaches the photodetector travels an arc-shaped path. The depth of the path is a function of the distance between the emitter and the detector. The measured value is the oxygen saturation of the tissue through which the light travels on its way to the detector. It is a primarily venous-weighted value. *(Redrawn from Casati A: New technology for noninvasive brain monitoring: continuous cerebral oximetry.* Minerva Anestesiol *72:605, 2006.)*

use of reflectance spectroscopy with light in the visible spectrum (VLS) or in the near-infrared spectrum (NIRS).

Reflectance spectroscopy probes have light emitters and receivers positioned in line (Fig. 51-8). When they are placed on a tissue surface, light transmission through the tissue is affected by reflection, absorption, and scatter. Reflection depends on the angle of incidence of the light beam and the wavelength of light, whereas scatter depends on the number and type of tissue interfaces. As previously outlined, the Beer-Lambert law relates the absorption of light by the tissue to the concentration of tissue chromophores, the extinction coefficient of each, and the path length of the light through the tissue.[106] The predominant tissue chromophore is Hb. The path length of the light is affected by both reflection and scatter, so it cannot be measured directly and must be estimated. Most of the detected photons travel in an arc between the two detectors (see Fig. 51-8). The depth of penetration of the arc into the tissue is proportional to the wavelength of light and the distance between the transmitter and the detector.[106,107]

VLS makes use of white light with wavelengths of 500 to 800 nm, whereas NIRS employs light in the range of 700 to 1100 nm.[108] In general, the depth of penetration of VLS is less than that of NIRS, thus allowing superficial measurements on the order of millimeters and making it suitable for small subsurface volumes. NIRS can penetrate tissue to a depth of several centimeters and allows sampling of a larger volume of tissue.[109] The O_2 saturation displayed is that of a volume of tissue. This volume includes arteries, capillaries, and veins and has a predominantly venous weighting.[110]

CLINICAL APPLICATIONS

Several applications have been described for VLS. Buccal microvascular Hb saturation has been associated with survival in patients with sepsis.[111] VLS has also been used for monitoring flap viability following reconstructive surgical procedures.[112] During gastrointestinal and esophageal surgical procedures, reductions in gastrointestinal tissue saturation, measured by VLS, have been associated with postoperative anastomotic complications.[113,114] Endoscopic VLS differentiates between normal and ischemic areas of the colon,[115] and it may be useful for the diagnosis of mesenteric ischemia.[116] In addition, mucosal O_2 saturation of the gastric conduit following esophagectomy is useful and explores the benefits of ischemic preconditioning.[117]

The most widespread application of NIRS is in cerebral oximetry, with probes placed on the forehead to measure frontal cortical oxygenation (rSo_2). Several NIRS systems are commercially available, and each manufacturer offers different specific technology. Because no gold standard exists for cerebral oximetry, it is difficult to compare the accuracy of the devices, and each device has its own set of "normal" values. For this reason, acquisition of baseline values for each patient at the start of the procedure is recommended.[118] Typical values of rSo_2 range from 55% to 80%. A reduction of rSo_2 to less than 20% to 25% of the baseline, or lower than an absolute value of 50%, is a recommended threshold for intervention.[119,120]

The utility of cerebral oximetry has been explored in cardiovascular, abdominal, thoracic, and orthopedic surgery. In the cardiac surgical setting, intraoperative reductions in rSo_2 have been associated with early postoperative cognitive dysfunction and prolonged ICU and hospital lengths of stay.[120-123] As a guide to therapy, interventions for rSo_2 reductions to less than 75% of baseline in patients undergoing coronary artery bypass graft surgery significantly reduce the incidence of major organ morbidity and mortality, as well as ICU length of stay.[119]

The use of rSo_2 for cerebral monitoring during carotid endarterectomy has also been investigated. Intraoperative reductions in rSo_2 correlate well with changes in transcranial Doppler variables,[124-128] electroencephalographic waveforms,[129-131] and stump pressure,[128,132] which are consistent with ischemia. Although some studies indicate that reductions in rSo_2 that are less than 20% of baseline are well tolerated, data are lacking for a clear rSo_2 threshold for carotid shunt placement (see also Chapter 69).[133,134]

In older patients undergoing major abdominal surgical procedures, protocol-based intraoperative treatment of reductions in rSo_2 results in decreases in postoperative cognitive decline and hospital length of stay.[135] In patients undergoing thoracic surgical procedures with single-lung ventilation, early postoperative cognitive dysfunction is directly related to intraoperative exposure time to rSo_2 less than 65%.[136] Patients undergoing shoulder operations in the beach chair position have a lower baseline rSo_2 and a larger number of episodes of cerebral desaturation, although the clinical implications of these findings are unclear.[137-139]

Shock is a condition in which patients may have inadequate *regional* perfusion in the setting of normal *global* perfusion parameters. In such circumstances, the use of NIRS to monitor tissue perfusion holds some promise. Values obtained by the application of an NIRS probe to

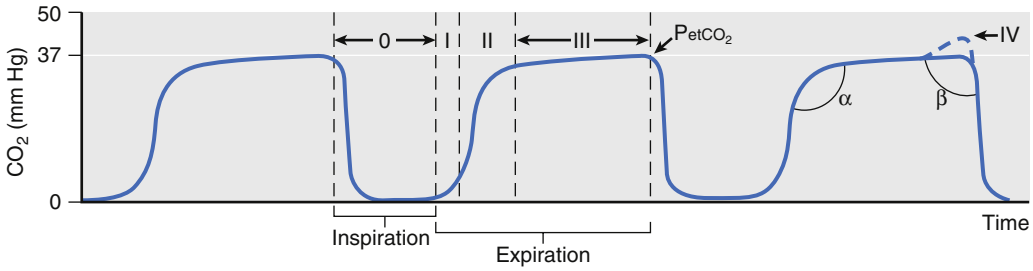

Figure 51-9. Representative time capnogram for three breaths. The expiratory segment is divided into phases I, II, III, and IV. The inspiratory segment is referred to as phase 0 in this figure. α Denotes the angle between phases II and III, whereas β denotes the angle between phase III and the descending limb of phase 0. Phase IV (*dashed line* in third breath) denotes the upstroke observed at the end of phase III in some patients. *$PetCO_2$,* Partial pressure of end-tidal carbon dioxide. *(Courtesy Respironics, Inc.)*

the thenar eminence (StO_2) discriminate between healthy volunteers and patients with shock.[140] Furthermore, in patients with major trauma who present with shock, StO_2 values can identify patients who proceed to develop multiorgan dysfunction or actually die.[141,142]

Although information to warrant clinical decision making exclusively based on NIRS measurements is limited, further investigations are improving the understanding of the measurement and its relevance for clinical management.

CAPNOMETRY AND CAPNOGRAPHY

GENERAL CONCEPTS

The presence of CO_2 in exhaled breath reflects the fundamental physiologic processes of ventilation, pulmonary blood flow, and aerobic metabolism. Its continued monitoring assures the anesthesiologist of correct placement of an endotracheal tube (ETT) or laryngeal mask airway (LMA), as well as the integrity of a breathing circuit. Exhaled CO_2 provides information primarily on ventilation. It is also used to estimate the adequacy of cardiac output. In combination with $Paco_2$, exhaled CO_2 can be used to estimate the ratio of physiologic dead space (V_D) to tidal volume (V_T) by using the Bohr equation[143]:

$$\frac{V_D}{V_T} = \left(\frac{Paco_2 - P\bar{E}co_2}{Paco_2}\right) \qquad [15]$$

where $P_{\bar{E}}CO_2$ is the mixed expired CO_2 partial pressure, such as measured in exhaled air collected in a mixing bag or chamber, or computed from a volumetric capnogram. The ability to detect and quantify CO_2 is a crucial component of respiratory monitoring in anesthesia and critical care medicine.

Considerable confusion arises from inconsistent and interchangeable terminology as applied to medical CO_2 gas analysis.[143-145] In a very general sense, *capnometry* refers to the measurement and quantification of inhaled or exhaled CO_2 concentrations at the airway opening. *Capnography*, however, refers not only to the method of CO_2 measurement, but also to its graphic display as a function of time or volume. A *capnometer* is simply a device that measures CO_2 concentrations. A capnometer may display a numeric value for inspired or exhaled CO_2. A *capnograph*, however, is a device that records and displays CO_2 concentrations, usually as a function of time. A *capnogram* refers to the graphic display that the capnograph generates. Figure 51-9 illustrates a typical CO_2 concentration profile for three breaths as a function of time.

MEASUREMENT PRINCIPLES

Various methods exist for detecting and quantifying CO_2 concentrations in respiratory gases, such as mass spectrometry, Raman spectrometry, or gas chromatography.[146,147] The most commonly used method in clinical environments relies on nondispersive infrared absorption.[148] With this technique, a beam of infrared light is passed through a gas sample, and the resulting intensity of the transmitted light is measured by a photodetector.[144] Gaseous CO_2 absorbs light over a very narrow bandwidth centered around 4.26 μm. Its presence in the sample cell decreases the amount of infrared light at this wavelength that reaches the detector in proportion to its concentration. Because the absorption spectrum for CO_2 partially overlaps with the spectra of other gaseous species commonly encountered in anesthesia (i.e., water and nitrous oxide[149]), infrared filters and compensation algorithms are used to minimize this interference and improve accuracy.[150]

Most capnometers rely on an infrared-light source that is focused on a chopper disk that rotates at approximately 60 revolutions/second. The chopper allows the beam to be alternately directed through (1) the sample cell with the gas to be analyzed and (2) a reference cell with no detectable CO_2. In addition, the light source is completely blocked at various points during the revolution of the chopper disk. The photodetector and associated circuitry process these three signals to estimate the changes in CO_2 concentration continuously in the sample cell. Alternatively, CO_2 concentration may be estimated with solid-state technology, using a beam splitter instead of a chopper wheel. The splitter allows for the measurement of infrared energy at wavelengths within and outside the absorption spectrum of CO_2.

The two general categories of capnometers are sidestream (diverting) and mainstream (nondiverting). Sidestream analyzers are more frequently used in clinical environments. Their CO_2 sensors are physically located away from the airway gases to be measured. Sidestream analyzers incorporate a pump or compressor that aspirates gases into a sample cell located at the unit's console

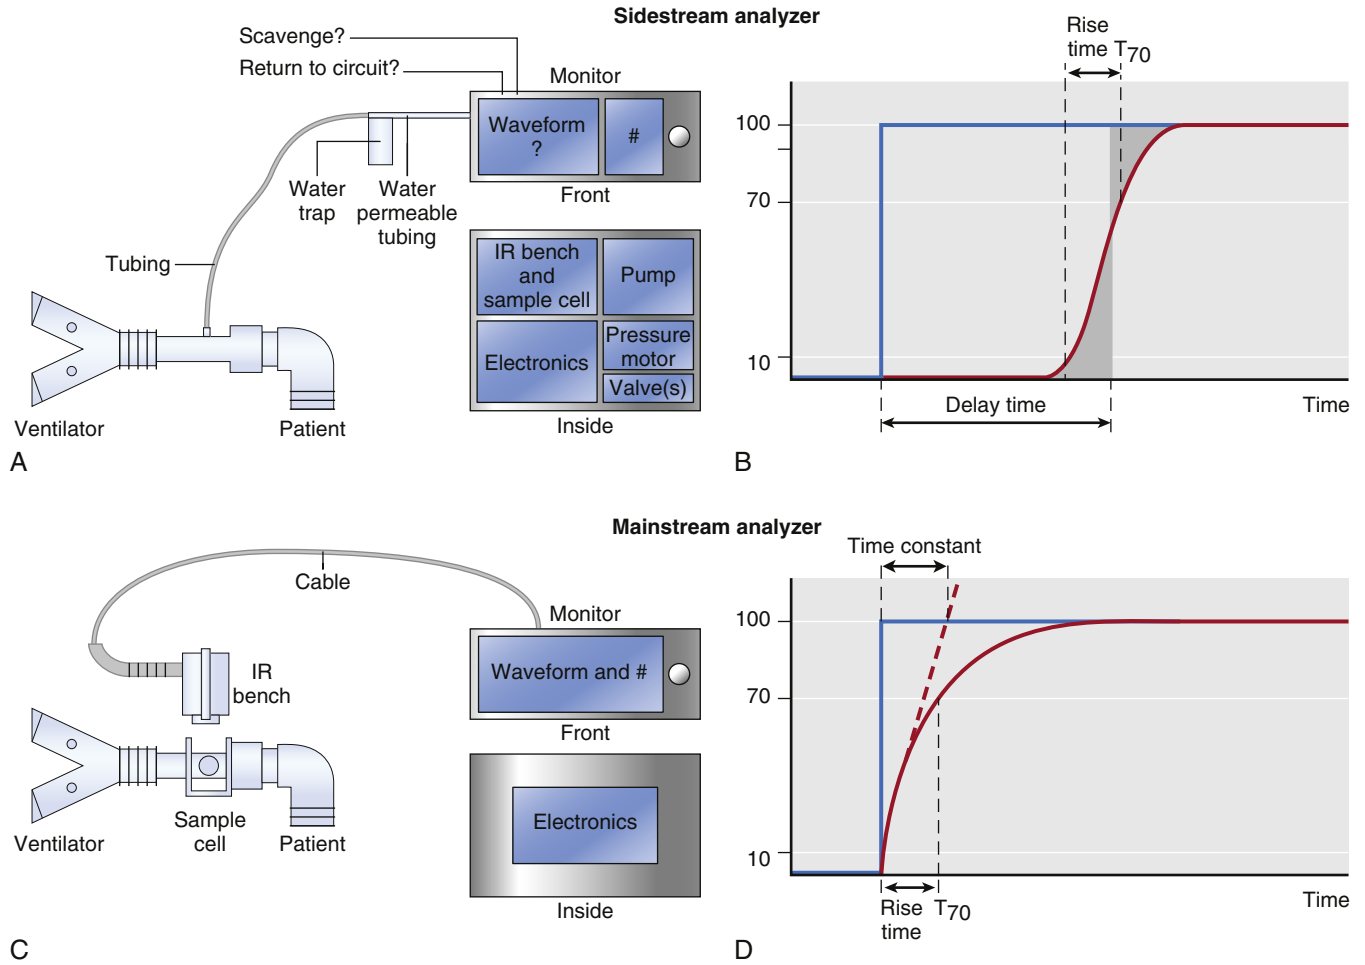

Figure 51-10. Schematics of sidestream (**A**) and mainstream (**C**) capnometry sampling methods, along with corresponding representative time capnograms (*red curves* in **B** and **D**) following a step increase in carbon dioxide concentration *(blue lines)*. Rise time (T_{70}) corresponds to the time required for either sensor to change from 10% to 70% of its final value. A delay time is observed for the sidestream analyzer, corresponding to the aspiration rate of the sampled gas and the washout of the analyzing chamber. *IR,* Infrared. *(Modified from Jaffe MB: Mainstream or sidestream capnography? Technical considerations. Wallingford, Conn, 2002, Respironics Novametric, Inc; and Brunner JX, Westenskow DR: How the rise time of carbon dioxide analysers influences the accuracy of carbon dioxide measurements,* Br J Anaesth *61: 628-638, 1988.)*

(Fig. 51-10, *A*). Typical tubing length for this aspiration may be 6 feet, and gas withdrawal rates may vary from 30 to 500 mL/minute. This lost gas volume may need to be considered during closed-circuit anesthesia or during ventilation of neonates and infants. The volume can be returned to the circuit, or it can be routed to a scavenger to prevent contamination of the environment with anesthetic or waste gases. Gases must also pass through various filters and water traps before they are presented to the sample cell.[144] Sidestream capnometers have a transport delay time corresponding to the rate at which gas is sampled and the washout of the analyzing chamber (Fig. 51-10, *B*). The capnograms generated by sidestream analyzers also have an associated rise time, defined as the time required for the analyzer to respond to a sudden change in CO_2 concentration.[151] By convention, this is usually the time interval required for the analyzer output to change from 10% to 70% of its final value.[151] Typical increase times for commercially available capnometers range from 10 to 400 msec, and they can depend on the rotation of the chopper wheel, the rate of gas aspiration, the volume of aspiration tubing and water traps, and the dynamic response of the infrared filters and other electronics.

With mainstream analyzers, the sample cell is placed directly into the patient's breathing circuit. Thus, the inspiratory or expiratory gases pass directly through the infrared light path (Fig. 51-10, *C*). An advantage of mainstream analyzers is that they have no delay time (Fig. 51-10, *D*). Moreover, their rise time is generally faster than that of sidestream analyzers.[151] A disadvantage is the potential increase in dead space, although more recent developments in solid-state electronics have made this much less of an issue.[152] In addition, the sample cell is usually heated to 40° C to minimize the condensation of water vapor, which can bias the measurement. This increase in temperature, combined with the proximity of the sensor to the patient's airway, can potentially increase the risk of facial burns.

TIME CAPNOGRAM

The simplest and most widely used form of display for exhaled CO_2 is the *time capnogram*. The time capnogram displays both inspiratory and expiratory phases.

Figure 51-9 shows a typical time capnogram for three breaths. The expiratory phase is divided into three distinct components. Phase I corresponds to the exhalation of dead space gas from the central conducting airways or any equipment distal to the sampling site, which ideally should have no detectable CO_2 (i.e., partial pressure of CO_2, P_{CO_2} ~0). During phase II, a sharp rise in P_{CO_2} to a plateau indicates the sampling of transitional gas between the airways and alveoli. The plateau region of the capnogram, phase III, corresponds to the P_{CO_2} in the alveolar compartment. For a lung with relatively homogeneous ventilation, phase III is approximately flat throughout expiration. In fact, various mechanisms contribute to the slight upsloping of CO_2 concentration versus time during phase III. Most of these mechanisms reflect a heterogeneous distribution of ventilation-perfusion ($\dot{V}/\dot{Q}$) or alveolar CO_2 partial pressure (P_{ACO_2}) throughout the lung. Well-ventilated and well-matched $\dot{V}/\dot{Q}$ regions tend to have lower P_{CO_2} and shorter time constants, and they empty earlier during the expiratory phase. Less well-ventilated and poorly matched $\dot{V}/\dot{Q}$ regions have higher CO_2 levels, and they empty later in the expiratory cycle. Respiratory disorders associated with an increase in ventilation heterogeneity, such as asthma, chronic obstructive pulmonary disease (COPD), or acute lung injury,[153] yield a steeper upslope of phase III. Interventions that improve ventilation homogeneity, such as positive end-expiratory pressure (PEEP) or bronchodilators, flatten phase III. Mechanical disturbances may also be present during phase III, thus reflecting processes such as spontaneous breathing efforts, cardiogenic oscillations, or surgical manipulation (Fig. 51-11). Following phase III, a sharp downstroke of P_{CO_2} occurs as fresh inspired gas moves past the sampling site and washes out the remaining CO_2. This is referred to as the beginning of phase 0 by some authors,[145,154] or phase IV by others.[146] Occasionally, a sharp upstroke in P_{CO_2} is observed at the very end of phase III, which is termed phase IV or IV′, depending on the author.[155] This upstroke probably results from the closure of lung units with relatively low P_{CO_2} and allows for regions of higher CO_2 to contribute a greater proportion of the exhaled gas to be sampled.[145] Additional insight into various abnormalities in ventilation or perfusion are also obtained by trending time capnograms over many breaths for long periods (Fig. 51-12).

The term "end-tidal" CO_2 ($PetCO_2$) generally refers to the final value of the exhaled P_{CO_2} curve, at the very end of the expiratory phase. The method used to determine this number is not universal and varies according to the manufacturer of the particular capnograph in use. For example, $PetCO_2$ may simply be (1) the P_{CO_2} value just before inspiration, (2) the largest P_{CO_2} value during a single exhalation cycle, or (3) the P_{CO_2} value at a specified time in the capnogram averaged across several breaths. If $PetCO_2$ is measured during a reasonably flat and undistorted phase III, it may be well correlated with Pa_{CO_2}.[150] This may not be the case if the duration of phase III is truncated or if CO_2 is measured from gas that is contaminated with room or O_2-enriched air (i.e., during spontaneous breathing with a nasal cannula or facemask). Potential causes of increased or decreased $PetCO_2$ are listed in Table 51-2. In healthy individuals with homogeneous ventilation, the difference between Pa_{CO_2} and $PetCO_2$ is usually less than 5 mm Hg, thereby expressing the equilibration between alveolar and pulmonary capillary blood. Several disease states compromise this equilibration and produce increased Pa_{CO_2} – $PetCO_2$ difference (Box 51-2). In some situations, $PetCO_2$ can be greater than Pa_{CO_2}, especially in the presence of severe ventilation heterogeneity and lung units with very low $\dot{V}/\dot{Q}$. For steady-state conditions, the $PetCO_2$ usually reflects the relative balance between CO_2 production and alveolar ventilation.

VOLUME CAPNOGRAM

Although time capnography is relatively straightforward to monitor in clinical environments, a major limitation of the technique is its lack of information regarding flow or volume.[154] The *volume capnogram* is a graphic display of CO_2 concentration or partial pressure versus exhaled volume.[146] The inspiratory phase is not defined in a volume capnogram. Similar to its temporal counterpart, it is also partitioned into three distinct phases (I, II, and III) corresponding to anatomic dead space, transitional, and alveolar gas samples (Fig. 51-13). However, it possesses several advantages over the time capnogram. First, it allows for estimation of the relative contributions of anatomic and alveolar components of V_D.[156] Second, it may be more sensitive than the time capnogram in detecting subtle changes in dead space that are caused by alterations in PEEP, pulmonary blood flow, or ventilation heterogeneity (Fig. 51-14). Finally, the numeric integral of P_{CO_2} as a function of volume allows for determination of the total mass of CO_2 exhaled during a breath and provides for estimation of $\dot{V}_{CO_2}$.

BLOOD GAS ANALYSIS

PHYSIOLOGIC FUNDAMENTALS

Arterial blood gas analysis is used to assess oxygenation, ventilation, and acid-base status. This section focuses on the use of arterial blood gases to assess oxygenation and ventilation. For a discussion of acid-base status, see Chapter 60. Oxygenation is reflected in the PaO_2, which is a function of the alveolar partial pressure of O_2 (PAO_2) and the efficiency of O_2 transfer from alveoli to the pulmonary capillary blood. In healthy adults breathing room air at sea level, PaO_2 ranges between 80 and 100 mm Hg. The normal value of PaO_2 decreases with increasing age and increasing altitude. Hypoxemia is defined as a PaO_2 less than 80 mm Hg. Hypoxemia has five physiologic causes:

1. Hypoventilation
2. $\dot{V}/\dot{Q}$ mismatching
3. Right-to-left shunt
4. Diffusion limitation
5. Diffusion-perfusion mismatch

The first three causes explain most cases of hypoxemia in the perioperative setting. Reduced inspired PO_2 (e.g., in faulty closed or partially closed anesthesia breathing circuits or at high altitude) is an additional cause of hypoxemia.

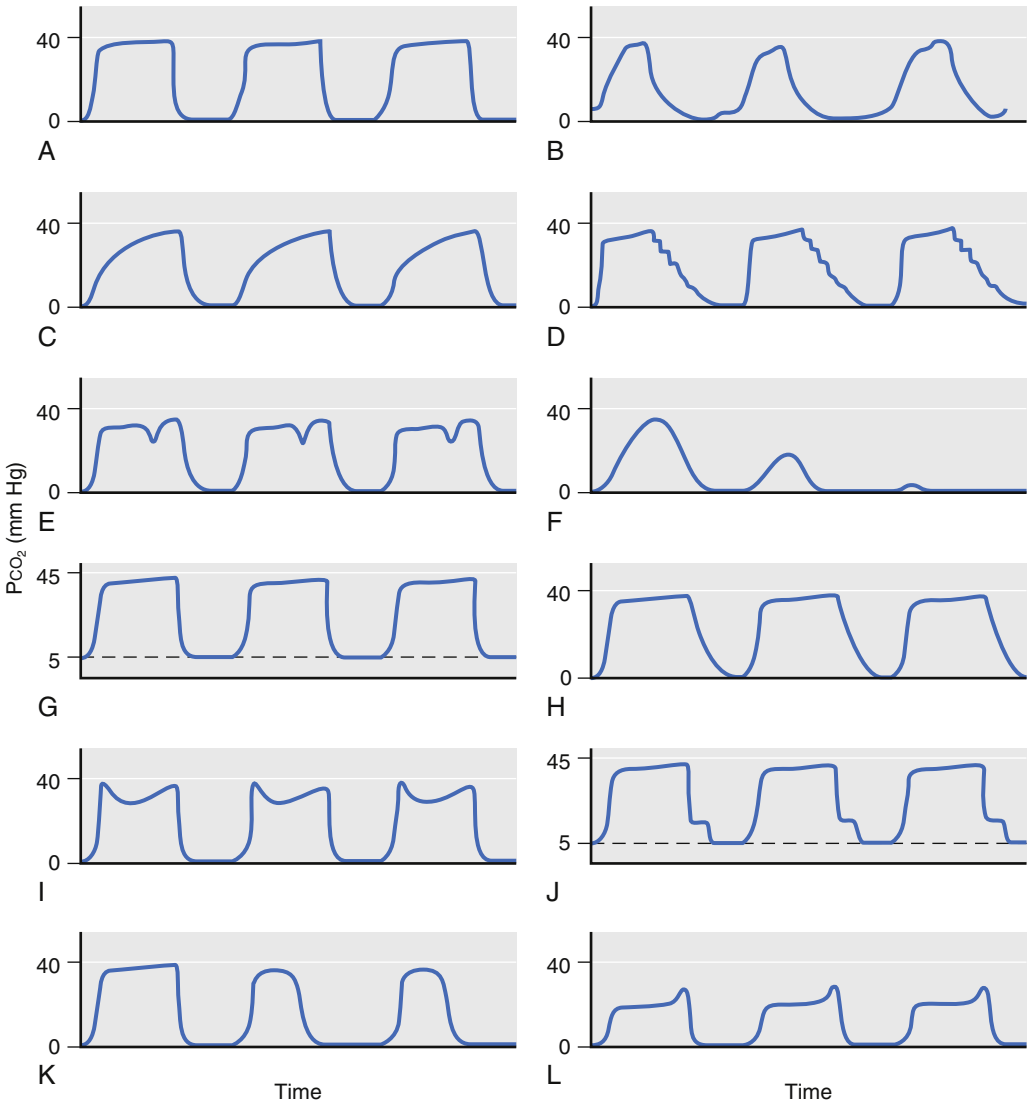

Figure 51-11. Representative time capnograms under normal and abnormal conditions. **A,** Normal capnogram during controlled mechanical ventilation. **B,** Normal capnogram during spontaneous breathing. **C,** Increased upslope of phase III, as may occur during bronchospasm (asthma, chronic obstructive pulmonary disease), or partially obstructed endotracheal tube or breathing circuit. **D,** Cardiogenic oscillations at the end of exhalation as flow decreases to zero and the beating heart causes emptying of different lung regions and back-and-forth motion between exhaled and fresh gas. **E,** Clefts during phase III that indicate spontaneous breathing efforts during controlled mechanical ventilation. **F,** Esophageal intubation. **G,** Rebreathing of carbon dioxide (CO_2), as may occur with a faulty expiratory valve or exhausted absorber system. Inspiratory CO_2 is consistently greater than zero. **H,** Faulty inspiratory valve, resulting in a slower downslope, which extends into the inhalation phase (phase 0) as CO_2 in the inspiratory limb is rebreathed. **I,** Two peaks in phase III that suggest sequential emptying of two heterogeneous compartments, as may be seen in a patient with a single-lung transplant. **J,** Faulty inspiratory valve. **K,** Sudden shortening of the duration of phase III during controlled mechanical ventilation that suggests the abrupt onset of a ruptured or leaking endotracheal tube cuff. **L,** Dual plateau in phase III that suggests the presence of a leak in a sidestream sample line. The early portion of phase III is abnormally low because of dilution of exhaled gas with ambient air. The sharp increase in CO_2 at the end of phase III reflects a diminished leak resulting from the increased circuit pressure at the onset of inspiration. P_{CO_2}, Partial pressure of CO_2. *(Modified from Hess D: Capnometry and capnography: technical aspects, physiologic aspects, and clinical applications,* Respir Care *35:557-576, 1990; Roberts WA, Maniscalco WM, Cohen AR, et al: The use of capnography for recognition of esophageal intubation in the neonatal intensive care unit,* Pediatr Pulmonol *19:262-268, 1995; and Eskaros SM, Papadakos PJ, Lachmann B: Respiratory monitoring. In Miller RD, Eriksson LI, Fleisher LA, editors:* Miller's anesthesia, *ed 7, New York, 2010, Churchill Livingstone, p 1427.)*

These factors produce hypoxemia by affecting different steps of O_2 transport from the environment to the arterial blood. A low inspired PO_2, as well as hypoventilation, reduces the PAO_2. $\dot{V}/\dot{Q}$ mismatch, right-to-left shunt, and alveolar diffusion limitation affect the efficiency of O_2 exchange. Diffusion limitation plays a role in conditions that thicken the alveolar-capillary barrier, such as interstitial lung diseases, and in hypoxemia induced by exercise or altitude.[157,158] In the clinical setting, impairment of diffusion of O_2 or CO_2 rarely occurs to a significant extent. The remainder of this section focuses on $\dot{V}/\dot{Q}$ mismatch and right-to-left shunt.

$\dot{V}/\dot{Q}$ mismatch is the most common cause of hypoxemia in the clinical setting. Ventilation and perfusion are nonuniformly distributed throughout the normal lung, with worsening mismatch in the setting of general

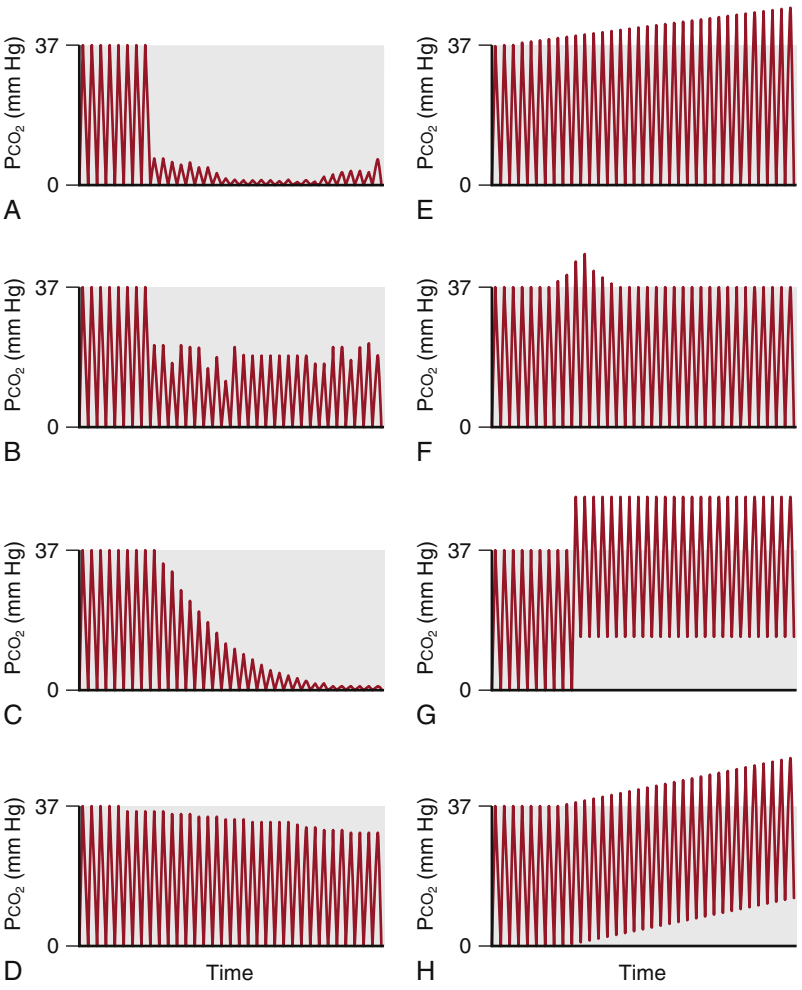

Figure 51-12. Representative time capnograms trended over many breaths that illustrate various abnormalities in ventilation or perfusion, or both. **A,** Sudden drop in carbon dioxide (CO_2) secondary to catastrophic loss of ventilation. **B,** Leak or partial obstruction in the breathing circuit. **C,** sudden interruption in pulmonary perfusion, as may occur during cardiac arrest. **D,** Gradual decrease in CO_2 resulting from hyperventilation, decreased metabolism, or decreased pulmonary perfusion. **E,** Gradual increase in CO_2 as may occur during hypoventilation, laparoscopic insufflation, increased metabolism, or increased pulmonary perfusion. **F,** Transient rise in CO_2 that indicates an acute increase in CO_2 delivery to the lungs, as may occur during release of a tourniquet or administration of a bicarbonate bolus. **G,** Rise in both the baseline and end-tidal CO_2 that is consistent with a contaminated sample cell. **H,** Gradual rise in baseline and end-tidal CO_2 that is consistent with rebreathing. P_{CO_2}, Partial pressure of CO_2. *(Modified from Swedlow DB: Capnometry and capnography: the anesthesia disaster early warning system,* Semin Anesth *5:194-205, 1986.)*

BOX 51-2 ***Causes of Increased Arterial-to-End-Tidal Carbon Dioxide Pressure Difference***

Increased ventilation-perfusion heterogeneity particularly with high ventilation-perfusion regions
Pulmonary hypoperfusion
Pulmonary embolism
Cardiac arrest
Positive-pressure ventilation (especially with PEEP)
High-rate low-tidal-volume ventilation

Modified from Hess D: Capnometry and capnography: technical aspects, physiologic aspects, and clinical applications, Respir Care *35:557-576, 1990.*
PEEP, Positive end-expiratory pressure.

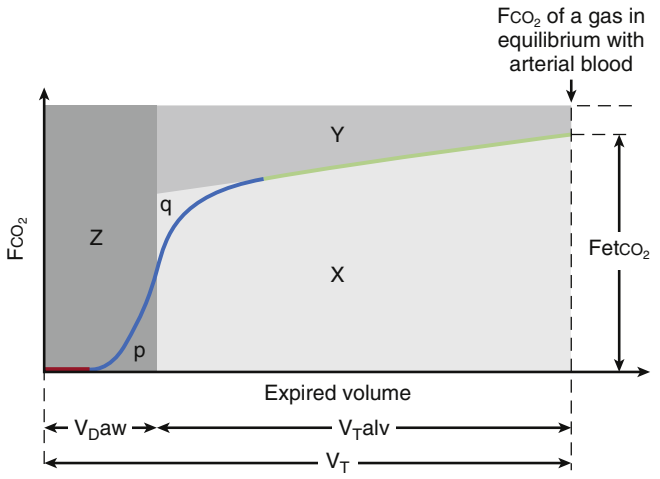

Figure 51-13. The volume capnogram is a plot of the fraction of carbon dioxide (F_{CO_2}) in exhaled gas versus exhaled volume. It is divided into three phases, which reflect the same sources of expired gas as present in the time capnograph: anatomic dead space (phase I, *red*), transitional (phase II, *blue*), and alveolar gas (phase III, *green*). The volume capnogram allows for the partition of total tidal volume (V_T) into airway dead space volume ($V_D$aw) and an effective alveolar tidal volume ($V_T$alv) by a *vertical line* through phase II, positioned such that the approximately triangular areas p and q are equal. It also provides the slope of phase III as a quantitative measure of the heterogeneity of alveolar ventilation. The total area below the *horizontal line* (denoting the F_{CO_2} of a gas in equilibrium with arterial blood) can be divided into three distinct areas: X, Y, and Z. Area X corresponds to the total volume of CO_2 exhaled over a tidal breath. This value can be used to compute the CO_2 production ($\dot{V}_{CO_2}$), and the mixed expired CO_2 fraction or partial pressure (P_{CO_2}) to be used in the Bohr equation (Equation 15) based on the division of the exhaled CO_2 volume by the exhaled tidal volume. Area Y represents wasted ventilation secondary to alveolar dead space, whereas area Z corresponds to wasted ventilation secondary to anatomic dead space ($V_D$aw). Thus, areas Y + Z represent the total physiologic dead space. The volume capnogram can also be plotted as a P_{CO_2} versus exhaled volume curve. *Fet_{CO_2},* Fraction of end-tidal CO_2. *(Modified from Fletcher R, Jonson B, Cumming G, Brew J: The concept of deadspace with special reference to the single breath test for carbon dioxide,* Br J Anaesth *53:77-88, 1981.)*

Following resolution (day 5), a noticeable reduction in the slope of phase III occurs. *CO_2,* Carbon dioxide. *(Modified from Thompson JE, Jaffe MB: Capnographic waveforms in the mechanically ventilated patient,* Respir Care *50:100-108, 2005.)*

anesthesia, lung disease, and mechanical ventilation. Areas with low or zero $\dot{V}/\dot{Q}$ yield low end-capillary PO_2, whereas areas with normal or high $\dot{V}/\dot{Q}$ produce higher end-capillary PO_2. However, because of the plateau of the O_2Hb dissociation curve (see Fig. 51-2), the normal and high $\dot{V}/\dot{Q}$ regions are limited in the extent to which they increase the O_2 content and compensate for the low $\dot{V}/\dot{Q}$ regions (Fig. 51-15). As a consequence, $\dot{V}/\dot{Q}$ mismatch results in hypoxemia.

Right-to left shunt is the amount of blood that flows from the pulmonary artery to the systemic arterial circulation without undergoing pulmonary gas exchange.

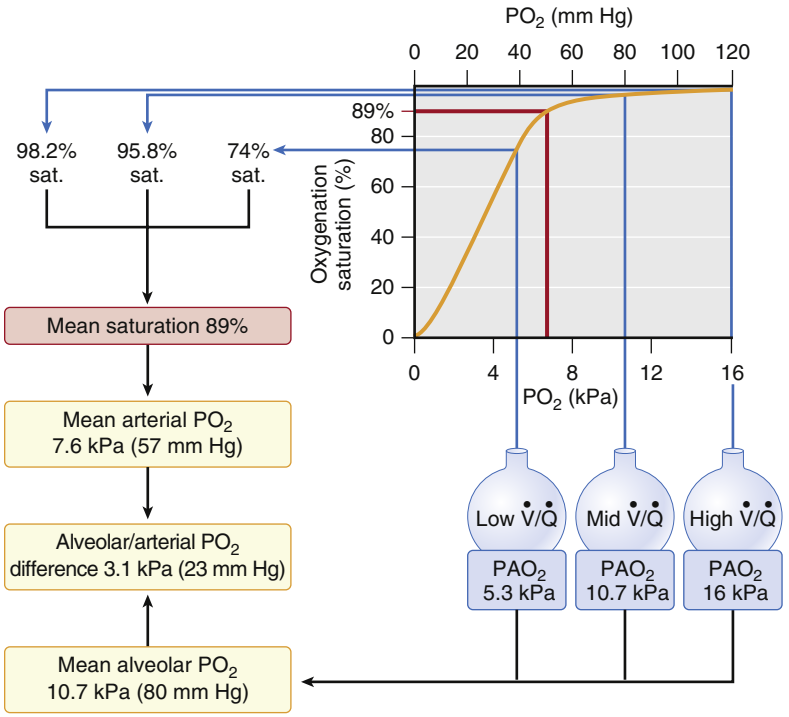

Figure 51-15. Effect of different ventilation-perfusion $\dot{V}/\dot{Q}$ regions on partial pressure of arterial oxygen (PaO_2). Because of the shape of the oxyhemoglobin dissociation curve, regions of lung with low $\dot{V}/\dot{Q}$ have a disproportionately greater effect on lowering the arterial saturation than do regions of lung with normal or higher $\dot{V}/\dot{Q}$ to increase PaO_2. Assuming equal blood flow, the average partial pressure of alveolar oxygen (PAO_2) of the $\dot{V}/\dot{Q}$ regions represented in the illustration is 10.7 kPa (80 mm Hg). Based on the oxyhemoglobin dissociation curve, however, the average saturation of the arterial blood is 89%, producing an average PaO_2 equal to 7.6 kPa (57 mm Hg). *PO_2,* Partial pressure of oxygen. *(Modified from Lumb AB:* Nunn's applied respiratory physiology, *ed 6, Philadelphia, 2005, Butterworth Heinemann.)*

It represents an extreme case of $\dot{V}/\dot{Q}$ mismatch in which the ratio equals zero and the end-capillary gas partial pressures are equal to the values found in mixed venous blood. In healthy awake spontaneously breathing subjects, intrapulmonary shunt is negligible,[159] and a small (<1% of cardiac output) extrapulmonary shunt results from drainage of the bronchial and thebesian veins into the arterial side of the circulation.[160] During general anesthesia, a right-to-left shunt can develop as a result of atelectasis.[161,162] Right-to-left shunt can also be seen in pathologic conditions such as pneumonia and acute lung injury. The effect of the shunt on PaO_2 is a function of the magnitude of the shunt, and the cardiac output (Fig. 51-16). Increases in FiO_2 have a small effect on PaO_2 in the presence of a large true right-to-left shunt (see Fig. 51-16).

The traditional method to estimate flow through shunting regions ($\dot{Q}_S$) as a fraction of the total cardiac output ($\dot{Q}_T$) is based on modeling of the lung as a three-compartment system (Fig. 51-17).[163] The three compartments represent (1) lung regions receiving both ventilation and perfusion, (2) a shunt compartment ($\dot{V}/\dot{Q}=0$), and (3) a dead space compartment with ventilation but no perfusion ($\dot{V}/\dot{Q}=$ infinity). The application of the concept of mass balance to this model yields the shunt fraction ($\dot{Q}_S/\dot{Q}_T$) expression:

$$\dot{Q}_s/\dot{Q}_T = \frac{\left(Cc'_{O_2} - CAO_2\right)}{\left(Cc'_{O_2} - C\bar{v}_{O_2}\right)} \qquad [16]$$

where $\dot{Q}_S$ is shunted blood flow, Cc'_{O_2} is end-capillary O_2 content, and $C\bar{v}_{O_2}$ mixed venous. Cc'_{O_2} is calculated using Equation 1 and assuming equilibration between the end-capillary blood and alveolar gas. The PAO_2 is calculated using the ideal alveolar gas equation:

$$PAO_2 = FiO_2 \times (P_{atm} - P_{H_2O}) - Pa_{CO_2}/R \qquad [17]$$

where FiO_2 is inspired O_2 fraction, P_{atm} is barometric pressure, P_{H_2O} is partial pressure of water vapor (47 mm Hg at 37° C). R, the respiratory quotient, is the ratio of pulmonary CO_2 elimination to $\dot{V}_{O_2}$ ($R=\dot{V}_{CO_2}/\dot{V}_{O_2}$), which equals 0.8 under normal diet and rest conditions.

The three-compartment model is a simplification of the real lung. As a result, under conditions of FiO_2 less than 100%, $\dot{Q}_S/\dot{Q}_T$ represents a combination of all factors producing hypoxemia, predominantly true right-to-left shunt and $\dot{V}/\dot{Q}$ mismatch. Under such conditions, $\dot{Q}_S/\dot{Q}_T$ is referred to as venous admixture. When FiO_2 is 100%, the effects of $\dot{V}/\dot{Q}$ heterogeneity on O_2 exchange are eliminated, and the equation exclusively yields the right-to-left shunt fraction.[164] The administration of FiO_2 of 100% can lead to the development of absorption atelectasis in compartments with very low $\dot{V}/\dot{Q}$, thus leading to an increase in the true right-to-left shunt.[164]

If the assumptions are made that end-capillary blood has an O_2 saturation of 100% and the O_2 content of blood is predominantly determined by Hb saturation, the shunt fraction equation can be simplified to:

$$\dot{Q}_s/\dot{Q}_T = \frac{(1 - SaO_2)}{(1 - S\bar{v}_{O_2})} \qquad [18]$$

where SaO_2 is arterial saturation, and $S\bar{v}_{O_2}$ is mixed venous saturation.

Other Indices of Oxygenation

The calculation of the shunt fraction is a fundamental measure of O_2 exchange impairment. However, a pulmonary artery catheter is required for the measurement of $S\bar{v}_{O_2}$. For this reason, indices of oxygenation have been developed that rely on less invasive measures. The PaO_2 certainly reflects oxygenation. However, it is limited in providing a measure of the magnitude of the O_2 exchange deficiency because of its dependence on the FiO_2 and the

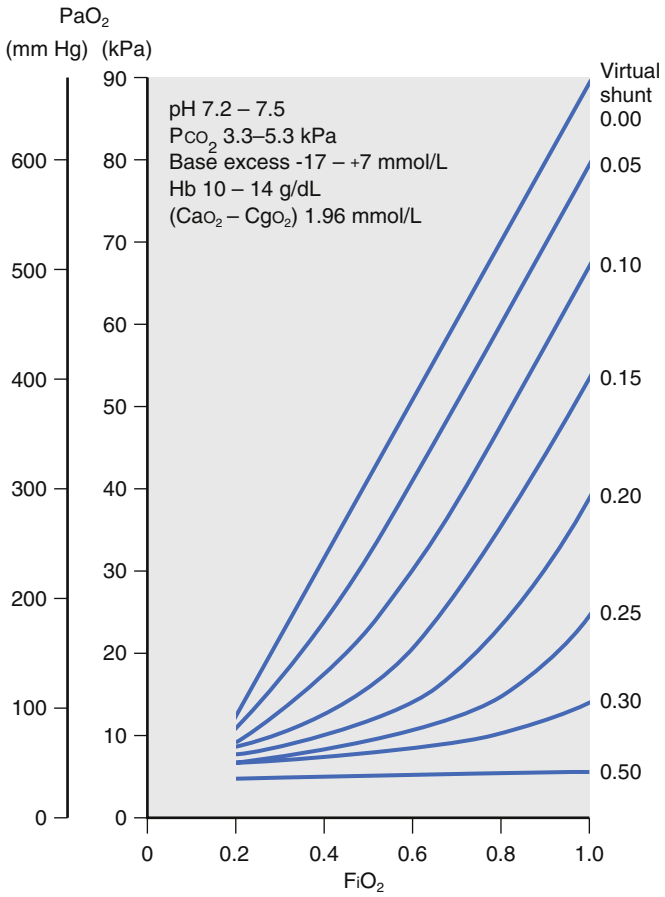

Figure 51-16. Relationship between partial pressure of arterial oxygen (PaO_2) and fraction of inspired oxygen (FiO_2) for different values of shunt fraction computed for normal values of barometric pressure, pH, partial pressure of carbon dioxide (P_{CO_2}), base excess, hemoglobin (Hb) concentration, and arterial–mixed venous oxygen content difference ($CAO_2 - C\dot{v}O_2$). Note the small increase in PaO_2 with FiO_2 in the presence of large shunt. This graph corresponds to the so-called isoshunt diagram presented in Lawler PG, Nunn JF: A reassessment of the validity of the iso-shunt graph, *Br J Anaesth* 56:1325-1335, 1984.

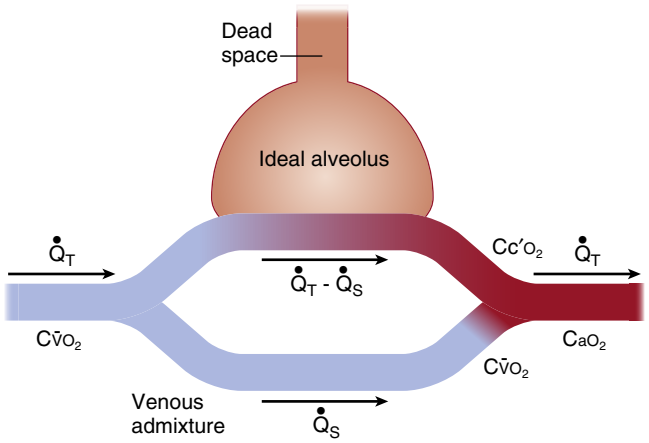

Figure 51-17. Three-compartment model of gas exchange. The lung is represented as three functional units: alveolar dead space, "ideal" alveoli, and venous admixture (shunt). The model does not differentiate between true shunt or true dead space and components of shunt and dead space that are caused by ventilation-perfusion ($\dot{V}/\dot{Q}$) mismatch. CAO_2, Arterial oxygen content; $Cc'o_2$, oxygen content of end pulmonary capillary blood; $C\bar{v}o_2$, mixed venous oxygen content; $\dot{Q}_S$, shunted blood flow; $\dot{Q}_T$, total blood flow. *(Redrawn from Lumb AB:* Nunn's applied respiratory physiology, *ed 6, Philadelphia, 2005, Butterworth Heinemann.)*

nonlinear relationship between PaO_2 and blood O_2 content.[165] As a consequence, several indices based on the PaO_2 that account for the FiO_2 or the PAO_2 have been developed: the alveolar-arterial partial pressure gradient of O_2 ($[A\text{-}a]PO_2$), the respiratory index ($[A\text{-}a]PO_2/PaO_2$), the arterial-alveolar ratio of O_2 partial pressures (PaO_2/PAO_2), and the ratio between PaO_2 and FiO_2 (PaO_2/FiO_2).[165]

The ideal index should reflect the efficiency of oxygenation, change with changes in lung function, remain constant with changes in extrapulmonary conditions (e.g., FiO_2), and provide clinically useful diagnostic and prognostic information.[165] The advantages of indices based on the PO_2 are that their calculations are fairly simple and require only arterial blood sampling. However, an important limitation is that these indices vary with the FiO_2, P_{aCO_2}, Hb, and O_2 consumption ($\dot{V}O_2$).[166,167] Consequently, changes in those variables can lead to changes in the values of the indices in the absence of any change in lung gas exchange function. Another limitation is the failure of these indices to account for changes in $\dot{V}/\dot{Q}$ matching resulting from changes in the FiO_2. Additionally, indices that use PAO_2 rely on the assumptions of the alveolar gas equation, including $P_{ACO_2} = P_{aCO_2}$, which may not hold true in pathologic conditions.

An early index developed to assess oxygenation that used only peripheral blood sampling was the $(A\text{-}a)PO_2$.[168] The $(A\text{-}a)PO_2$ helps to differentiate $\dot{V}/\dot{Q}$ mismatch, shunt, and diffusion limitation from hypoventilation and low FiO_2 as causes of hypoxemia. This is because the $(A\text{-}a)PO_2$ is unchanged under conditions of decreased FiO_2 and hypoventilation but increased with $\dot{V}/\dot{Q}$ mismatch, shunt, and diffusion limitation.

The A-a gradient is calculated as follows:

$$(A\text{-}a)PO_2 = PAO_2 - PaO_2 \qquad [19]$$

The normal value of the $(A\text{-}a)PO_2$ is less than 10 mm Hg in young adults breathing room air, and it increases with age and the administration of supplemental O_2. The change in $(A\text{-}a)PO_2$ with age can be estimated by[169]:

$$(A\text{-}a)PO_2 = 0.21 \times (age + 2.5) \qquad [20]$$

The $(A\text{-}a)PO_2$ varies significantly with the FiO_2 such that the application of supplemental O_2 can lead to an increase in the $(A\text{-}a)PO_2$ independent of pulmonary disease.[166] Like the $(A\text{-}a)PO_2$, the respiratory index $(A\text{-}a)PO_2/PaO_2$ and the PaO_2/PAO_2 are sensitive to FiO_2, particularly in the presence of a high degree of $\dot{V}/\dot{Q}$ mismatch, such as during the acute respiratory distress syndrome (ARDS), and less so in the absence of true shunt or when low $\dot{V}/\dot{Q}$ regions are minimal (e.g., in healthy lung or pulmonary embolus).[170]

Unlike the other indices based on partial pressures, the PaO_2/FiO_2 ratio does not use the PAO_2 and its associated assumptions. This index is more stable, particularly under conditions relevant to ARDS such as PaO_2 lower than 100 mm Hg in the setting of an FiO_2 greater than 0.5.[166,167] PaO_2/FiO_2 values are part of the diagnostic criteria for ARDS and have been correlated with outcomes in these

patients.[171] When repeated arterial blood sampling is not possible, the SpO_2/FiO_2 (also referred to as SF) ratio may be useful. SF ratio values have shown good correlation with PaO_2/FiO_2 values in both adults and children with respiratory failure who have SpO_2 in the range of 80% to 97%.[172,173]

Unlike PaO_2, $Paco_2$ can be maintained in the normal range in the presence of significant $\dot{V}/\dot{Q}$ mismatching. The reason is that the CO_2 content curve has no plateau. In this way, compensatory hyperventilation can be used to reduce elevations in $Paco_2$.[174] The dependence of $Paco_2$ on CO_2 elimination ($\dot{V}co_2$) and alveolar ventilation ($\dot{V}_A$) with k in the equation as a conversion factor equal to 0.863 is expressed by:

$$Paco_2 = k \times (\dot{V}co_2/\dot{V}_A) \quad [21]$$

In steady-state conditions (constant $\dot{V}co_2$), $Paco_2$ changes inversely with the alveolar ventilation. The traditional measure of ventilation inefficiency has been the fraction of dead space to tidal volume (V_D/V_T), calculated using the Bohr equation (see Equation 15) and the assumption that the arterial and alveolar partial pressures of CO_2 are equivalent ($Paco_2 = Paco_2$). The dead space fraction determined in this manner includes alveolar (i.e., nonperfused alveoli) and anatomic dead space, as well as regions of high $\dot{V}/\dot{Q}$ ratio. As with the discussion on shunt, the dead space fraction characterizes not only real anatomic dead space, but also areas of inefficient ventilation (see Fig. 51-17).

MEASUREMENT PRINCIPLES

PaO_2 is measured using a Clark electrode. The electrode consists of a cathode (electron source, platinum or gold) and an anode in an electrolyte bath, surrounded by a thin O_2-permeable membrane. The electrode is inserted into the sample, and O_2 diffuses through the membrane and is reduced by the cathode, thus generating a current. The current is proportional to the PO_2 in the sample.[175] The Pco_2 electrode measures the change in pH brought about by the equilibration of blood with a bicarbonate solution.[176]

A continuous blood gas monitor has been described using an optical PO_2 sensor; however, clinical investigations have shown inaccuracies of PaO_2 measurements under conditions of rapidly changing values. Clear clinical indications for this monitor have not been established.[177] Fluorescence quenching of O_2 technology has been shown to detect PaO_2 oscillations during mechanical ventilation in experimental studies and to bring information on cyclic derecruitment.[178,179]

Effect of Temperature

The solubility of CO_2 and O_2 in blood is affected by temperature. At lower temperatures, solubility is increased, leading to a reduction in partial pressure. Blood gas analyzers measure gas partial pressures at 37° C. As blood from a hypothermic patient is warmed to 37° C by the analyzer, CO_2 and O_2 come out of solution, leading to $Paco_2$ and PaO_2 higher than those present in the patient. Blood gas analyzers make use of algorithms to correct the reported values to the patient's actual temperature.[180] The temperature effects on blood gas analysis are most relevant during management of hypothermic patients such as during hypothermic cardiopulmonary bypass (HCPB) or deep hypothermic circulatory arrest (DHCA).

Two strategies have been developed for the management of arterial gas partial pressures under these conditions: alpha-stat and pH-stat. During alpha-stat management, blood gas measurements obtained after the analyzer warms the sample to 37° C are used for acid-base and gas exchange management. Potential benefits of alpha-stat management include the preservation of cerebral autoregulation and the maintenance of protein function.[181] During pH-stat management, measurements are corrected to the patient's temperature before they are used for acid-base and gas exchange management. Because patients are hypothermic, the PaO_2 and $Paco_2$ at the patient's temperature are lower and the pH higher than those measured in the analyzer at 37° C. CO_2 is usually added to the oxygenator to maintain the temperature-corrected $Paco_2$ and pH at normothermic values. The theoretic benefits of pH-stat management are increased cerebral vasodilation leading to more homogenous cerebral cooling.[182]

Studies have compared the two strategies with respect to outcomes, with varying results.[183-190] In general, clinical studies support the use of pH-stat management in pediatric cardiac surgical procedures during HCPB or DHCA.[185,189,191] In adult patients, the use of alpha-stat management is supported for HCPB.[192] For procedures involving DHCA in adults, use of pH-stat management has been suggested to increase the rate and uniformity of cooling and alpha-stat management during rewarming.[193]

LIMITATIONS AND SOURCES OF ERRORS

Proper handling of arterial blood gas samples is important to prevent errors. Two common sources of error are delays in sample analysis and the presence of air in the sampling syringe.[194] A delay in sample analysis by 20 minutes at room temperature or at 4° C can lead to a decline in PaO_2.[194] The decline is attributed to the metabolic activity of leukocytes and is not observed in samples placed on ice. The presence of an air bubble in the syringe can lead to a change in the measured PaO_2 toward the PO_2 of the bubble and a decline in $Paco_2$.[194]

MONITORING LUNG FLOWS, VOLUMES, AND PRESSURES

As an organ of gas exchange, the human respiratory system relies on both convective and diffusive gas transport processes for $\dot{V}o_2$ and elimination of CO_2. The transport of air to the alveoli and alveolar gas to the environment requires the creation of a pressure gradient, which will result in volume changes in the elastic components of the respiratory system, flow in the airways, velocity in moving tissues, and acceleration of air and tissues. The lung consists of a complex branching network of airway segments and viscoelastic tissues that, during the processes of breathing or ventilation, gives rise to tremendous variations in gas velocities and flow regimens. The movement of gas flow ($\dot{V}$) into and out of the lungs requires driving

pressures (P) to overcome the resistive (P_R), elastic (P_E), and at times inertial (P_I) forces offered by the airway tree, parenchymal tissues, and chest wall:

$$P = P_R + P_E + P_i \quad [22]$$

Equation 22 can be used to describe the mechanical behavior of the total respiratory system, the lungs alone, or the chest wall, depending on whether P refers to airway pressure relative to atmosphere, airway pressure relative to pleural pressure, or pleural pressure alone.[195-197]

DYNAMIC RESPIRATORY MECHANICS

As a first approximation to Equation 22, the mechanical behavior of the respiratory system during breathing or ventilation can often be described according to the simple equation of motion that encompasses its resistive (R), elastic (E), and inertial (I) properties[195,198]:

$$P = R\dot{V} + EV + I\ddot{V} + P_O \quad [23]$$

where V is volume, $\ddot{V}$ denotes volume acceleration, and P_O is the distending pressure at end expiration. The resistive properties of the respiratory system probably arise from viscous and turbulent losses associated with gas flowing through the airway tree and the deformation of parenchymal and chest wall tissues. Hence, airway resistance may reflect airway caliber.[199] Provided that variations in flow are small, resistive pressure losses are assumed to be linearly related to flow according to the first term of Equation 23. With more rapid flow rates, as with exercise or forced vital capacity maneuvers, resistive losses vary nonlinearly with flow, which may more accurately be described according to[200]:

$$P_R = K_1\dot{V} + K_2\dot{V}^2 \quad [24]$$

where K_1 and K_2 are empirically determined constants. Additional energy losses arise from the tension within the alveolar surface film,[201] friction within the pleural space, and various tissue components of the parenchyma and chest wall,[196] as well as cross-bridge cycling of contractile elements within the airway walls and lung tissues.[202,203] Such losses are collectively termed *tissue resistance*.[204,205] If these tissue resistive losses are assumed to be proportional to flow according to Equation 23, one will observe that they vary inversely with breathing frequency,[202,206] a phenomenon commonly associated with viscoelastic materials.[196] In adult patients, lung tissue resistance comprises approximately 60% of subglottal total lung resistance at typical breathing rates.[207] During volume-cycled ventilation with an end-inspiratory pause, resistance can quickly be estimated from the difference between the peak (P_{peak}) and plateau (P_{plat}) pressures (i.e., the resistive pressure loss P_R) divided by the inspiratory flow ($\dot{V}_I$) immediately before the end-inspiratory pause:

$$R = \frac{P_{peak} - P_{plat}}{\dot{V}I} = \frac{P_R}{\dot{V}I} \quad [25]$$

Thus, for a specified flow rate, alterations in P_R may reflect changes in airway caliber, as may occur during intraoperative asthma exacerbation (Fig. 51-18, *center panel*), or obstruction within the ETT or breathing circuit.

Elastic pressures arise from the recoil of the lungs and chest wall when their normal anatomic configurations are deformed, either by contraction of the diaphragm and intercostal muscles or by some external force (e.g., a ventilator).[208] Elastance is simply defined as the change in distending pressure (transrespiratory, transpulmonary, or intrapleural) for a given change in volume. Dynamic elastance refers to the change in elastic (i.e., nonresistive) distending pressure per unit volume during the process of breathing or ventilation. Elastance of the total respiratory system (E_{RS}) comprises both lung (E_L) and chest wall (E_{CW}) elastances:

$$E_{RS} = E_L + E_{CW} \quad [26]$$

In clinical settings, elastance is usually expressed as its reciprocal, compliance (i.e., change in volume per unit change in pressure). This leads to an alternate form of Equation 26, expressing the relationships of the compliant components of the total respiratory system (C_{RS}), lungs (C_L), and chest wall (C_{CW}):

$$\frac{1}{C_{RS}} = \frac{1}{C_L} + \frac{1}{C_{CW}} \quad [27]$$

Factors that reduce total respiratory or lung compliance include consolidation, pulmonary edema, pneumothorax, atelectasis, interstitial disease, pneumonectomy or surgical resection, lung overdistention, and mainstem intubation. Lung compliance generally increases in emphysema. Factors that reduce chest wall compliance are abdominal distention, abdominal compartment syndrome, chest wall edema, thoracic deformity, muscle tone, and extensive thoracic or abdominal scar (e.g., from burns); C_{CW} is reduced with muscle relaxation and flail chest.

Respiratory system elastance (E_{RS}) is most easily determined during periods of zero flow (when resistive pressures are zero) as the difference between P_{plat} and PEEP (i.e., the elastic pressure P_E) divided by the V_T:

$$E_{RS} = \frac{P_{plat} - PEEP}{V_T} = \frac{P_E}{V_T} \quad [28]$$

The corresponding C_{RS} is usually between 50 and 100 mL/cm H_2O in normal mechanically ventilated lungs. Alterations in P_E for a specified V_T may be observed during processes that alter lung or chest wall elastance, such as a pneumothorax during thoracotomy or abdominal insufflation during laparoscopic surgical procedures (see Fig. 51-18, *right panel*). In general, dynamic elastance is higher than static elastance as a result of viscoelasticity[198] and gas redistribution.[209]

Finally, inertial pressures are associated with acceleration of the gas column in the central airways, as well as the motion of the respiratory tissues.[210] Inertia is usually not a significant contributor to the work of breathing, except during sudden changes in air flow, as may occur during inspiratory step profiles or high-frequency ventilation (HFV).[211]

Equations 25 and 28 cannot be used to estimate resistive (R) and elastic (E) properties if an end-inspiratory pause is not present in the ventilator waveform. This is because one cannot easily separate the resistive and elastic pressures just by visual inspection. For example, during pressure-controlled ventilation (PCV), the airway opening is exposed to a constant inflation pressure during inspiration (Fig. 51-19). Airway flow and V_T during PCV are determined not by the

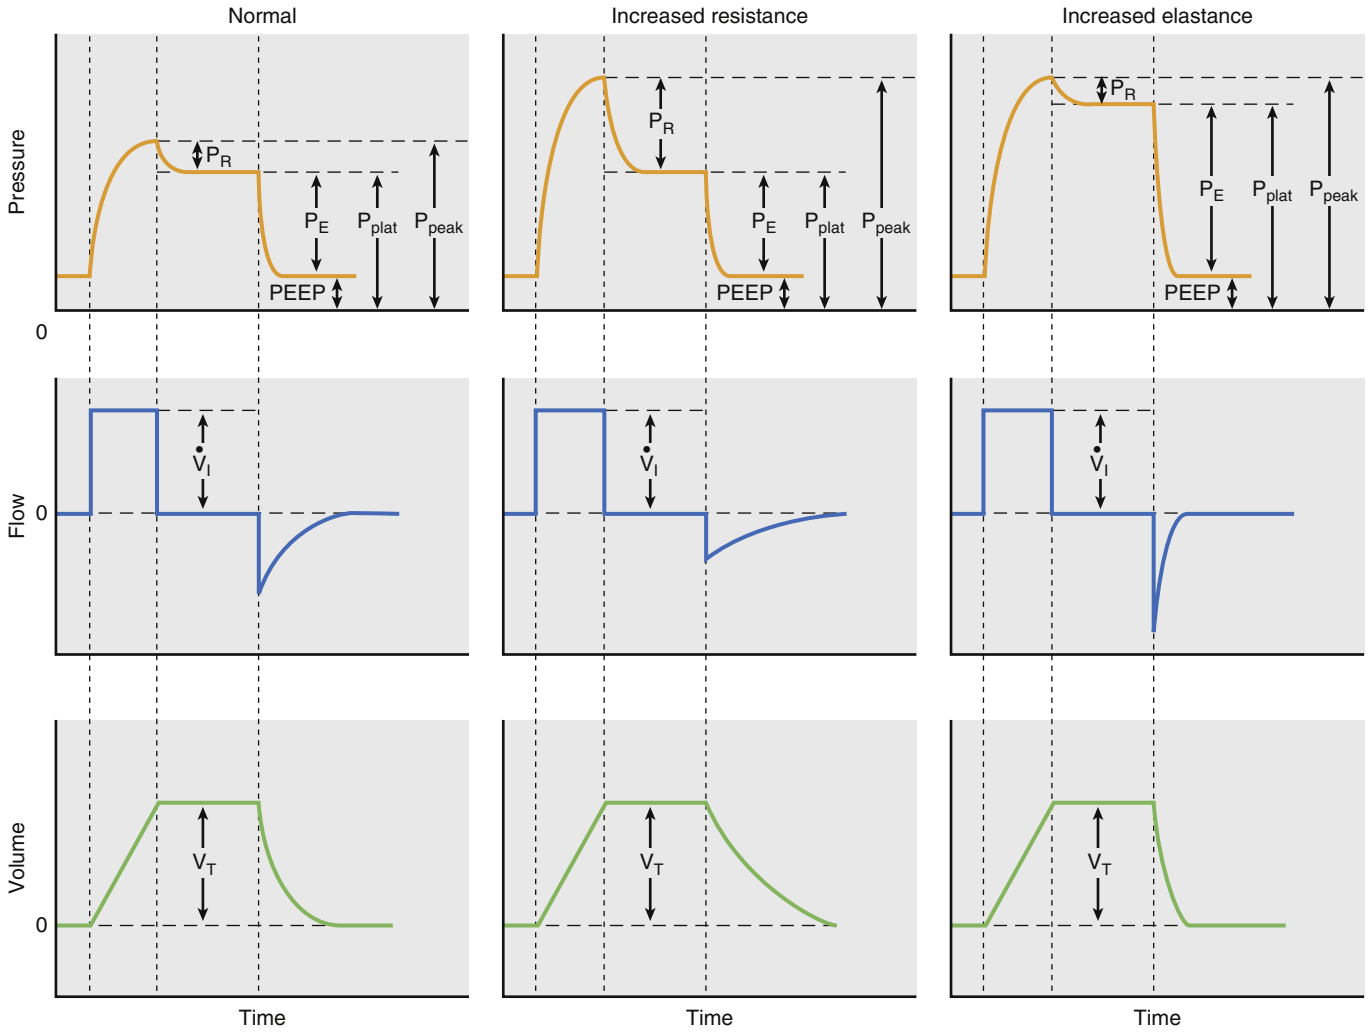

Figure 51-18. Airway pressure, flow, and volume waveforms during constant-flow volume-cycled ventilation with an end-inspiratory pause. The components of the peak inspiratory pressure (P_{peak}) and the plateau pressure (P_{plat}) are presented: resistive pressure (P_R), elastic pressure (P_E), and positive end-expiratory pressure (PEEP). The same peak flow ($\dot{V}_I$) and tidal volume (V_T) are delivered by the mechanical ventilator in each case. The *leftmost panels* represent waveforms in a healthy patient. A small P_R component is noted, with most of the peak pressure consisting of elastic pressure. Expiratory flow decreases to zero before the start of the next inspiration, this indicating an appropriate inspiratory-expiratory (I:E) ratio and the absence of slowly emptying lung regions. Volume, as the integral of flow, also returns to zero before the initiation of the next breath. The *middle panels* represent waveforms in a patient with an increase in airway resistance. A significant increase in the resistive component P_R, and consequently P_{peak}, is seen. The elastic component is unchanged, as reflected in identical P_{plat} as compared with the healthy condition. Because increased resistance slows the process of lung emptying, the expiratory phase of the flow and volume curves now takes longer to reach the zero. In several cases, zero is not reached, and a change in the I:E ratio is necessary to avoid volume trapping and auto-PEEP. The *rightmost panels* represent a subject with increased P_E, as may occur during laparoscopic insufflation or pneumothorax. The increase in P_{plat} is consistent with the increased elastance of the respiratory system and fast emptying of the lungs during exhalation.

ventilator, but rather by the gradient between airway and alveolar pressures. A more robust method of estimating respiratory R and E involves multiple linear regression of the coefficients in Equation 23 on sampled flow and pressure data.[212-214] Such numeric approaches are present in commercially available respiratory mechanics monitors, and they can be used on almost all ventilator waveforms. They are not restricted to volume- or time-cycled waveforms with an end-inspiratory pause. Moreover, one can separately estimate R and E during the inspiratory and expiratory phases, which may be different in some patients because of dynamic airway compression or derecruitment.[215,216]

Dynamic estimates of total respiratory R and E based on positive airway opening pressures are valid only during controlled modes of ventilation when the chest wall is relaxed. Although this is certainly the case during general anesthesia with neuromuscular blockade, the situation is more complicated during spontaneous breathing or assisted modes of ventilation. In such situations, the mechanics of the chest wall can be accounted for in estimates of R and E if transpulmonary pressure is estimated using esophageal manometry, as described later.

STATIC RESPIRATORY MECHANICS

As previously illustrated, elastance (or compliance) is most easily measured during periods of zero flow because

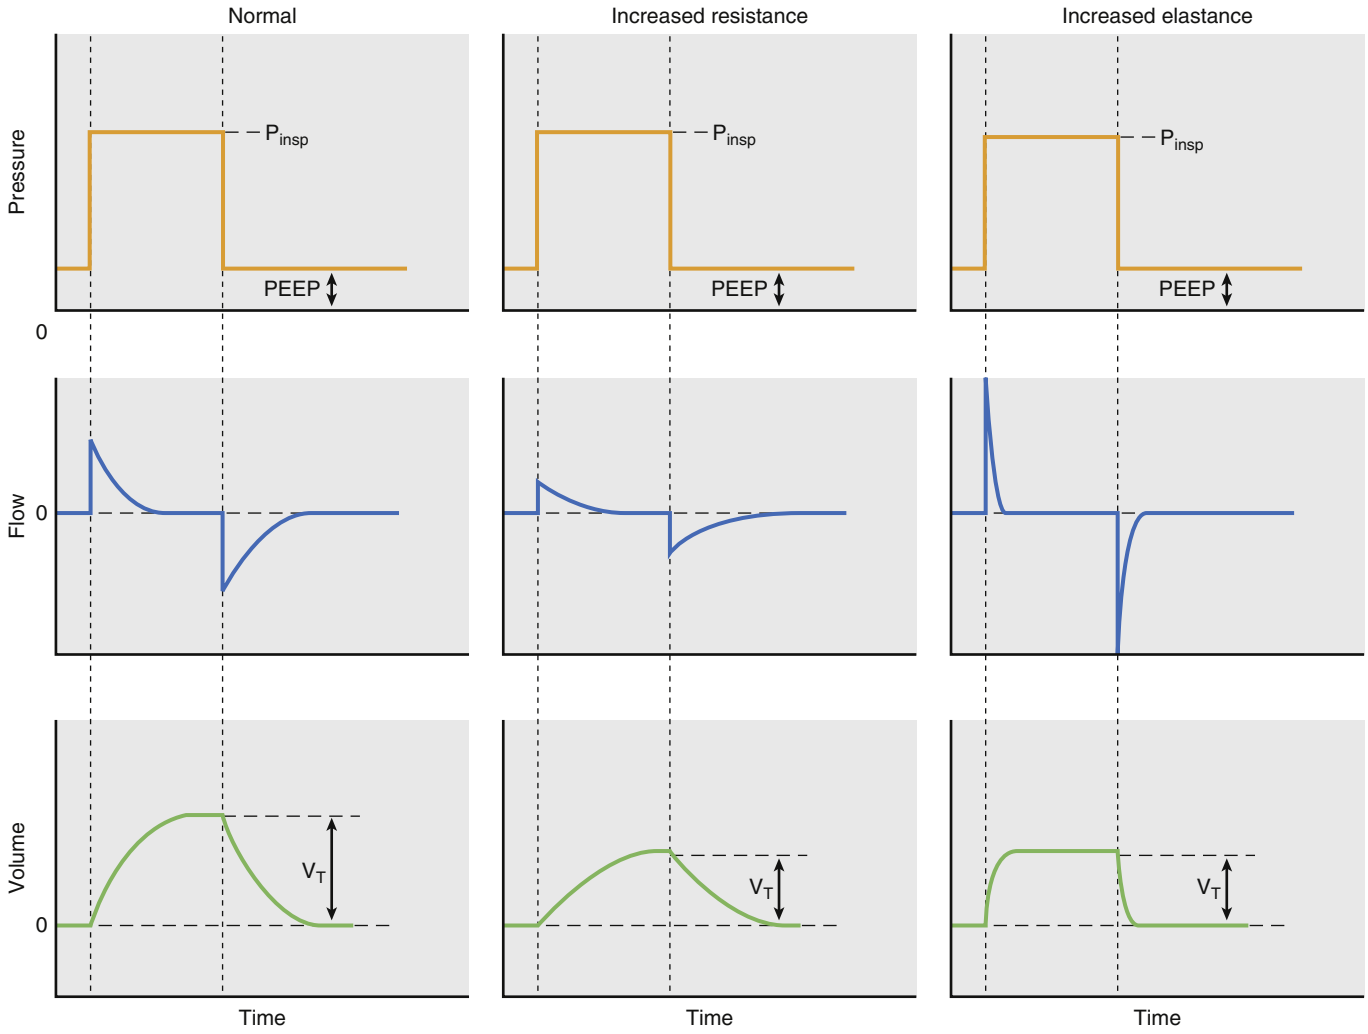

Figure 51-19. Airway pressure, flow, and volume waveforms during pressure-controlled ventilation (PCV) for the same patients depicted in Figure 51-18. In this ventilatory mode, the ventilator delivers a fixed pressure during the inspiratory phase, irrespective of the resistance and compliance. Airflow and tidal volume will consequently change with changes in those parameters. The *leftmost panels* represent waveforms in a patient with normal lungs. The *middle panels* represent waveforms in a patient with airway obstruction. Note the absence of a peak-plateau difference as compared with the volume-controlled mode, a lower tidal volume (V_T), and a prolonged time for airflow to reach zero during exhalation as compared with the normal patient. The *rightmost panels* represent a subject with increased elastance, as may occur during laparoscopic insufflation or pneumothorax. Note a reduction in V_T and a shorter time to reach zero flow, consistent with a more rigid respiratory system. *PEEP,* Positive end-expiratory pressure; P_{insp}, inspiratory pressure.

during these conditions the measured distending pressure is exclusively associated with elastic processes. However, a more comprehensive characterization of elastance can be obtained by plotting cumulative inspired or expired lung volume against the distending pressure across the lungs or total respiratory system. This quasistatic pressure-volume (PV) curve can be constructed during very slow inflations or deflations[217] (when resistive pressures are negligible), or during periodic flow occlusions.[218] For example, the expiratory limb of the PV curve can be constructed by inflating the lungs to a specified volume (usually total lung capacity) and then allowing passive deflation with flow interruptions lasting 1 to 2 seconds.

The PV curve is typically nonlinear (Fig. 51-20); that is, compliance, defined as the local slope dP/dV of the PV curve, varies with lung volume. Empirically, PV curves are usually described using single exponential[219] or sigmoidal[220] functions. When they are described using sigmoidal functions, two points are usually demarcated on such curves, incorrectly termed the upper inflection point (UIP) and lower inflection point (LIP).* The UIP is thought to represent the point at which lung overdistention occurs, as during parenchymal strain-stiffening.[196] The LIP is thought to reflect the process of maximum alveolar recruitment. During protective lung ventilation, one seeks to ventilate a patient in the most linear region of the PV curve, with enough PEEP to avoid the LIP where cyclic recruitment and derecruitment occurs, but with lower V_T to avoid the UIP and overdistention.[218] In addition, PV curves exhibit hysteresis, a phenomenon in which the

*The formal mathematical definition of an inflection point is a point on a *curve* at which its concavity (i.e., its second derivative) changes *sign* from positive to negative or vice versa.

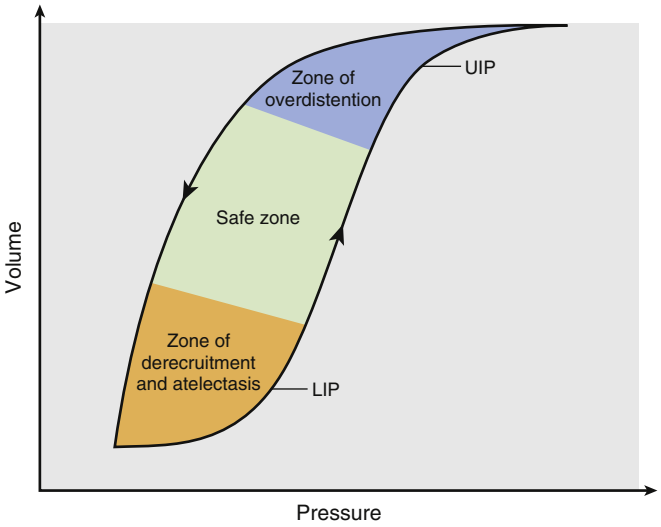

Figure 51-20. Schematic of a pressure-volume curve for the lungs or total respiratory system that demonstrates hysteresis between inspiratory and expiratory limbs. The upper inflection point (UIP) and lower inflection point (LIP) are demarcated on the inspiratory limb. During mechanical ventilation, lung regions should be in the safe zone for optimal lung protection. *(Redrawn from Froese AB: High-frequency oscillatory ventilation for adult respiratory distress syndrome: let's get it right this time!* Crit Care Med *25:906-908, 1997.)*

lung volume at a specified pressure depends on the direction from which the distending pressure is approached (i.e., either inspiration or expiration). The reasons that the PV curve of the lungs or total respiratory system exhibits hysteresis are numerous and complex, and include the biophysical properties of surfactant,[221] time-dependent recruitment or derecruitment,[222] as well as contact friction among various connective tissue elements.[223]

Several problems arise with managing ventilation based on PV curves. First, PV curves are constructed only during periods of zero flow or near zero flow, and they do not reflect the mechanics of the lungs or total respiratory system during the dynamic processes of breathing or mechanical ventilation. In fact, the dynamic PV relationships for the same patient may be very different. Second, the UIP and LIP are not always visually apparent. Finally, a PV curve for the lungs or total respiratory system represents the averaged static behavior of a population of many lung units, with each operating on different portions of their own individual PV curves.

WORK OF BREATHING

The work of breathing (W) represents the energy required to inflate or deflate the lungs, or chest wall, or both, by a specified volume. In its simplest form, it can be represented as the product of the applied distending pressure and resulting volume change:

$$W = PV \quad [29]$$

However when pressure and volume vary as functions of time (as during the course of a spontaneous or controlled breath), work may be expressed as the cumulative product[224]:

$$W = \int PdV \quad [30]$$

or equivalently as the integral of the pressure-flow product with respect to time[225]:

$$W = \int_0^T P(t)\dot{V}(t)dt \quad [31]$$

where T is the duration over which W is determined. For example, if T corresponds to the duration of inspiratory period and P the transpulmonary pressure, then W corresponds to the work required to overcome both the resistive and elastic forces opposing the entry of air into the lungs (Fig. 51-21). If T corresponds to the duration of an entire breath, the energy initially stored in the elastic recoil of the lung tissues will be recovered during a passive exhalation. In this case, the area of resulting PV loop represents the work performed (i.e., energy lost) overcoming purely resistive losses in the airways and tissues. In general, W is assessed during inspiration only because the respiratory musculature (or a ventilator) must overcome both elastic and resistive pressures to bring air into the lungs. For a given V_T, W varies as a function of respiratory rate and, in most cases, achieves a minimum at a specified frequency. This frequency is termed the *energetically optimum breathing frequency,*[225] because this is the rate at which energy expenditure is minimized.

MONITORING OF RESPIRATORY PRESSURES

Fundamental to any quantitative assessment of respiratory mechanics is the measurement of pressure. Such pressures include those measured in the inspiratory or expiratory limb of the anesthesia machine, at the proximal end of an ETT, or within the trachea or esophagus. Pressure allows for the inference of the forces associated with the movement of gases through the airway tree, as well as the distention of the parenchymal tissues and chest wall, according to the elements described in Equation 22. The most accessible and familiar pressure to the anesthesiologist or intensivist is the airway pressure during controlled mechanical ventilation. Ideally, this should be the pressure measured in the trachea or at the airway opening, exclusive of any distortions from airway devices or breathing circuits. However, for practical reasons, this "airway" pressure is not the actual pressure at the airway opening or within the trachea, but it is the pressure transduced at the anesthesia machine or ventilator and reflects the resistive and compliant properties of the breathing circuit and facemask or ETT, as well as the mechanical properties of the respiratory system. Although many ventilators now use computer algorithms to provide some compensation for flow and pressure losses in the breathing circuit,[226] such approaches often rely on idealized, linear models that do not truly reflect the complex processes of turbulent air flow, polytropic gas compression, or viscoelastic tubing walls.[227,228] Therefore, one must use caution when making physiologic inferences based on airway pressures and volumes reported by a ventilator.

Often airway pressure is improperly used as a surrogate for lung distention. *Transrespiratory pressure* refers to the pressure decrease across the lungs and chest wall, which during positive-pressure ventilation is usually determined by the difference between airway pressure and atmospheric pressure. Several processes that may contribute to increased transrespiratory pressure do not correspond to

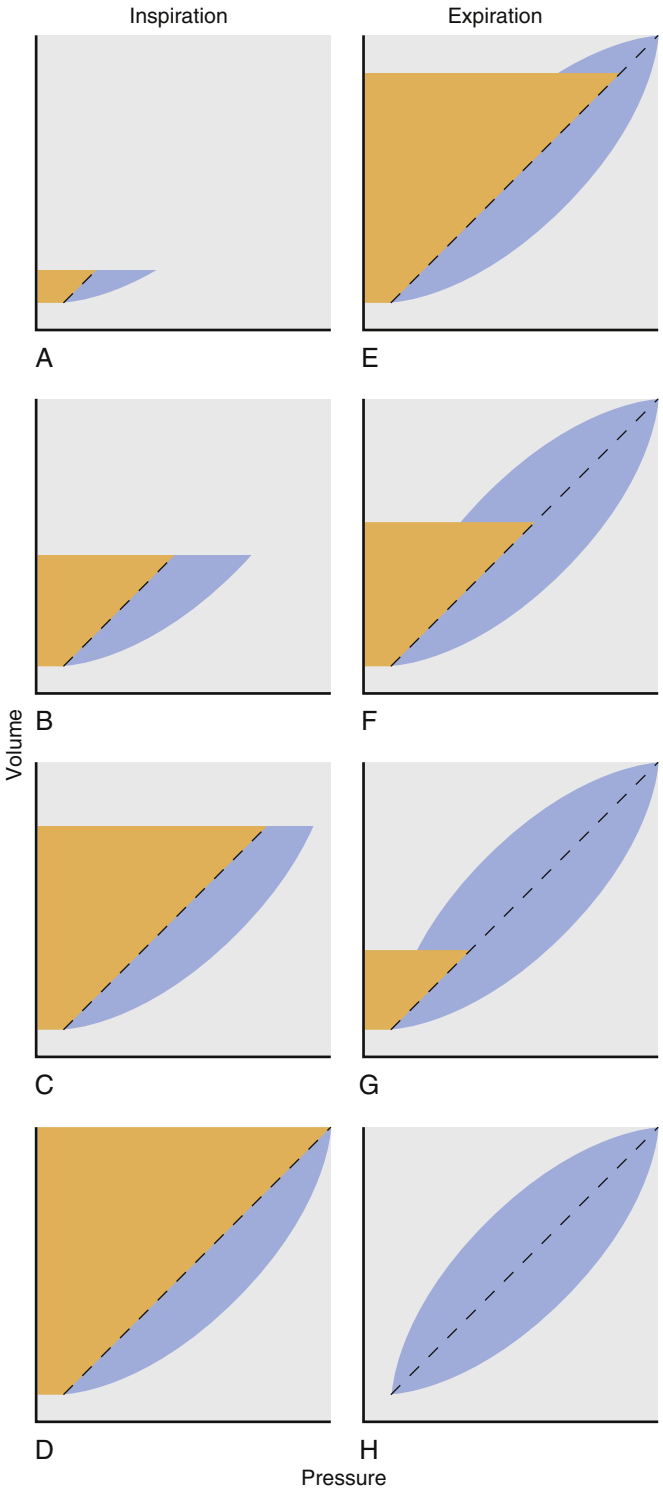

Figure 51-21. Volume plotted against transpulmonary or (transrespiratory) pressure during the course of a single breath. Plots are shown during inspiration (**A**-**D**) and expiration (**E**-**H**). The *yellow area* denotes the work of breathing related to tissue elasticity, whereas the *blue area* denotes the work of breathing related to airway and tissue resistance. Energy stored in elastic recoil at the end of inspiration is entirely recovered during expiration. However, resistive energy is always lost during both inspiration and expiration.

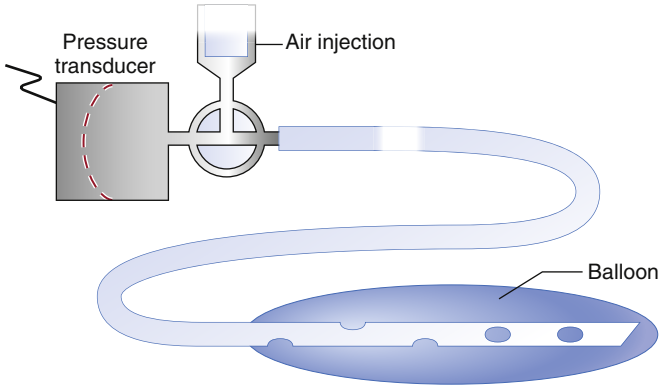

Figure 51-22. Example of an esophageal balloon catheter. The proximal end of the catheter is connected to a pressure transducer, and air is injected into the balloon through a three-way stopcock. *(Modified from Bates JHT:* Lung mechanics: an inverse modeling approach, *Cambridge, 2009, Cambridge University Press, p 220.)*

excessive lung inflation. For example, obesity, abdominal insufflation, or steep Trendelenburg position all may contribute to high airway opening pressures, but they do not necessarily indicate parenchymal overdistention (see also Chapters 41 and 71).

By contrast, *transpulmonary pressure* refers to the distending pressure across the lungs alone. Its determination requires not only measurement of airway opening pressure, but also estimates of the pressure within the pleural space. This determination can be obtained relatively noninvasively using an esophageal balloon catheter, because the pressure measured within the esophagus is relatively close to intrapleural pressure.[229] Such catheters are typically 100 cm long, with side holes in the distal tip covered by a thin-walled balloon (Fig. 51-22). The catheter can be placed through the mouth or nares and positioned in the middle-to-distal third of the esophagus. The catheter is connected to a transducer by a three-way stopcock, and a small amount of air is injected into the balloon such that its walls remain flaccid and do not contribute an additional recoil pressure to the measurement. Because the local values of pleural pressure vary depending on gravity, the balloon should be several centimeters in length to provide an average estimate of the pressure field surrounding the lungs. Estimating pleural pressure based on esophageal manometry has several limitations, including mediastinal compression of the balloon in supine patients, catheter migration, and cardiac artifact on the tracing.[230,231] Nonetheless, its use in critically ill patients may be valuable in the adjustment of appropriate levels of PEEP.[232] Peak and plateau pressures, usual in clinical practice, are obtained from the transrespiratory pressure. Accordingly, they do not characterize the pressures acting exclusively on the lungs, but rather on the whole respiratory system. Plateau pressures should range from 26 to 30 cm H_2O to minimize alveolar overdistention,[233] and they should be applied carefully.

Auto-PEEP or *intrinsic-PEEP* is the positive pressure present within the alveoli at end-exhalation and is typically observed in ventilated patients with COPD, who demonstrate dynamic airway compression and expiratory flow limitation, as well as a significant portion of patients with

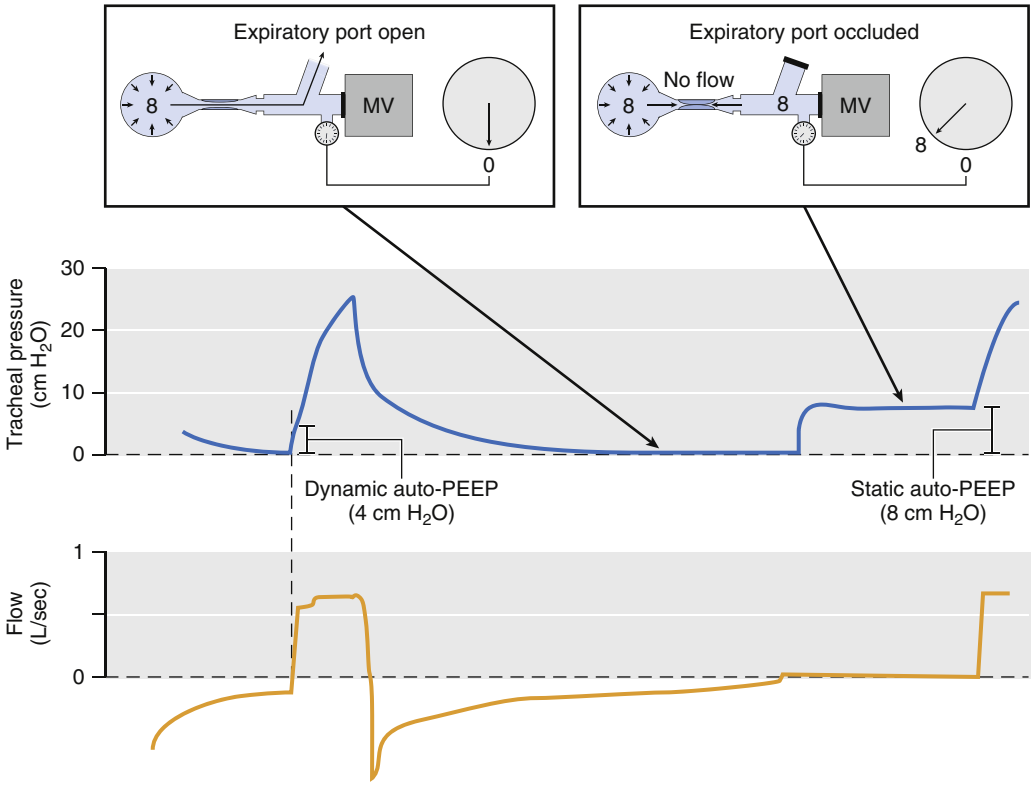

Figure 51-23. Concept of intrinsic positive end-expiratory pressure (auto-PEEP). Shown are tracheal pressure and flow waveforms during controlled mechanical ventilation. Dynamic auto-PEEP can be estimated at the beginning of inspiration as the tracheal pressure when the flow trace equals zero. Static auto-PEEP can be estimated as the tracheal pressure following prolonged expiratory occlusion. *MV,* Mechanical ventilator. *(Modified from Blanch L, Bernabé F, Lucangelo U: Measurement of air trapping, intrinsic positive end-expiratory pressure, and dynamic hyperinflation in mechanically ventilated patients,* Respir Care *50:110-123, 2005, and Moon RE, Camporesi EM: Respiratory monitoring. In Miller RD, Fleisher LA, Johns RA, editors:* Miller's anesthesia, *ed 6, New York, 2005, Churchill Livingstone, pp 1255, 1295.)*

ARDS, sepsis, and respiratory muscle weakness.[234] Auto-PEEP can promote significant respiratory and hemodynamic compromise. It is usually caused by a combination of increased airway resistance and reduced lung elastic recoil (i.e., an increase in the expiratory time constant of the respiratory system). Other factors are a decrease in expiratory time, an increase in V_T, an increase in external expiratory resistance, and persistent inspiratory muscle activity during exhalation. The amount of auto-PEEP can be estimated in mechanically ventilated patients by occluding the airway at end-exhalation and observing a rise in airway pressure during the occlusion maneuver until a plateau is visible (<4 seconds) (Fig. 51-23). Auto-PEEP is then defined as the difference between end-occlusion and preocclusion airway pressures. Other methods can be used to assess auto-PEEP under dynamic conditions, as well as in spontaneously breathing patients with use of an esophageal balloon.[234,235]

Any measurement of pressure requires pressure transducers. Most pressure transducers are differential sensors with two input channels, and they produce an electrical output that is proportional to the pressure difference between these channels (Fig. 51-24, *A*). Such transducers must have a high *common-mode rejection ratio* (CMRR), defined as the tendency of the transducer to produce zero output if both its inputs are exposed to identical pressures. Many pressure waveforms are transduced relative to atmosphere with one of the two inputs left opened

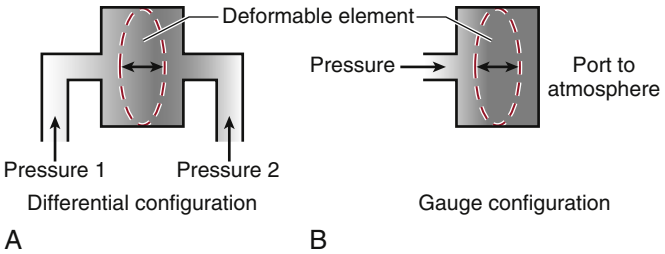

Figure 51-24. Pressure transducers arranged in differential (**A**) or gauge (**B**) configurations. *(Modified from Bates JHT:* Lung mechanics: an inverse modeling approach, *Cambridge, 2009, Cambridge University Press, p 220.)*

to ambient air (Fig. 51-24, *B*), otherwise referred to as gauge configuration. In clinical settings, pressure is most commonly measured using relatively inexpensive, piezoresistive transducers.[198] These devices rely on a pressure-sensing diaphragm whose electrical resistance changes when it is deformed in response to a differential pressure. This change in electrical resistance can be sensed with a standard Wheatstone bridge circuit, which produces an output-voltage signal appropriate for amplification and filtering. In general, piezoresistive transducers have adequate frequency responses sufficient for most respiratory applications.[236,237] However, this frequency response can be easily degraded if the transducer is connected to the pressure-sensing location with long, compliant tubing.[238]

MONITORING OF RESPIRATORY FLOWS

Ideally, any measurement of flow should indicate the exact rate at which gas is entering and leaving the patient's lungs. This can be most easily accomplished by placing the flow-measuring device as close to the patient as possible, such as between the circuit Y-connector and the proximal end of the ETT or LMA. However, for practical reasons, most ventilators and anesthesia machines measure flow close to the machine console. This flow can be considerably different from that close to the patient because of the effects of gas compression, wall distention of the breathing circuit, and changes in gas humidity.

An important clinical use of flow monitoring is the detection of nonzero end-expiratory flows. This indicates that a gradient of pressure exists between alveolar regions and the upper airway with incomplete lung emptying at end-expiration, characteristic of auto-PEEP. As a consequence, end-expiratory lung volumes would be larger than those in the absence of auto-PEEP, with risk of dynamic lung hyperinflation and reduction of venous return. Increase in expiratory time and reduction of V_T or respiratory rate should be considered to eliminate the issue.

During ventilation, airway flow can often be inferred according to time-dependent changes in delivered or inspired V_T or from the displacement waveform of a piston or cylinder arrangement or bellows.[239-241] Preferably, flow is measured using transducers designed specifically for this task. The most common method involves the measurement of a differential pressure decrease (ΔP) across a fluid resistive element. Ideally, this ΔP is linearly related to the corresponding flow through the device. Such a principle forms the basis for one of the oldest and most widely used flowmeters, the pneumotachograph. Although they provide accurate measurement of flow, pneumotachographs are very sensitive to changes in temperature, humidity, and gas composition,[242] and they require frequent calibration using various electronic or software-based techniques to ensure accurate measurements.[243,244] This sensitivity, combined with difficulties in cleaning and sterilization, limits the routine use of these instruments in clinical environments. Orifice flowmeters also have the advantage of having relatively large internal diameters that limit the formation of condensation and minimize obstruction with secretions. Given that these devices can be manufactured using inexpensive plastic injection molding techniques, many orifice flowmeters are designed to be disposable, thus making their use increasingly popular for respiratory applications in clinical environments.[245]

Most anesthesia machines use hot wire anemometers for flow measurement,[246] which rely on temperature-dependent changes in the electrical resistance of a current carrying wire. When gas flows pass the wire, the corresponding temperature drop changes the conductivity of the filament, which can be sensed with appropriate electronic circuits.[247] Because a single wire filament cannot sense the direction of flow, two different anemometers can be used in the ventilator circuit: one for the inspiratory limb, and the other for the expiratory limb. Alternatively, two wires in series must be used for sensing bidirectional flow through a single conduit,[248] with the flow direction determined according to which wire is cooled first. Generally, hot wire anemometers have a better dynamic response compared with pneumotachographs or orifice flowmeters,[249] and therefore they are ideal for flow measurement during HFV.[250]

MONITORING OF RESPIRATORY VOLUME

Similar to flow measurement, the ideal measurement of volume should be an accurate accounting of the gas quantity moving into and out of the patient. However, delivered or exhaled V_T measurement is subjected to the same limitations of flow measurement because most anesthesia machines and ventilators determine volume by electrically or numerically integrating the corresponding flow signal.[198] Care must be taken to ensure that any drifts or offsets from the flow transducer are minimized, given that their integration will result in errors in estimated volume. This may be accomplished by appropriately zeroing the transducer periodically, such as at the end of a breath. Although electronic or digital high-pass filters may be used to remove drifts and offsets in real-time, these tend to have long transient responses.

Finally, besides the pathophysiologic and monitoring applications described in this section, monitoring of pressures, volumes, and flows has been applied to monitoring, training, and education for neonatal resuscitation[251] (see also Chapter 95).

PLETHYSMOGRAPHIC MONITORING

Respiratory inductance plethysmography (RIP) is a noninvasive respiratory monitoring technique that quantifies changes in the cross-sectional area of the chest wall and the abdominal compartments. The method is used to assess V_T, respiratory rate, adequacy of high-frequency oscillatory ventilation (HFOV), lung volume changes during tracheobronchial suctioning, and thoracoabdominal synchrony.[252] RIP relies on the principle that a current applied through a loop of wire generates a magnetic field normal to the orientation of the loop (Faraday's law) and that a change in the area enclosed by the loop creates an opposing current within the loop directly proportional to the change in the area (Lenz's law). Two elastic bands containing a conductor are used: one typically placed around the patient's chest, 3 cm above the xiphoid process; and the other around the abdomen. Each of these bands produces an independent signal representative of the thoracic and abdominal cross-sectional area, and the sum of these two signals calibrated against a known gas volume yields lung volume change.

RIP has been used in several pediatric applications to monitor V_T and respiratory rate, building on the advantage that a facemask, LMA, or ETT is not required for measurements.[253] This technique could also guide lung-protective ventilation strategies by facilitating the construction of PV curves for individual patients. These can be used to optimize lung recruitment, maintain an open lung, and limit overdistention (see the section on static respiratory mechanics).

Intraoperatively, RIP may find applications in areas for which accurate monitoring of V_T are required but not possible with the usual anesthesia machine monitors. This could occur with a shared airway (e.g., laryngotracheal surgery,[254] flexible and rigid bronchoscopy) or a patient whose trachea is not intubated (e.g., monitored anesthesia care and noninvasive pressure support ventilation).

Unfortunately, RIP cannot be used during thoracic and abdominal surgical procedures, given the need for the measurement bands. Moreover, the calibration characteristics of the device are affected by changes in the pattern of breathing.

RESPIRATORY RATE MONITORING: APNEA MONITORING

Apnea and bradypnea are life-threatening events frequently observed in the intraoperative and postoperative periods of anesthesia. Prematurity, morbid obesity, age, obstructive sleep apnea, and central nervous system depressant medications have been associated with the risk of apnea or bradypnea (see also Chapters 71 and 80).[255,256] Accordingly, many different approaches have been developed for detecting those events.[257,258] Two main types of apnea are observed: central and obstructive. Central apnea is defined as apnea resulting from a failure of the central nervous system to drive respiration. Obstructive apnea is that resulting from upper airway obstruction. Current monitors assess at least one of three processes occurring during breathing to detect apnea[258]: chest wall expansion, gas flow, and gas exchange.

Chest wall expansion is usually measured as follows:

1. Changes in thoracic electrical impedance (impedance pneumography) of the chest wall. The method is based on the changes in electrical conductivity of the chest to an electrical current as air moves in and out of the lungs during breathing and blood volume changes in the same period. This is because air is a poor electrical conductor and blood is a good electrical conductor. A low electric current at high frequency is applied in two chest electrodes, corresponding changes in voltage of the chest are measured, and the impedance continuously calculated from these. The technique is implemented in several commercial systems using routine electrocardiographic leads and is also used in home monitoring of neonatal apnea.
2. Inductive plethysmography. This is described in the section "Monitoring Lung Flows, Volumes, and Pressures."
3. Abdominal and chest fiberoptic and resistive strain gauges (pressure pad placed beside the infant's rib cage, pneumatic abdominal sensors) are used.
4. Electromyographic signal of respiratory muscles is not frequently used because of the low signal-to-noise ratio.

An important drawback of techniques based on chest expansion is their inaccuracy in the presence of movement. Thus, obstructive apnea may be falsely assessed as normal respirations.[259]

Gas flow methods are based on measurements of different variables directly related to the presence of air flow in the airway:

1. Pressure gradients along the breathing circuit. This approach uses the Poiseuille principle ($\Delta P = k \cdot V$) and differential pressure transducers to detect flow.
2. Temperature of the breathed air in the nose or mouth is used.
3. Rapid response hygrometer is based on assessment of humidity in the exhaled air.

Techniques based on gas exchange focus essentially on exhaled CO_2 as routinely used in intubated patients in the OR. In nonintubated patients, use of specifically designed cannulas combining Do_2 and breathed gas sampling facilitate the monitoring of exhaled CO_2. The usual technique uses off-line or in-line infrared sensors. Respiratory rate measurements using this technique were more accurate than those obtained with thoracic impedance tomography in patients in postanesthesia care units even with supplemental O_2 at high flows.[260] Accurate end-tidal CO_2 measurements through a nasal cannula may be difficult in mouth breathers, including obese patients and those with obstructive sleep apnea. In such cases, a nasal cannula with an oral guide may improve measurement accuracy.[261]

Pulse oximetry cannot be used as the primary monitor of apnea or bradypnea because O_2 desaturation occurs only late in a well-oxygenated apneic patient (see also Chapter 44). However, pulse oximetry adds an additional level of safety combined with primary monitors of ventilation. For example, in a study using pulse oximetry and noninvasive capnography for continuous monitoring of 178 patients receiving patient-controlled analgesia, respiratory depression measured by O_2 desaturation occurred in 12% of the patients, in line with previous studies.[255] In contrast to previous estimates, episodes of bradypnea (respiratory rate <10 breaths/minute) were present in 41% of patients, far more frequently than the previously reported 1% to 2%.[262-264]

Respiratory rate monitoring is critical for infant apnea monitoring (see also Chapter 95). Combinations of transthoracic impedance and pulse oximetry may maximize the detection of true episodes of apnea in home monitors for neonatal apnea.[265] This is because pulse oximetry provides an additional level of monitoring in cases of poor performance of transthoracic impedance secondary to motion artifacts. The value of combining monitors of ventilation such as capnography with pulse oximetry to maximize detection of alveolar hypoventilation has been confirmed.[266] Capnography allowed for early detection of arterial O_2 desaturation in cases of alveolar hypoventilation in the presence of supplemental O_2.

False-positive and false-negative alarms occur during apnea monitoring. The most dangerous conditions occur when artifacts are detected as breathing, and alarms are not activated. Such artifacts include vibrations, cardiac motion, patient movement, and electromagnetic interference from other instrumentation. Impedance pneumographs are subject to cardiovascular artifacts, whereas pressure pads are subject to patient motion artifacts. A more common (yet less dangerous)

problem is when an alarm sounds in a patient without apnea. Frequent causes include inadequate sensitivity settings, malfunctioning electrodes, and movement of the patient. Motion transducers based on sensing of acceleration were used in neonates undergoing HFOV, and results showed that monitoring of regional tidal displacement may enable early recognition of deteriorating ventilation during HFOV that eventually leads to hypoxemia.[267]This study found that approximately half of the cases of hypoxemia had causes other than slowly deteriorating ventilation.[267]

Current recommendations of the Anesthesia Patient Safety Foundation for Essential Monitoring Strategies to Detect Clinically Significant Drug-Induced Respiratory Depression in the Postoperative Period [http://www.apsf.org/initiatives.php] state that continuous electronic monitoring of oxygenation and ventilation should be available and considered for all patients, not only those considered at risk for postoperative respiratory insufficiency. Clearly, respiratory depression can occur in patients without risk factors. These recommendations stress that maintaining status quo while awaiting newer technology is not acceptable, and intermittent "spot checks" of oxygenation (pulse oximetry) and ventilation (nursing assessment) are not adequate for reliably recognizing clinically significant evolving drug-induced respiratory depression. However, continuous electronic monitoring should not replace traditional intermittent nursing assessment and vigilance. Capnography or other monitoring modalities that measure ventilation and airflow are indicated when supplemental O_2 is needed to maintain acceptable O_2 saturations. The recommendations also call attention to threshold-based alarm limits on individual physiologic variables, which may result in failure to recognize early signs of progressive hypoventilation by either being insufficiently or too sensitive (excess false alarms).

IMAGING FOR RESPIRATORY MONITORING

Imaging is a monitoring technique that provides tremendous insight into pulmonary structure, function, and inflammation in both health and disease.[268-270] However, exposure to radiation and bulky devices have prevented its use at the bedside. Technologic advances have led to the introduction of newer modalities with more compact equipment for clinical use. This may herald an important shift in respiratory monitoring toward increased use of bedside imaging. Such improvements come with the advantages of less radiation exposure, noninvasiveness, and more detailed physiologic information.

CHEST RADIOGRAPHY

Chest radiography has been the traditional imaging method to assess intrathoracic conditions in the OR, postoperative anesthesia care unit, and ICUs. Accordingly, anesthesia providers should be familiar with basic radiologic findings representative of important pulmonary conditions such as interstitial infiltrates, hyperinflation, pneumothorax, pleural effusion, and consolidation. The image during chest radiography, as well as computed tomography (CT), is based on the physical principle that x-rays reaching a detector (e.g., film) depend on tissue absorption, which varies linearly with tissue density. However, radiation exposure restricts frequency of use. Furthermore, technical difficulties limit image quality. These difficulties include reduced resolution caused by movement of the patient during image acquisition and image distortion related to proximity of the x-ray beam source to the film and posterior position of the film cassette.

ULTRASONOGRAPHY

Lung ultrasonography is an emerging technique in anesthesia and critical care medicine in adults and children.[271,272] Critical and systematic approaches have proved that important clinical information can be obtained with lung ultrasonography. This adds to the advantages of practicality, low cost, and absence of radiation or other significant biologic side effects. Lung ultrasonography has been applied successfully in the assessment of pneumothorax, interstitial syndrome (i.e., cardiogenic and permeability pulmonary edema), lung consolidation, and pleural effusion. Currently available multipurpose ultrasonography probes can be used for specific portions of the pulmonary examination. For instance, the high-frequency linear array probe allows for detailed examination of the pleura and superficial changes, such as pneumothorax. This probe's limitations include its size, which impedes access to larger areas of lung tissue because of the interference of the ribs, and high frequency, which limits assessment of deeper structures. To optimize visualization of the lung, probes should have an emission frequency of 5 to 7 MHz and be small with a tip shaped so that an acoustic window on the lung parenchyma can be obtained on intercostal spaces. The 5-MHz microconvex probe is frequently favored.[271,272]

When examining the patient, a methodical approach should be used to ensure comprehensive assessment of lung structure and function. In the supine patient, each hemithorax should be assessed in at least six zones: two anterior (separated by the third intercostal space), two lateral, and two posterior zones.[273,274] Because of the significant acoustic impedance differences among air, tissue, and bone (ribs), thoracic ultrasound is based primarily on characteristic artifacts and not only on the visualization of anatomic structures.[275] The ribs are seen as hyperechoic lines producing significant ultrasonography shadow (Fig. 51-25, *A*). Approximately, 0.5 to 1.0 cm deeper and between the ribs, the pleural line is found. This is typically a bright, slightly curved line. These are major structures to be identified because many disorders of relevance to the anesthesiologist affect their observed pattern. In the normal lung, lung sliding represents the movement of the visceral on the parietal pleura during respiration and is another key sonographic finding to be appreciated. The magnitude of the movement is larger in regions closer to the diaphragm than in those near the lung apex.

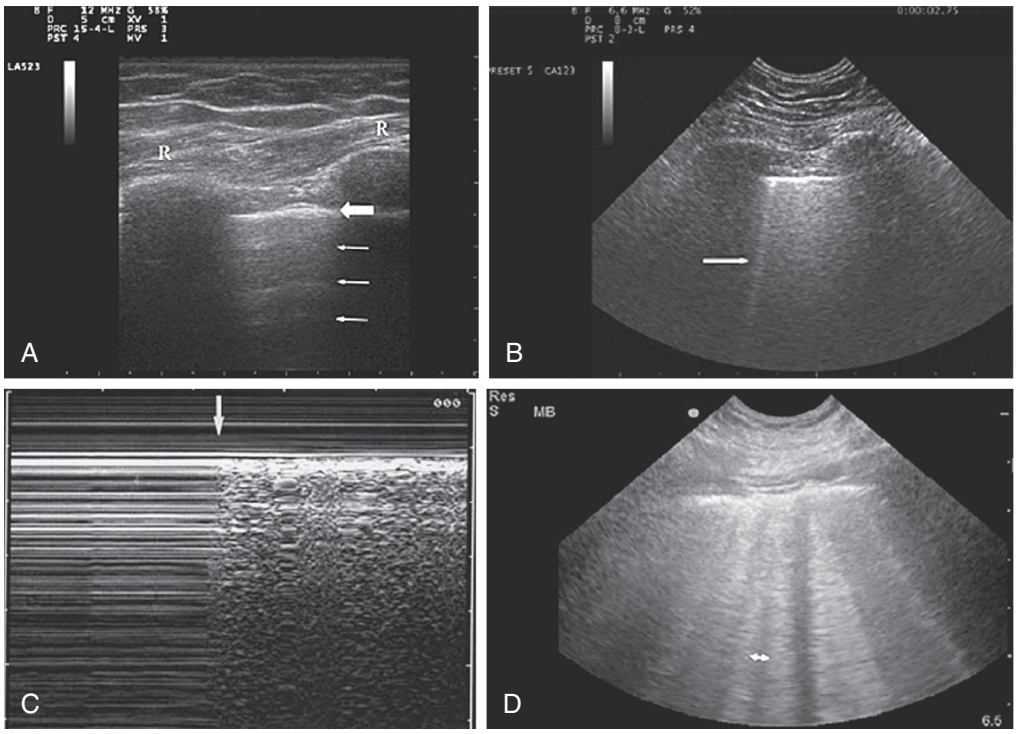

Figure 51-25. A, Typical thoracic view depicting adjacent ribs (R) producing acoustic shadowing. The white echogenic pleural line (*block arrow*) is approximately 0.5 cm below the ribs. A-line artifacts (*line arrows*) are seen at equidistant spaces below the pleural line. **B,** B-line, or comet-tail, artifact is the hyperechoic artifact extending from the pleural line to the edge of the screen and erasing the A line. A solitary B line is a usual finding in normal lungs. **C,** M-mode lung ultrasound image illustrative of the "lung point" for diagnosis of pneumothorax. The sudden inspiratory transition from a parallel line pattern indicative of absence of lung motion (pneumothorax) to a granular pattern indicative of lung tissue can be observed (*arrow*). **D,** Interstitial syndrome case showing B lines 7 mm or less apart (*arrow*). The pleural line and ribs are also appreciated. *(From Bouhemad B, Zhang M, Lu Q, Rouby JJ: Clinical review: bedside lung ultrasound in critical care practice,* Crit Care *11:205, 2007, and Turner JP, Dankoff J: Thoracic ultrasound,* Emerg Med Clin North Am *30:451, 473, ix, 2012.)*

Below the pleura, horizontal reverberation artifacts at regular distances are referred to as A lines (see Fig. 51-25, *A*). Another artifact is the B line, a discrete laser-like vertical hyperechoic reverberation artifact that arises from the pleural line (previously described as ''comet tails''), extends to the bottom of the screen without fading, moves synchronously with lung sliding, and erases A lines (Fig. 51-25, *B*). The physical and anatomic basis of the B lines is not established.[272] Solitary B lines are normal findings in the normal lung, and increased numbers are observed in disease.

Based on the recognition of such artifacts, pathologic conditions are identified.[271,272,276] Most acute disorders involve the lung surface, and this explains the utility of thoracic ultrasound in visualizing them. Ultrasonography findings for pneumothorax are the absence of lung sliding, B lines, and lung pulse, and the presence of lung points. The M-mode ultrasound scan shows parallel lines indicative of no moving structure underlying the probe. The ultrasonography finding designated as lung point is found in the presence of pneumothorax and represents imaging of the cyclic transition during breathing from the absence of any sliding or moving B lines at a physical location (i.e., air with no lung parenchyma) to the visualization of lung sliding, B lines, or altered A lines indicative of lung tissue (Fig. 51-25, *C*).[272,277] Bedside ultrasound scans can detect pneumothorax with sensitivity similar to that of a CT scan.[271,272]

An interstitial syndrome is characterized by the presence of multiple B lines. A positive region is defined by three or more B lines in a longitudinal plane between two ribs (Fig. 51-25, *D*). Lung consolidation is characterized sonographically by a subpleural echo-poor region or one with tissue-like echo texture. Lung consolidations may be caused by infection, pulmonary embolism, lung cancer and metastasis, compression atelectasis, obstructive atelectasis, and lung contusion. Additional sonographic signs that may help to determine the cause of lung consolidation include the quality of the deep margins of the consolidation, the presence of comet-tail reverberation artifacts at the far-field margin, the presence of air or fluid bronchograms, and the vascular pattern within the consolidation. Pleural effusions are characterized by a usually anechoic space between the parietal and visceral pleurae and by respiratory movement of the lung within the effusion (''sinusoid sign''). The presence of echogenic material within the effusion suggests an exudate or hemorrhage, although some exudates are anechoic. Most transudates are anechoic.

Advances in clinical research and experience in lung ultrasonography allowed for the proposal of an algorithm to assess severe dyspnea in the acute setting (Fig. 51-26). The BLUE protocol is a stepwise ultrasonographic approach to the patient with acute respiratory failure that aims at expeditious diagnosis with 90.5% accuracy.[276,278]

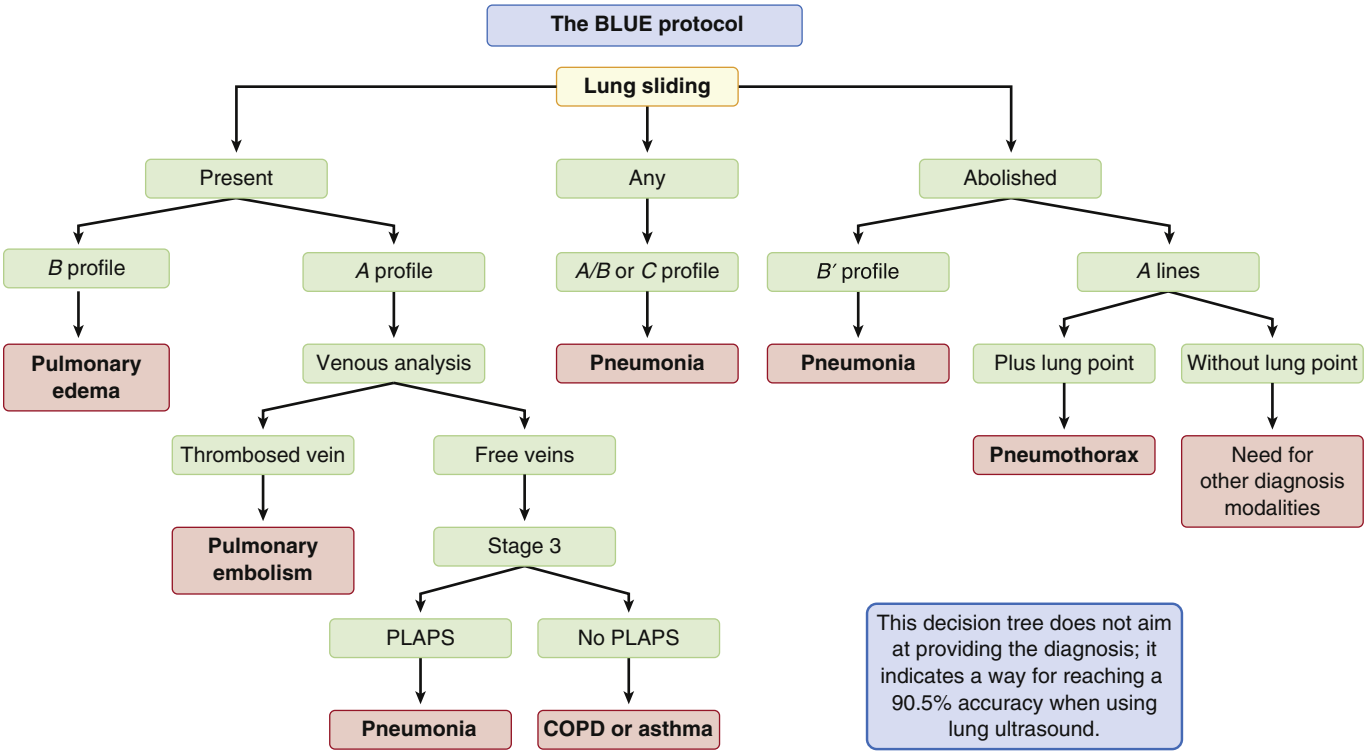

Figure 51-26. The BLUE protocol algorithm based on the particular ultrasound profile of the different kinds of respiratory failure. It uses three lung ultrasound signs with binary answers: anterior lung sliding, multiple B lines visible between two ribs in the anterior lung, and posterior and/or posterolateral alveolar and/or pleural syndrome (PLAPS). These signs are combined with venous analysis to yield 90.5% accuracy in the diagnosis of respiratory failure.[15,16] *COPD,* Chronic obstructive pulmonary disease. *(Redrawn from Lichtenstein DA, Meziere GA: Relevance of lung ultrasound in the diagnosis of acute respiratory failure: the BLUE protocol,* Chest *134:117-125, 2008.)*

ELECTRICAL IMPEDANCE TOMOGRAPHY

Electrical impedance tomography (EIT) is a noninvasive and radiation-free imaging modality used to assess regional lung function at the bedside. The method is clinically available and has moderate to low spatial resolution but high temporal resolution, thus allowing for assessment of regional ventilation in real-time.[270,279] Its use in estimating regional lung volume and optimizing mechanical ventilation settings brought significant attention to applications in ICUs and ORs.[270]

EIT is based on electrical impedance, a physical variable that reflects the opposition to the passage of a current through an object when a voltage is applied across it.[280] The impedance of biologic tissues depends on the tissue composition. High concentration of electrolytes, extracellular water content, large cells, and number of cell connections by gap junctions as present in blood and muscles reduce impedance. Air, fat, and bone have high electrical impedance. Pathologic changes of tissue composition influence impedance. These include extravascular lung water, (e.g., pulmonary edema), intrathoracic blood volume, fluid in cavities (pleural effusion, pericardial effusion, bronchial and alveolar fluid), foreign bodies (pleural drain), and lung fibrosis (e.g., after ARDS or as a primary disorder). During the breathing cycle, thoracic bioimpedance is influenced fundamentally by both ventilation and perfusion.

EIT relies on an array of electrodes (typically 16 to 32) around the chest region of interest. The location is chosen based on the clinical information desired, usually at the fifth intercostal space for standard lung assessment. A measurement consists of the application of a low electrical current to a pair of adjacent electrodes generating voltages measured by the other electrodes. A measurement cycle corresponds to a complete sequence of these measurements deriving from the electrode pairs encircling the chest. The surface impedance allows for the reconstruction of an image proportional to regional impedance in the studied thoracic cross section. Usually, images are presented with pixels representing relative impedance change, so called functional EIT. Because air corresponds to high impedances and fluid and tissue to low impedances, the image represents regional ventilation. Absolute EIT (a-EIT) is the modality in which the image represents the actual impedance values. Direct assessment of lung conditions can be accomplished by comparing low impedance (e.g., hemothorax, pleural effusion, atelectasis, and lung edema) with high impedance (e.g., pneumothorax, emphysema).[281] EIT has compared successfully with standard methods, including CT.[270,280,282]

Because the technique provides direct real-time assessment of changes in regional aeration, several applications related to regional lung function have been identified.[279] These include the effect of induction and tracheal intubation at the expiratory lung level and regional ventilation in children (see also Chapter 95) (Fig. 51-27),[283] perioperative monitoring of the distribution of ventilation during spontaneous and controlled breathing,[284] effects of PEEP on regional ventilation during laparoscopic surgery,[285]

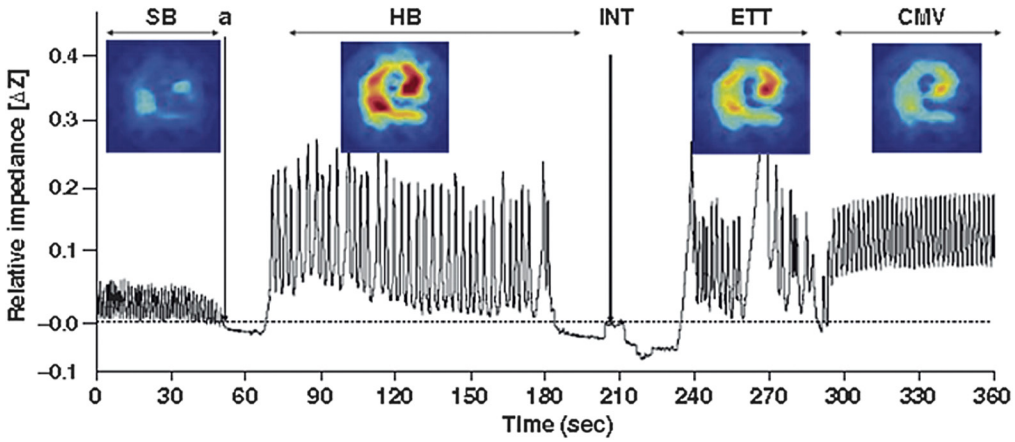

Figure 51-27. Relative impedance signal at five key stages during induction of anesthesia in children. A small impedance signal is noted during spontaneous breathing (SB) as muscle paralysis develops. Effective hand bagging (HB) produces a high-intensity signal, which is reduced to zero during tracheal intubation (INT). Distribution of regional impedances during hand bagging with the endotracheal tube (ETT) and conventional mechanical ventilation (CMV) are also visualized. *(From Humphreys S, Pham TM, Stocker C, Schibler A: The effect of induction of anesthesia and intubation on end-expiratory lung level and regional ventilation distribution in cardiac children,* Paediatr Anaesth *21:887-893, 2011.)*

assessment of ventilation distribution during mechanical ventilation,[282] bedside recruitment, PEEP titration with assessment of alveolar collapse and hyperdistention in patients with ADRS (see also Chapter 101),[286] and assessment of HFOV.[252,287] Given that optimization of lung inflation is key not only to improving gas exchange but also to minimizing ventilator-induced lung injury intraoperatively and postoperatively, EIT may be of value in patients at risk for intraoperative and postoperative respiratory complications.[288] EIT may also allow for real-time detection of pneumothorax.[289] EIT may eventually provide regional measurements of regional perfusion,[290] which could be valuable for bedside assessment of $\dot{V}/\dot{Q}$ matching during spontaneous and mechanical ventilation.

POINT-OF-CARE TESTS

Point-of-care testing (POCT) is the performance of laboratory measurements near the site of patient care. POCT technology includes portable analyzers and use of small blood samples. This implies the availability of rapid, precise, and accurate measurements in ORs and ICUs. POCT yields improvements in patient outcome through expeditious detection of physiologic deterioration and prompt treatment. Respiratory monitoring is a major element of POCT and includes analysis of arterial blood gases (PaO_2, $Paco_2$, pH), Hb, and lactate.

Blood gas measurements can be obtained with acceptable levels of accuracy and precision. For instance, three platforms for arterial blood gases and Hb were found to show a coefficient of variation of approximately 3%.[291] Mean differences among the measurements were less than 3.2 mm Hg for PaO_2 in the range of 53 to 272 mm Hg, –1.5 mm Hg for $Paco_2$ in the range of 29 to 55 mm Hg, and 0.03 for pH in the range of 6.55 to 7.50.

Hb is measured using either conductivity-based methods where hematocrit is assessed and the Hb concentration is calculated (Hb [g/dL] = hematocrit × 0.34) or with optical methods, such as using the azide-metHb reaction and photometry absorbance (see also Chapter 61).[292] Conductivity-based Hb measurements can be less than those reported by standard systems, with a clinically significant bias of –1.2 g/dL in the Hb range of 8.5 to 14.2 g/dL and a trend to underestimate the Hb value at low ranges.[291] Optical measurements have a precision of ± 1.5% compared with laboratory analysis and a correlation of 0.89.[293] The method provides precise and accurate results when used on venous blood in laboratory conditions with a coefficient of variation between 1.4% and 2.2%, only slightly higher than the precision of current hematology analyzers.[19] In patients undergoing hemorrhagic urologic surgical procedures,[19] the bias in optical-based measurements as compared with a laboratory analyzer was –0.2 ± 1.1 g/dL, and the precision was 0.7 ± 0.8 g/dL. High deviations (beyond ±1.0 g/dL) from standard laboratory analyzers occurred in 16% of those patients,[19] as well as in 1 of 78 measurements in adult patients undergoing surgical procedures of the spine.[294]

The site of blood sampling can influence POCT results. For capillary blood samples obtained from finger and ear punctures, a significant correlation exists between optical-based and automated laboratory Hb analysis, with a nonsignificant bias. Fingerstick samples may approximate standard laboratory Hb measurements better than ear lobe samples.[19] Capillary blood samples (lancet puncture to middle or ring finger and fourth drop used) in patients with gastrointestinal bleeding resulted in high deviations (>1 g/dL) in 21% of cases and very high deviations (>2 g/dL) in 4% of cases.[295] In critically ill patients, poor agreement with reference measurements is reported,[296] especially with capillary blood samples and in patients with extremity pitting edema. POCT proved relevant in the assessment of arterial blood gases during pseudohypoxemia (also called "spurious hypoxemia" and "leukocyte larceny"). This is a known cause of inaccurate blood gas measurements and occurs when PaO_2 is reduced by increased O_2 consumption as a result of markedly elevated white blood cell counts in the arterial blood sample. Measurement

error is further aggravated by delayed laboratory analysis or incorrect sampling. Pseudohypoxemia occurs not only in hyperleukocytosis but also in thrombocytosis associated with polycythemia vera.

As POCT progresses, relevant limitations will need to be addressed, including cost, accuracy, data management, and evidence for improved outcomes. Contrary to some expectations, availability of POCT in academic centers does not increase the number of tests performed.[297] Characteristics of individual institutions must be considered before implementation of POCT. For instance, POCT blood-gas analysis may offer minimal time savings and cost benefits compared with central laboratory analysis in an institution with short turnaround time.

RESPIRATORY MONITORING IN SPECIAL CONDITIONS

As methods for life support are advanced, the physiologic patterns that serve as the basis for assessment of gas exchange and respiratory mechanics can be dramatically changed. This occurs, for instance, during HFV when significant reductions in V_T are combined with large increases in respiratory rate. During rigid bronchoscopy or laryngeal interventions, the anesthesiologist is required to share management of the airway with the surgeon. This may result in intermittent loss of information regarding airway flow, volume, and pressure, as well as end-tidal gas concentration. In these situations, clinical assessment based on physical examination (i.e., inspection, auscultation) becomes paramount. Specific considerations for respiratory monitoring in special conditions are detailed later.

HIGH-FREQUENCY VENTILATION

HFV is a ventilatory mode using V_T smaller than the anatomic dead space, tenfold to fiftyfold higher respiratory frequencies, and high instantaneous flow rates. HFV is a broad term encompassing various modalities. These include high-frequency jet ventilation (HFJV) and high-frequency percussive ventilation (HFPV), both of which allow for passive exhalation, as well as HFOV, in which exhalation is actively driven by the device. The mechanisms for gas exchange during HFV are complex and include convective transport, turbulence, pendelluft, velocity profile distortion and asymmetry, Taylor dispersion, molecular diffusion, collateral ventilation, and cardiogenic mixing.[298-300] This method results in a fundamentally different relationship for CO_2 elimination ($\dot{V}_{CO_2}$) compared with conventional ventilation.[301] For example, during conventional ventilation:

$$\dot{V}_{CO_2} \propto f(V_T - V_D) \quad [32]$$

where f is the breathing frequency and V_D is dead space volume. However, during HFOV[302]:

$$\dot{V}_{CO_2} \propto f \frac{V_T^2}{V_D} \quad [33]$$

Although the use of HFOV is not uncommon for neonates in respiratory distress in whom conventional ventilation has failed is,[303-305] its use in adult patients with ARDS has been limited by its perceived lack of efficacy.[306,307] Interest has been renewed in the use of HFOV in adult patients with ARDS because HFOV could facilitate lung-protective ventilation by using high mean airway pressures and low V_T to achieve alveolar recruitment without overdistention.[308-312]

Most high-frequency oscillators use pistons to drive flow actively into and out of the airway at respiratory rates between 3 and 20 Hz.[313,314] However some oscillators, and most jet ventilators, rely on solenoid valves.[315-317] With HFOV, fresh gas and CO_2 may be removed by a continuous bias flow of warmed, humidified gas past the proximal end of the ETT, and mean airway pressure is regulated by an adjustable valve venting the bias flow and exhaled gas from the circuit. These devices may be either pressure or time cycled, and both the mean airway pressure and oscillatory pressure amplitude are displayed on the console to the clinician. However, for the frequencies used during HFV, a significant portion of the oscillatory pressure amplitude results from the inertia of the gas column contained in the breathing circuit and the patient's airways, and thus it should not be used as a surrogate for lung distention.

Clinically useful physiologic information inferred from airway flow and pressure measurements is somewhat limited during HFV. During conventional mechanical ventilation, airway pressure and flow are related according to basic mechanical properties of the respiratory system, such as airway resistance and tissue compliance. However, during HFV, airway pressure and flow reflect complex resistive and inertial gas properties in the central airways. Many investigators have assessed respiratory mechanics during HFV by transiently switching patients to conventional mechanical ventilation to obtain basic estimates of resistance and compliance,[318] or even making intermittent low-frequency oscillatory measurements to measure airway and tissue properties.[319] The pressure transmission index, defined as the ratio of the pressure measured directly in the trachea to the pressure at the proximal end of the breathing circuit (i.e., the pressure amplitude measured at the oscillator), is strongly correlated with tissue elastance.[319,320]

An important component of monitoring during any form of HFV is the assessment of mechanical function. Many important physiologic parameters, such as mean airway pressure and V_T, are not explicitly controlled by most high-frequency ventilators. Thus, the relationship between pressure transduced at the proximal end of the breathing circuit and the V_T delivered to the patient is difficult to assess. Indeed, this relationship is highly nonlinear,[303] and it depends on frequency, gas composition and inertia, and the overall mechanics of the patient's respiratory system.[211,250] Given the important role that V_T plays in CO_2 elimination during HFV (Equation 33), accurate measurement of airway flow is important for the development and standardization of clinical trials.[307] Hot wire anemometry yields the most accurate estimates of airway flow and delivered V_T during HFOV compared with other measuring devices.[211,250]

Adequacy of gas exchange is essential during HFV. Analysis of arterial blood gases should be performed within 30 minutes of any change in ventilator settings, and at least twice per day on stable settings.[308] Whereas oxygenation is usually assessed with continuous pulse oximetry, CO_2 elimination is more technically challenging to monitor. Attempts have been made to incorporate various forms of capnography into HFV circuits,[321-324] with varying degrees of success. Depending on where exhaled gases are sampled, the correlation between $PetCO_2$ and $Paco_2$ may be adequate during HFV.[323,324] The discrepancy between $PetCO_2$ and $Paco_2$ is often a reflection of the slower response time of many sidestream CO_2 analyzers.[151] The Pco_2 sampled at the airway opening may thus underestimate the true alveolar CO_2 levels.[322] The most accurate measurement of alveolar Pco_2 is obtained when it is measured at the very distal tip of the ETT,[325] although this is not always clinically feasible. Transcutaneous measurements of Pco_2 may hold considerable promise for assessment of CO_2 clearance during HFV.[326]

Although HFOV has not been shown to improve outcomes in adult patients with ARDS significantly,[301,306] this finding may reflect the variable effects of frequency, amplitude, and mean airway pressure with oscillating of a heterogeneously injured lung,[310] as well as the poorly understood phenomena of gas distribution, volume recruitment, and $\dot{V}/\dot{Q}$ matching in individual patients. Nonetheless, this ventilatory modality represents a promising approach to lung-protective ventilation. Future clinical trials will guide both therapy and technologic development of HFOV,[309] thus providing a scientific basis for the rational use of this technology in critically ill patients.

JET VENTILATION

Jet ventilation is commonly used for procedures in which the surgeon requires unobstructed access to the airway.[327] During inspiration, O_2 or an O_2-air mixture is applied under high pressure to the airway through either a specialized catheter or a rigid bronchoscope. This jet of gas, along with entrained air from the surrounding environment, leads to insufflation of the lungs. Expiration takes place through passive recoil. The entire system is open to the environment, thus leading to significant escape of respiratory gases.[316]

Oxygenation during jet ventilation can be adequately monitored using pulse oximetry. Ascertaining the presence and adequacy of ventilation, especially during HFJV, is more challenging because the composition and volume of the exhaled gases cannot be directly measured. Arterial sampling of $Paco_2$ is accurate but intermittent and invasive. Gas can be sampled at the distal end of the catheter or rigid bronchoscope through a dedicated channel. Quantitative capnography during HFJV does not accurately reflect $Paco_2$ because V_T is smaller than dead space.[328] This problem can be overcome by the intermittent suspension of HFJV or reduction in frequency to 10 breaths/minute or less. $PetCO_2$ measurements obtained in this manner accurately reflect the $Paco_2$ and allow the intermittent monitoring of ventilation.[324,329-331] The measurement of transcutaneous Pco_2 ($Ptcco_2$) is noninvasive and continuous. Although $Ptcco_2$ is not as accurate as capnometry, its use has been suggested to allow for tracking of changes in $Paco_2$.[331] The absence of V_T and continuous $PetCO_2$ monitoring precludes standard ventilator disconnect monitoring during intraoperative HFJV. RIP, which uses changes in the inductance of bands placed around the chest to monitor respirations, has been demonstrated to discriminate reliably between the presence and absence of HFJV and may be developed as a monitor to detect disconnect or the absence of adequate thoracic excursion during HFJV.[254]

INTRAHOSPITAL TRANSPORT OF PATIENTS

Intrahospital transport of critically ill patients is a frequent occurrence. Transport of adult and pediatric patients from locations with advanced monitoring to more remote locations is fraught with difficulty, ranging from simple equipment malfunction to major disasters.[332-334] Complex monitoring and numerous pieces of equipment are often required for safe transfer, especially when additional devices such as extracorporeal membrane oxygenators and ventricular assist devices are present. The lack of standardized monitoring techniques and terminology explain the wide reported discrepancies in the incidence of adverse events. Previous studies demonstrate a frequent incidence of respiratory compromise and gas exchange deterioration following transport.[333-335]

Respiratory monitoring during transport should ideally be the same as that in the OR or ICU before relocation. In practice, at least clinical signs (e.g., skin color, chest expansion, auscultation, endotracheal secretions), pulse oximetry, and respiratory rate should be monitored throughout intrahospital transport. If a transport ventilator is used, airway pressures should be readily available in numeric or graphic formats. Human factors are essential during transport, and a specialized transport team using standardized management procedures with preparatory, transfer, and posttransport stabilization phases likely limits the frequency of adverse events.[336-338] This is particularly important when high-risk patients are involved.[337] Equipment and medications needed to establish and maintain a secure airway and hemodynamics should be available during any transfer. Adequate O_2 supply with functioning low-pressure alarms should be verified during pretransport preparation. A transport ventilator can provide better oxygenation and reduce variability in pH and Pco_2 compared with manual ventilation.[335,339] The transfer phase may require several professionals under the coordination and supervision of an attending anesthesiologist.

AUTOMATED DATA SYSTEMS

Electronic anesthesia records are gaining increased use in anesthesiology (see also Chapters 1 and 5). These systems provide data from medical devices, clinical information management systems, and laboratory data. The availability of large amounts of real-time data in digital form allows for introduction of new approaches to monitoring that may have been conceptualized, but not yet clinically

implemented. In fact, although decision support research has been done for years, little progress has been made in clinical decision support for the acute management of unstable patients, a major challenge in the OR and ICU.[340]

Computerized monitoring has the potential to improve clinical monitoring.[341] However, it has limitations resulting from typical requirements not well-suited to human performance, such as monitoring graphic displays over extended periods or the execution of overt responses to low-probability events. Humans are limited in their ability to analyze large quantities of data accurately and continuously. Accordingly, computer algorithms that identify subtle but meaningful trends in physiologic data are desirable. Such tools require relevant contextualization of measurement to improve accuracy, as well as minimization of false-negative and false-positive alarms. This automated monitoring should depend not only on timely measurements, but also on prior information. Alarms should not be fixed to specified thresholds, but rather dynamically adapted to information as it becomes available. Algorithms with established clinical rules provide the opportunity to detect subtle changes in time-series data,[342] which exceed human discrimination.[343] Such automated systems minimize monitoring failures and promote timely responses, thus enhancing the performance of anesthesia delivery during long periods. Some tools of respiratory monitoring have been assessed in adult and pediatric populations.[340,344-346] Data banks have been developed for research.[347] Another potential interest in these systems is that of creating closed-loop systems, such as those currently implemented to adjust settings in commercial mechanical ventilators.[345,348]

Although these methods are not currently established for clinical use, they are expected to find increasing application as reliable monitoring algorithms are implemented and validated. Such automated systems allow for the implementation of additional levels of safety. The detection of potentially dangerous events, such as continuously low SaO_2 or the absence of $PetCO_2$ measurements for several breaths, can generate an automated alarm, a screen alert, or an automated page to the supervising clinician.[349] This type of alert system is already used in many airplanes. In a different condition (e.g., when changes in oxygenation occur over a period of minutes), improved processes should be directed to the anesthesia provider in direct contact with the patient, to initiate prompt treatment, assess artifacts, and/or call for assistance.[349]

ADDITIONAL MONITORED VARIABLES

NITROGEN WASHOUT AND END-EXPIRATORY LUNG VOLUME

A resurgence of interest has occurred in the use of nitrogen washout methods for adult[350,351] and pediatric[352] patients (see also Chapter 95). Nitrogen washout techniques are in commercial mechanical ventilators for use in ICUs (see also Chapter 101). The main parameter of interest has been the end-expiratory lung volume, a potentially valuable measurement to optimize lung expansion during mechanical ventilation and to assess ventilatory interventions such as PEEP adjustment.[351] The measurements are performed by introducing a step change in the inspired air (traditionally from room air to 100% O_2, in current systems a nitrogen washout-washin method with 10% to 20% change in FiO_2) and solving mass balance equations for the lung volume. In patients with ARDS, measurements of end-expiratory lung volume demonstrated good accuracy and reproducibility, with a coefficient of variation of less than 4%.[351] In 30 patients in ICUs who were undergoing CT for clinical reasons, the end-expiratory lung volume measured with the modified nitrogen washout-washin technique was well correlated ($r^2 = 0.89$) with CT measurements with a bias of 94 ± 143 mL (15 ± 18%; $P = .001$), within the limits of accuracy provided by the manufacturer.[350] Nitrogen washouts can also provide measures of ventilation heterogeneity.[352]

TRANSCUTANEOUS MEASUREMENTS OF PARTIAL PRESSURES OF OXYGEN AND CARBON DIOXIDE

Gas exchange is a dynamic, at times rapidly changing, process. Conventional direct measurements of arterial blood gases, although still the gold standard for PaO_2, $Paco_2$, and pH monitoring, provide only an isolated picture of that process. Expeditious assessment of circulating blood gases could facilitate faster initiation of required therapy and adjustment of implemented ventilation. A method for noninvasive continuous monitoring of PaO_2 and $Paco_2$ is a current clinical need.

Transcutaneous measurements of PO_2 ($Ptco_2$) and Pco_2 ($Ptcco_2$) are monitoring methods that aim to provide noninvasive estimates of arterial O_2 and CO_2, or at least trends associated with these variables. These indices have been useful in intensive care management of neonates and infants[353] (see also Chapter 95), as well as in the fields of wound healing and hyperbaric therapy. An advantage is that transcutaneous monitoring can be applied when expired gas sampling is limited such as during HFOV, apnea testing, and noninvasive ventilation. The measurements are based on the diffusion of O_2 and CO_2 through the skin. Because the skin is not entirely permeable to gases, warming is used to facilitate gas diffusion. Such an increase in temperature (usually 42° C to 45° C) promotes increased O_2 and CO_2 partial pressure at the skin surface resulting from changes in structure of the stratum corneum that increase diffusion and dermal hyperemia and shift the Hb dissociation curve. This process ultimately results in arterialization of the regional blood. $Ptco_2$ and $Ptcco_2$ are thus influenced not only by the arterial gas partial pressures but also by skin O_2 consumption, CO_2 production, and regional blood flow. Accordingly, $Ptco_2$ is usually lower than PaO_2, and $Ptcco_2$ is higher than $Paco_2$.

O_2 transducers are electrochemical polarographic Clark-type electrodes in which the rate of chemical reaction is related to an electrical signal proportional to the O_2 concentration. For CO_2, a transducer using a pH electrode to measure the Pco_2 (Stow-Severinghaus electrode) is used, where a change in pH is proportional to the logarithm of the Pco_2 change. For CO_2 monitors, a temperature correction factor is used to estimate $Paco_2$ from

$Ptcco_2$. In vivo correction is available in some devices based on arterial blood gases. The thin epidermal layer of infants facilitates the measurements, in contrast to the diffusion barrier introduced by the thicker adult skin. A lower electrode temperature in $Ptcco_2$-monitoring produces systematic bias of the transcutaneous electrode. However, in very preterm babies, monitoring at 40° C or 41° C to reduce the risk of burns is possible, provided a bias correction of 12% to 15% is applied.[354]

The main application of $Ptcco_2$ is in the neonatal ICU population.[353] Even in very low-birth-weight infants, the mean difference between $Ptcco_2$ and $Paco_2$ is 3.0 mm Hg (95% confidence interval, 0.2 to 6.0 mm Hg; $P < .05$).[355] In addition, $Ptcco_2$ may be used to assess the efficacy of mechanical ventilation continuously during respiratory failure. In this setting, in children 1 to 16 years old, $Ptcco_2$ was more accurate and precise than $PetCO_2$ in relation to $Paco_2$. $Ptcco_2$-$Paco_2$ differences were 2.3 ± 1.3 mm Hg in children 1 to 3.4 years old and 2.6 ± 2.0 mm Hg in children 4 to 16 years old.[353] $PetCO_2$-$Paco_2$ differences were larger (6.8 ± 5.1 mm Hg and 6.4 ± 6.3 mm Hg) for the same age ranges. When compared with $PetCO_2$, $Ptcco_2$ monitoring is equally accurate in patients with normal respiratory function. Accuracy and precision in the perioperative period of cardiac surgery for congenital heart disease in infants and children were better for $Ptcco_2$ than $PetCO_2$ in relation to $Paco_2$ with exception of patients receiving significant amounts of vasoactive medications and in low cardiac output states (see also Chapter 94).

In adults, whereas $Ptcco_2$ has not proved to be a reliable surrogate for $Paco_2$ in the general population of anesthetized and critically ill patients, $Ptcco_2$ monitoring could be suitable to some specific conditions. $Ptcco_2$ could be a more accurate estimate of $Paco_2$ than $PetCO_2$ during laparoscopic surgery with prolonged pneumoperitoneum,[356] in which even trends provided by $PetCO_2$ may be unreliable to monitor $Paco_2$.[357] During deep sedation for ambulatory hysteroscopy in healthy patients, earlobe $Ptcco_2$ agreed better with $Paco_2$ than did nasal sidestream $PetCO_2$, with lower bias (1.7 versus −7.0 mm Hg) and smaller mean differences to $Paco_2$ (3.2 ± 2.6 versus 8.0 ± 6.0 mm Hg) (see also Chapter 89).[358] The sensitivity of the $Ptcco_2$ monitor for detecting $Paco_2$ higher than 50 mm Hg was also greater than for $PetCO_2$ (66.7% versus 33.3%; $P < .01$).[358] $Ptcco_2$ is also helpful during weaning from mechanical ventilation after off-pump coronary artery bypass graft.[359] $Ptcco_2$ monitoring over 8 hours in six hemodynamically stable adult intensive care patients suggested the possibility of reaching bias and limits of agreement of 0.4 and −5.5 to 6.4 mm Hg.[360] In adults admitted to an emergency department for acute respiratory failure, agreement between $Paco_2$ and $Ptcco_2$ was 0.1 mm Hg, and the limits of agreement were from −6 to 6.2 mm Hg. None of the patients experienced adverse effects from heating of the device clipped to the earlobe. However, in patients undergoing noninvasive ventilation, unacceptably wide variability may be observed.[361]

$Ptco_2$ from normal to extremely low-birth-weight infants agreed well with PaO_2 measurements, with mean $Ptco_2$-PaO_2 difference 2.3 (−1.5 to 6.8) mm Hg, clinically acceptable in current neonatal ICUs (see also Chapter 95). $Ptco_2$ in neonates is additionally important to detect hyperoxia, which is not feasible with pulse oximetry. The use of $Ptco_2$ in adults has been focused on wound management, peripheral vascular disease, and hyperbaric medicine. Although attempts for applications in adults were promising, such as the use of $Ptco_2$ to support resuscitative efforts,[362] measurements following off-pump coronary artery surgical procedures still present very high variability.[363] The dependence of $Ptco_2$ on low-flow states has been used in conjunction with analysis of arterial blood gases to estimate adequacy of cutaneous blood flow and, by inference hemodynamic, stability.[364,365]

$Ptcco_2$ monitoring does not replace $PetCO_2$ monitoring, which remains the standard of care to demonstrate the intratracheal location of the ETT following intubation and as a disconnect alarm in the OR (details are given in the section on tissue oxygenation).

In summary, transcutaneous measurements are favorably positioned for continuous gas exchange monitoring in neonates and infants. In contrast, widespread applications of transcutaneous techniques in the perioperative settings are still hindered by limitations, such as poor cutaneous blood flow; need for frequent calibration; slow response time, and risk for skin burns with prolonged application.

LUNG WATER

Pulmonary edema is a hallmark of lung injury. It can result from increased hydrostatic pressure in the pulmonary capillaries (cardiogenic), increased permeability of the alveolar capillary membrane (noncardiogenic), and reduced lymphatic drainage from the lungs. Such mechanisms can be caused by pulmonary and extrapulmonary factors. For these reasons, interest in the development of methods to quantify extravascular lung water (EVLW) has been considerable because this may assist in the diagnosis and management of those conditions, including fluid therapy, diuretics, and mechanical ventilation. In patients, assessment of pulmonary edema is made with imaging techniques (e.g., chest radiography, ultrasonograpy, CT, and EIT) and indicator dilution methods.

Imaging Techniques

The method used primarily in clinical practice remains the bedside chest radiograph. It allows for semiquantitative assessment of EVLW, its distribution, and its possible etiology. The chest radiograph has limited diagnostic accuracy. This is because: (1) edema may not be visible until the amount of lung water increases by 30%[366]; (2) any radiolucent material that fills the air spaces (e.g., alveolar hemorrhage, pus, and bronchoalveolar carcinoma) will produce a radiographic image similar to that of pulmonary edema; (3) technical issues including rotation, inspiration, positive-pressure ventilation, patient position, and underpenetration or overpenetration can reduce sensitivity and specificity; and (4) substantial interobserver variability exists in interpretation of chest radiographs.[367,368] CT is another radiographic technique to quantify EVLW. In animal experiments, CT densitometry could detect an increase in EVLW by as little as 50%.[162] CT-based studies indicated that significant hypoxemia secondary to pulmonary edema may not

develop until the increase in EVLW approaches 200% to 300%.[163] Lack of portability and high radiation exposure limit the use of CT as a continuous intraoperative monitor. Positron emission tomography[165] and nuclear magnetic resonance[166] are imaging techniques that can assess lung water. However, they are not amenable for routine clinical use in the perioperative setting. Ultrasound and EIT are methods described previously.

Indicator Dilution Methods

Such measurements of EVLW have been expected to be superior to blood oxygenation and chest radiography. They are based on the kinetics of one or two tracers injected centrally and measured in an artery. Initial techniques were based on a double-indicator dilution method. These techniques gained renewed attention with the introduction of a clinical device to assess EVLW by using transpulmonary thermodilution technology, which facilitated bedside measurements.[369] The device uses cold saline solution as the single indicator injected in a central venous line. EVLW and additional hemodynamic parameters (i.e., cardiac output) are computed from the curve of temperature in the peripheral artery.[370] Good reproducibility and correlation can occur with gravimetric methods and can be a useful clinical and research tool. EVLW may be a predictor of mortality in patients with severe sepsis[371] and ARDS.[372,373] It is a diagnostic tool in detecting early pulmonary edema[374] and in evaluating the effect of ventilatory modes during esophagectomy.[375] The measurement has also been proposed to guide intravascular fluid therapy in ARDS[376] and subarachnoid hemorrhage,[377] as well as assess the effect of steroids during cardiac surgical procedures (see also Chapter 67).[378] EVLW was the primary outcome variable in clinical trials to study the efficacy of salbutamol to resolve pulmonary edema in patients with ARDS (the Beta-Agonist Lung Injury Trial[379]) and lung resection (see also Chapter 66).[380]

The limitations on this technique derive from the considerable and at times conflicting assumptions.[370,381] Measurement premises include that the thermal indicator reaches all lung regions and equilibrates in all of them and that the central circulation volumes between the injection and temperature measurement sites can be described as a small number of individual well-mixed compartments, each showing a monoexponential decay of temperature with time. Experimental evidence indicated that assumptions for the method do not apply to all conditions; an important factor is the changes in the regional distribution of perfusion during lung injury.[370,382,383] These changes may significantly compromise the measurement.[381] Indeed, redistribution of lung perfusion can produce measurement changes larger than those seen in the Beta-Agonist Lung Injury Trial between treatment and control groups.[379,382] Such results are also consistent with the influence of the type of lung injury on the accuracy of EVLW measurements,[384-386] as well as with the poor correlation between transpulmonary thermodilution EVLW and qualitative CT estimates of EVLW.[387] Thus, the expected reliability of transpulmonary thermodilution EVLW to follow trends[388] cannot be taken for granted, and it requires interpretation in light of potential simultaneous changes in regional perfusion. Finally, the technique requires placement of arterial and central venous catheters, thereby increasing invasiveness. The hope is that future studies and experience will determine the place of such monitors in clinical practice.

Chapter 52

Renal Function Monitoring

KATHLEEN LIU • MARK STAFFORD-SMITH • ANDREW SHAW

Acknowledgment: The editors and publisher would like to thank Dr. Solomon Aronson for contributing a chapter on this topic to the prior edition of this work. It has served as the foundation for the current chapter.

Key Points

- The incidence of perioperative acute kidney injury (AKI) (previously referred to as acute renal failure) varies, depending on the definition used.
- Although uncommon, AKI requiring dialysis is associated with extremely high morbidity and mortality rates.
- The mechanism for perioperative AKI is complex and commonly involves multiple factors including ischemia-reperfusion injury, inflammation, and toxins.
- Repeated direct perioperative assessments of renal hemodynamics or tubular function are impractical; therefore indirect assessments, such as trends of serum creatinine concentrations, are the best practical perioperative tools to assess renal function.
- Intraoperative urine formation depends on many factors and is not validated as a measure of the risk of postoperative renal dysfunction. Yet postoperatively, patients with low intraoperative urine output may develop renal dysfunction. Therefore urine output should be carefully monitored in the intraoperative setting.
- Serum chemistries and urine indices, such as blood urea nitrogen, creatinine, and fractional excretion of sodium, are generally late indicators of renal function deterioration and do not enable the clinician to delineate clearly the cause of renal failure.
- The most sensitive and specific clinical method for determining renal function is direct measurement of glomerular filtration rate (GFR). However, this measurement is limited by time and measurement restrictions.
- Early biochemical markers for kidney injury may soon become new tests that can provide prompt clinical information.
- Volume overload is a risk factor for adverse outcomes in patients with AKI and may influence concentrations of conventional markers of kidney function such as serum creatinine.

Acute kidney injury (AKI) (previously known as acute renal failure) is characterized by rapid decline in the glomerular filtration rate (GFR) and the accumulation of nitrogenous waste products (blood urea nitrogen [BUN] and creatinine). AKI occurs in approximately 5% to 25% of all hospitalized patients, depending on the precise definition used for AKI, and with more frequent rates in patients who are critically ill in the intensive care unit (ICU) (also see Chapter 101). AKI is also a serious perioperative complication for patients undergoing major surgery.[1] As the incidence of AKI varies by the definition used, the mortality of AKI ranges from 10% to 35% for mild AKI, whereas AKI in the ICU setting is associated with a 50% to 80% mortality rate (see Chapter 101). However, supportive care with dialysis has reduced mortality from AKI. Whereas the mortality rate of oliguric AKI was 91% during World War II, mortality declined to 53% during the Korean War with the provision of dialysis.[2] AKI requiring dialysis develops in 1% to 7% of patients after cardiac or major vascular surgery and is strongly associated with morbidity and mortality in this context (Fig. 52-1) (see Chapters 67 and 69).[3-8] Although mortality after cardiac surgery in those with AKI has decreased, the odds of having AKI have increased. This combination actually results in an increase in the risk of death associated with AKI.[9]

Perioperative renal failure was long defined as a requirement for postoperative dialysis. However, the thinking concerning this concept has evolved during the past several years. First, because the implications of requiring postoperative dialysis are quite different for a patient starting with a normal baseline renal function compared with one starting with advanced chronic kidney disease and because the criteria for the use of dialysis are not standardized, the usefulness of dialysis alone to

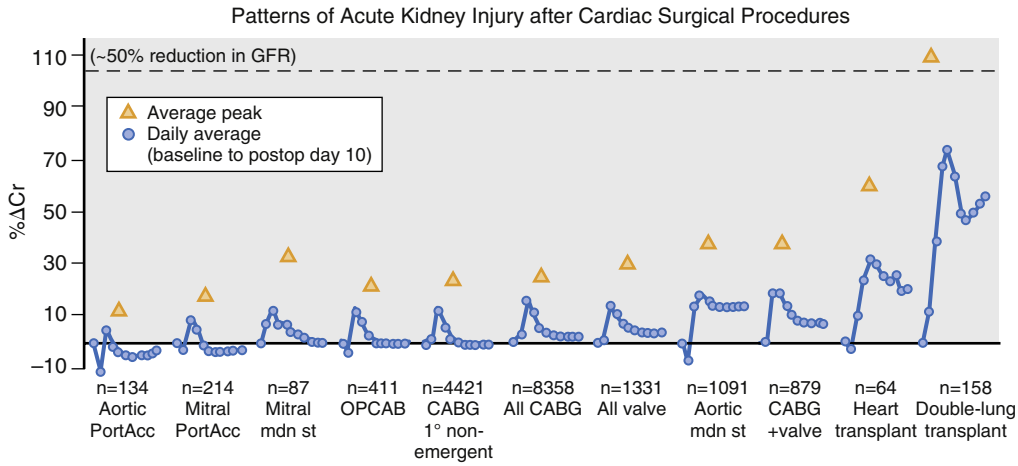

Figure 52-1. Average daily *(circles)* and unadjusted average peak *(triangles)* serum creatinine values for the first 10 days after several different cardiac surgery procedures are represented as change relative to preoperative serum creatinine. Note that for each procedure, the average peak value exceeds the highest average daily value because creatinine peaks on different days for different patients. *Aortic mdn st,* Median sternotomy aortic valve replacement; *Aortic PortAcc,* minimally invasive parasternotomy aortic valve replacement; *CABG 1° nonemergent,* coronary artery bypass surgery 1° nonemergent; *% ΔCr,* peak fractional serum creatinine rise; *GRF,* glomerular filtration rate; *Mitral mdn st,* median sternotomy mitral valve surgery; *Mitral PortAcc,* port access mitral valve surgery; *OPCAB,* off-pump coronary artery bypass surgery. *(From Stafford-Smith M, Patel U, Phillips-Bute B, et al: Acute kidney injury and chronic kidney disease after cardiac surgery,* Adv Chronic Kidney Dis *15:157-177, 2008. Used with permission.)*

define AKI has been questioned.[10-12] Second, studies are difficult to compare because of the use of nonstandard definitions for AKI. For example, in one review of 28 studies,[13] definitions for perioperative AKI varied. Third, consensus definitions that focus on small changes in serum creatinine and on changes in urine output to define AKI have received widespread adoption. This last conclusion is based on the recognition that small changes in renal function directly relate to an increased risk of death.

As a result, recent consensus criteria are being used to define AKI in both the perioperative and other medical settings. The first proposed consensus criteria were the RIFLE (**R**isk, **I**njury, **F**ailure, **L**oss, **E**nd-stage) kidney disease criteria developed by the Acute Dialysis Quality Initiative (Table 52-1).[14] These have subsequently undergone two modifications by the Acute Kidney Injury Network (AKIN) criteria[15] and in the recently published Kidney Disease: Improving Global Outcomes (KDIGO) AKI guidelines.[16] As detailed in Table 52-1, the central components of these criteria are the focus on relative and absolute changes in creatinine from a baseline value and the definition of several degrees of AKI severity. Consequently, milder AKI (e.g., KDIGO, Stage 1 disease) will be more common than Stage 3 disease and will also be associated with a lower mortality rate. These criteria have also proposed definitions for AKI based on urine output. However, using urine output criteria are not as well validated regarding their relationship to adverse outcomes including mortality because of other complexities, including a lack of correction for morbid obesity.[17]

As medical populations shift toward older and more critically ill patients undergoing increasingly high-risk procedures, patients are at an increased risk of AKI in the perioperative setting. Indeed, a recent study of dialysis after elective major surgery suggests that the incidence of dialysis-requiring AKI is rising from 0.2% in 1995 to 0.6% in 2009, with the majority of the increase occurring after vascular and cardiac surgery (see Chapters 67 and 69).[18] Although ischemic causes may be primarily responsible for perioperative AKI,[19,20] the successful development of renoprotective strategies has not occurred.[21] Furthermore, other pathophysiologic contributors to perioperative AKI may include contrast-induced nephropathy, pigment nephropathy (e.g., hemoglobin, myoglobin), cholesterol emboli (e.g., atheroembolic renal disease), aminoglycoside toxicity, norepinephrine-induced nephropathy, and sepsis, also known as systemic inflammatory response syndrome. Animal studies of such pure nephropathies treated with logical renoprotective interventions often demonstrate success; unfortunately, this success has rarely extended to equivalent renoprotection in humans. However, it is not surprising that a specific treatment for a pure nephropathy nonselectively applied to a mixture of nephropathies, variably expressed in different patients, would be unsuccessful. Protection from one type of renal failure may even add risk for another type; for example, augmenting renal blood flow (RBF) may attenuate ischemia-reperfusion injury while delivering more atheroembolic and inflammatory mediators. Postoperative AKI, rather than being a single entity, is likely a mosaic of several pure nephropathies, each of varying importance for a particular patient and procedure (Fig. 52-2).

Individualized renoprotection strategies, guided by timely point-of-care renal function monitoring, will be needed. Hence, advances in renal function monitoring are currently a major focus in the search for improved renal protection and risk stratification strategies for AKI (also see Chapter 23).

RENAL PHYSIOLOGIC FUNCTION

The kidneys are mesoderm-derived, bean-shaped retroperitoneal organs and weigh approximately 150 g each.

TABLE 52-1 COMPARISON OF THE RIFLE, AKIN, AND KDOQI CONSENSUS CRITERIA FOR AKI

	RIFLE		AKIN		KDIGO	
Class	SCr	Stage	SCr	Stage	SCr	Urine Output*
Risk	Increase in SCr to >1.5× baseline	1	Increase in SCr ≥0.3 mg/dL or to ≥1.5×-2× baseline	1	Increase in SCr ≥0.3 mg/dL within 48 hr or to ≥1.5×-2× baseline, which is known or presumed to have occurred within the past 7 days	Urine output <0.5 mg/kg/hr for >6 hr
Injury	Increase in SCr to >2× baseline	2	Increase in SCr to >2×-3× baseline	2	Increase in SCr to >2×-3× baseline	Urine output <0.5 mg/kg/hr for >12 hr
Failure	Increase in SCr to >3× baseline, or increase of ≥0.5 mg/dL to absolute value of ≥4 mg/dL	3	Increase in SCr to >3× baseline, or increase of ≥0.5 mg/dL to absolute value of ≥4 mg/dL, or need for RRT	3	Increase in SCr to >3× baseline, or increase to absolute value of ≥4 mg/dL, or need for RRT; in pediatric patients eGFR <35 mL/min/1.73 m^2	Urine output <0.3 mg/kg/hr for >12 hr or anuria for >12 hr
Loss	Need for RRT >4 wk					
End Stage	Need for RRT >3 mo					

The three consensus criteria use the same urine output criteria, but slight differences in the creatinine criteria are used to define AKI.
AKI, Acute kidney injury; *AKIN,* Acute Kidney Injury Network; *eGFR,* estimated glomerular filtration rate; *KDOGI,* Kidney Disease: Improving Global Outcomes; *RIFLE,* Risk, Injury, Failure, Loss, End-stage disease; *RRT,* renal replacement therapy; *SCr,* serum creatinine.
*Is common to all three consensus criteria.

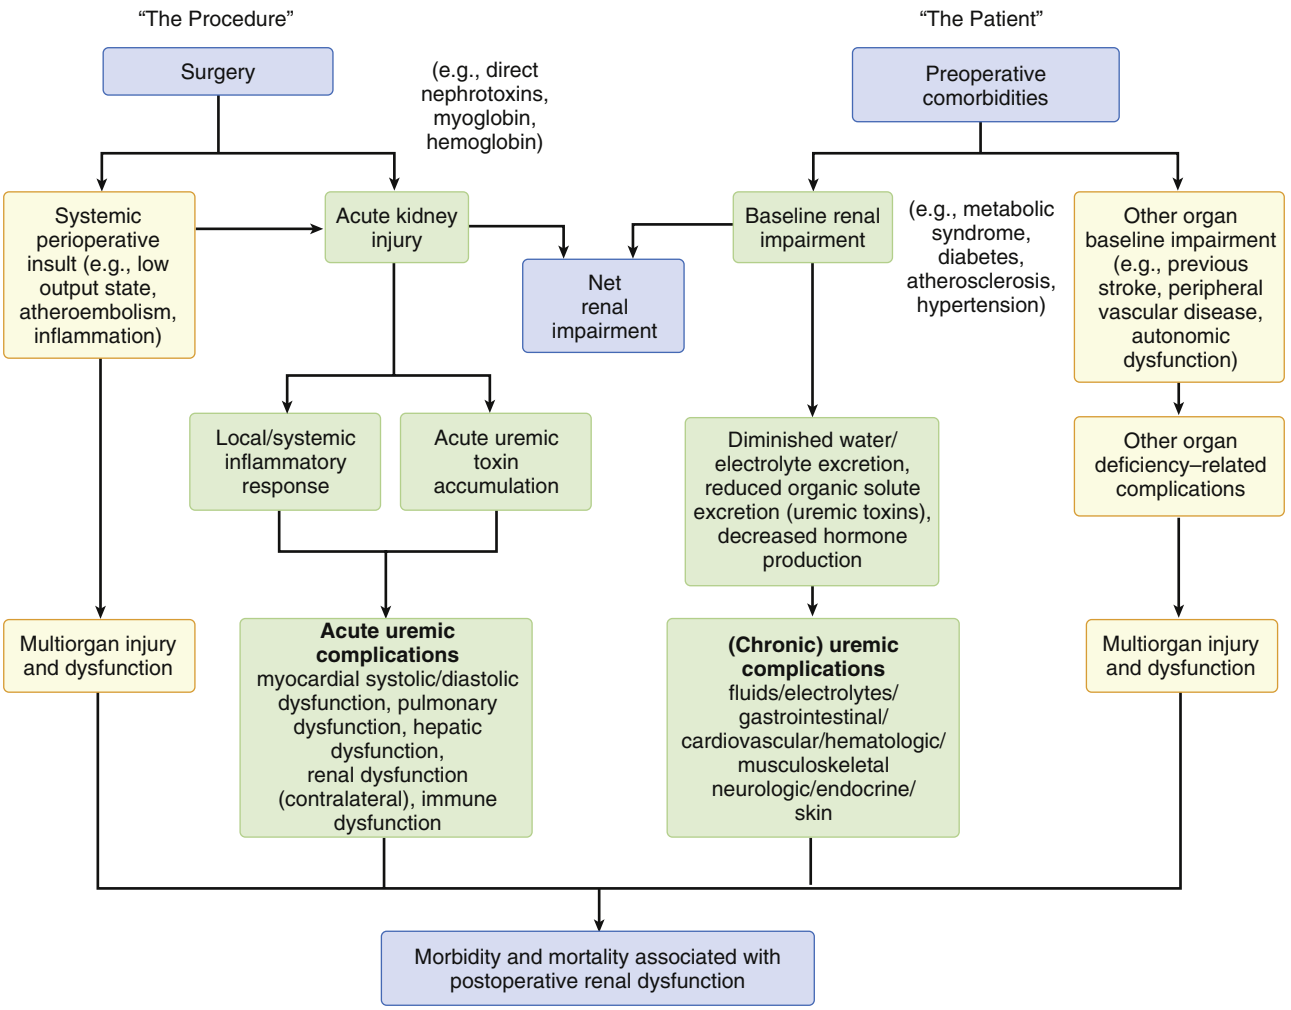

Figure 52-2. Procedural and patient factors related to surgery contributing to the risk of perioperative acute kidney injury (AKI) and postoperative morbidity and mortality. Of note, although AKI contributes to the risk of morbidity and mortality, a significant part of this association must also be attributed to other very serious conditions, such as sepsis, that can cause injury and are also major sources of adverse outcomes. *(Modified from Stafford-Smith M, Patel U, Phillips-Bute B, et al: Acute kidney injury and chronic kidney disease after cardiac surgery,* Adv Chronic Kid Dis *15:157-177, 2008. Used with permission.)*

They are the most highly perfused major organs in the body, representing only .4% of body weight but receiving an impressive 25% of cardiac output; as a comparison, at rest blood flow to the kidneys is eightfold greater per gram of tissue than blood flow to muscle during heavy exercise. Notably, RBF is not primarily linked to metabolic demand; it is this excess blood flow that allows filtration of plasma at rates as rapid as 125 to 140 mL per minute in adults. Autoregulatory reflexes do exist that regulate renal perfusion; these are myogenic and tubular-glomerular reflexes that exist to protect the glomeruli from damage attributable to excessive intravascular pressure by restricting RBF at higher pressures (e.g., >80 mm Hg).[22,23] However, significant regional differences in blood flow within the kidney and high metabolic demand paradoxically make some areas (e.g., the medulla) extremely vulnerable to ischemic injury. Cortical blood flow exceeds outer and inner medullary perfusion by 3- and 20-fold per gram of tissue, respectively.[24]

GROSS ANATOMY AND INTERNAL ARCHITECTURE

In simple terms, the internal morphologic structure of the kidney parenchyma is highly organized, including a deep medullary region and superficial cortical layer.[4] The medulla is further subdivided into inner and outer regions. Tightly packed nephrons are tubular structures that contain specialized segments including the glomerulus, proximal convoluted tubule, loop of Henle, distal convoluted tubule, and collecting duct (Fig. 52-3). The collecting ducts feed urine to the renal pelvis, which empties into the ureter and goes on to the bladder. Each kidney contains approximately 1 million nephrons. The loops of Henle and collecting ducts are found in the deeper parts of the kidney (medulla). Two types of nephrons are differentiated by glomerular location into cortical (85%) and juxtamedullary (15%) types; only the latter have loops of Henle that course deep into the medulla and participate in *countercurrent exchange,* a mechanism that makes possible the formation of highly concentrated urine.

VASCULAR ANATOMY

A single renal artery enters at the kidney hilum and then divides many times, ultimately producing *arcuate arteries* that pass along the boundary between the cortex and outer medulla (see Fig. 52-3).[25] Arcuate arteries give rise to interlobular arteries that branch toward the outer kidney surface, passing through the cortex as they produce numerous afferent arterioles, which in turn supply a capillary tuft to each glomerulus. The glomerular capillary tuft is the barrier where plasma elements are filtered and pass from the vascular to the tubular space. Specialized negatively charged fenestrated capillary endothelial cells and tubular epithelial cells (podocytes) separated by a basement membrane allow approximately 25% of plasma volume to pass into the glomerulus (Bowman capsule); normally, only elements smaller than 60 to 70 kDa are small enough to be filtered. Many disease conditions cause abnormalities of this interface and allow much larger proteins and even red blood cells to pass through, which manifests as either nephrotic syndrome (proteinuria >3.5 g per 24 hours) or glomerulonephritis (proteinuria and hematuria). As the vascular tuft exits the glomerulus, capillaries merge and become the efferent arteriole. Subsequent branches of the afferent arterioles become peritubular capillaries to nourish the tubules. Peritubular capillaries receive reabsorbed fluids and solutes from tubular cells before rejoining to form venules. Peritubular vessels of juxtamedullary glomeruli are known as vasa recta and accompany the loops of Henle deep into the medulla. The venous system of the kidney runs parallel and close to the arterial vasculature, finally returning blood to the inferior vena cava through the *renal vein.* Vascular supply to the kidney is strictly segmental, and embolic arterial or venous obstruction affects renal tissue in a pizza wedge parenchymal distribution involving all cortical and medullary tubular elements of affected nephrons.

Medullary hypoxia is a key concept that refers to the low oxygen levels that exist in the renal medulla, even during normal resting conditions. Sodium and water reabsorption depend on the hypertonicity of the medullary interstitium. The countercurrent multiplier system in the loop of Henle is a critical component of the kidney's ability to excrete or conserve salt and water.

The apparent overabundance of blood flow to the cortex is designed to maximize flow-dependent functions, such as glomerular filtration and tubular reabsorption. In the medulla, blood flow and oxygen reserve are restricted by a tubulovascular anatomy specifically designed for urinary concentration. The tubules carrying blood to the medulla are arranged in a hairpin-loop pattern to allow a countercurrent exchange of solute between the ascending and descending limbs of the hairpin loop.[26] The osmotic gradient in the deeper portions of the medulla requires active transport of sodium in the thick ascending loop of Henle and limited blood flow through the medullary vessels to prevent washout of the solutes in those deeper tubules. To maintain this concentration gradient in the thick ascending limb, high-energy demand (i.e., active sodium transport) must be coupled with low-oxygen delivery.

Factors necessary to allow countercurrent exchange and to create a urea gradient conspire to make normal medullary partial pressure of oxygen ($Po_{2)}$ very low (e.g., 10 to 20 mm Hg); these include high oxygen demand from active solute transport and sluggish blood supply (5% to 10% of RBF). Average blood flow is 5 mL/g/min and .03 mL/g/min for the cortex and medulla, respectively, and the oxygen extraction ratio (i.e., oxygen consumption over oxygen delivery) is 0.18 and 0.79 for the cortex and medulla, respectively. The descending vasa recta are vasoactive arteriolar microvessels that are anatomically positioned to regulate total and regional blood flow to the outer and inner medulla.[26] Normally, the Po_2 is approximately 50 mm Hg in the cortex and 8 to 15 mm Hg in the medulla, making the thick ascending loop of Henle most vulnerable to tissue hypoxia.[27] This precarious arrangement underpins some of the specialized homeostatic abilities of the kidney, particularly the formation of concentrated urine, but it

also underlies the extreme vulnerability of the renal medulla to ischemic injury[28]; that is, the high metabolic requirement of the thick ascending loop of Henle in a hypoxic environment makes it especially vulnerable to injury associated with an imbalance in oxygen supply and demand.[29,30]

NORMAL FUNCTION

The resting kidney continuously regulates body composition by processing plasma filtrate to keep fluid volume, osmolarity, acidity, and numerous electrolytes within narrow limits. Every 3 minutes a plasma volume equivalent to a 12-ounce soft drink is filtered, and all but 1%

(4 mL) is returned to circulation; the remnant is urine. Tightly regulated through tubular processing are extracellular solutes, including sodium, potassium, hydrogen ion, bicarbonate, and glucose. The kidney also generates ammonia and eliminates metabolic and nitrogenous wastes, including creatinine, urea, and bilirubin, as well as toxins and many classes of drugs. Finally, the kidneys generate glucose and secrete circulating hormones that influence erythrocyte generation, systemic blood pressure, and calcium homeostasis.

High concentrations of aldosterone stimulate the reabsorption of sodium and water, primarily in the distal tubule and collecting ducts. Aldosterone is produced by the adrenal cortex in response to the feedback from the renin-angiotensin-aldosterone system, simplified as follows. Reduced delivery of sodium to the macula densa causes release of renin from the granular cells of the juxtaglomerular apparatus. Renin catalyzes the release of angiotensin I from angiotensinogen. Angiotensin I is then transformed to angiotensin II in the lungs, catalyzed by angiotensin-converting enzyme. Angiotensin II stimulates the production of aldosterone.

Antidiuretic hormone (ADH, vasopressin) primarily acts on the collecting ducts to increase water reabsorption. ADH is released from the posterior pituitary gland in response to increased blood osmolarity, which stimulates osmoreceptors in the hypothalamus. ADH release is also influenced by stress and increased partial arterial pressure of carbon dioxide ($Paco_2$).[31] A high level of ADH results in the excretion of small volumes of concentrated urine. ADH is inhibited by the stimulation of atrial baroreceptors or increased atrial volume.[32]

Atrial natriuretic peptide (ANP) causes systemic vasodilation and promotes renal excretion of sodium and water by increasing glomerular filtration.[33] ANP is secreted by the cardiac atria and other organs in response to increased intravascular volume. It decreases systemic blood pressure by relaxing vascular smooth muscle, reducing sympathetic stimulation, and inhibiting the renin-angiotensin-aldosterone system. The kidney also synthesizes prostaglandins, which regulate the influence of other hormones. During hemodynamic instability and increased adrenergic stimulation, for example, prostaglandin E_2 decreases the vasoconstrictive effect of angiotensin II on the afferent arterioles and preserves RBF. Inhibition of prostaglandin synthesis during normal states of hydration, renal perfusion, and sodium balance does not affect renal function. When the kidney is confronted with a vasoconstricted state, such as hypotension and hypovolemia, however, the presence of renal prostaglandins is essential for preserving adequate RBF. Patients taking nonsteroidal antiinflammatory drugs (NSAIDs) are at risk during conditions of impaired circulatory status because these agents inhibit cyclooxygenase activity, an important enzyme in the prostaglandin synthesis pathway, thereby rendering the kidney (afferent arteriole) susceptible to the systemic vasoconstrictive effect of angiotensin II and other catecholamines normally secreted to preserve intravascular volume and perfusion pressure.

Interaction among the urinary bladder, the kidney, and the ureters influences urine production.[34] General anesthesia decreases the rate of ureteral contractility.[35] The autonomic nervous system also plays an important role in ureteral function and, consequently, in urine formation.[34] Cholinergic agonists generally increase the frequency and force of ureteral contraction. Drugs that primarily act on adrenergic receptors tend to stimulate ureteral activity, whereas agents that primarily activate adrenergic receptors tend to inhibit ureteral activity. Histamine stimulates ureteral activity. In a variety of preparations, morphine increases ureteral tone. In humans, irregular peristaltic contractions may occur with retroperitoneal inflammation resulting from appendicitis and peritonitis.[36]

A gross summary of plasma processing by the kidney involves glomerular filtration (approximately 120 mL per minute); subsequently, up to two thirds of the water and electrolytes are quickly returned to the circulation through active transport processes by the proximal convoluted tubule. Two thirds of the remaining tubular contents are more sluggishly reabsorbed in the loop of Henle and distal convoluted tubule. Finally, more water is reabsorbed from the remaining effluent in the collecting ducts (5 to 10 mL per hour) as it passes to larger urine collecting structures (1 to 2 mL per minute).

PATHOPHYSIOLOGIC PROCESSES OF ISCHEMIC ACUTE KIDNEY INJURY

In general, the causes for AKI can be divided into prerenal, intrinsic renal, and postrenal sources. In the perioperative setting, patients may be at increased risk for prerenal AKI, either attributable to volume depletion or to exacerbation of associated chronic prerenal physiologic conditions, such as congestive heart failure, which may be exacerbated by volume overload. Depending on the nature of the surgical procedure, the patient may also be at increased risk of postrenal AKI attributable to obstruction of the ureters, bladder, or urethra. However, the primary cause of perioperative AKI is *acute tubular necrosis* (ATN). Although the focus of this chapter is on renal hemodynamics, defining the cause of AKI is also critical because treatment of the underlying cause is critical for the reversal of AKI and potential renal recovery.

The two primary mechanisms of ATN are ischemia-reperfusion and nephrotoxic effects, with three sources of insult common to many surgical procedures during which postoperative AKI is prevalent: hypoperfusion, inflammation, and atheroembolism. Other sources of renal insult in selected patients may include rhabdomyolysis and specific drug-related effects. Certain classes of medications may also contribute to hypoperfusion by virtue of their hemodynamic effects (notably angiotensin-converting enzyme [ACE] inhibitor 1, angiotensin-receptor blockers [ARBs], and NSAIDs), and, consequently, the risk of ATN.

Ischemic renal failure related to shock or severe dehydration is always preceded by an early compensatory phase of normal renal adaptation (e.g., pre-prerenal failure), followed by a condition termed *prerenal azotemia* during which the kidney maximizes activities at the expense of the retention of nitrogenous end-products to preserve the internal environment through extreme retention of solutes and water (Fig. 52-4). In studies of community-acquired

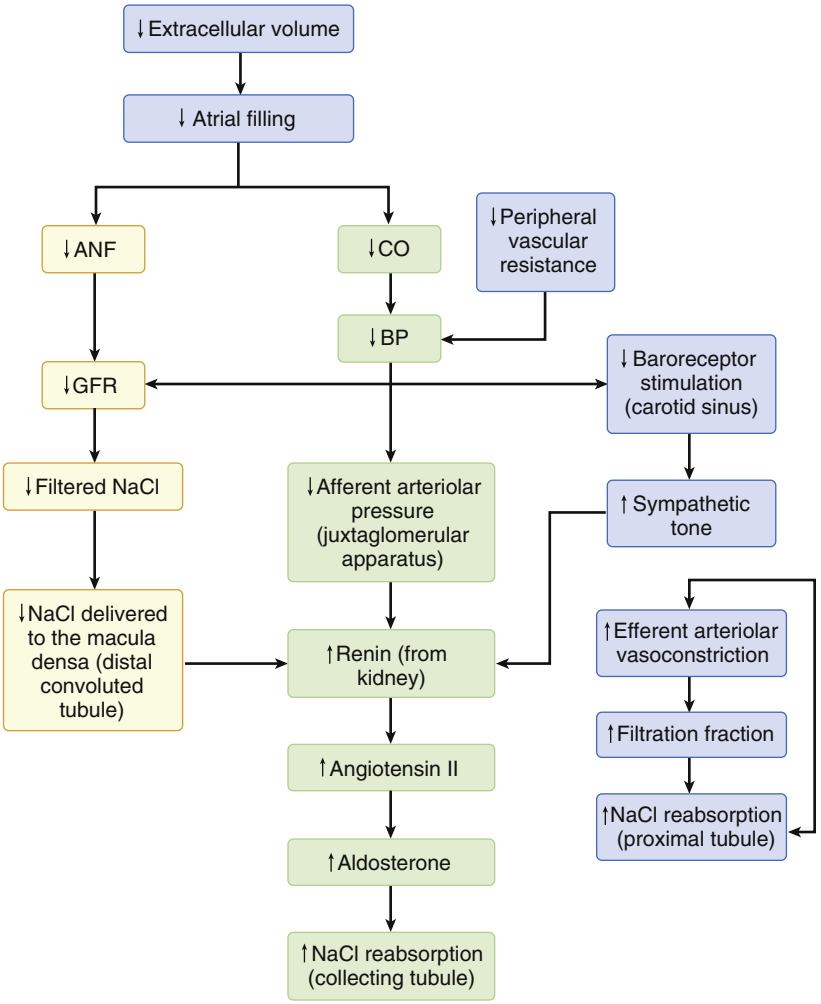

Figure 52-4. Mechanism for renal sodium and volume regulation in response to decreased extracellular volume (e.g., hypovolemia, hemorrhage). *ANF,* Atrial natriuretic factor; *BP,* blood pressure; *CO,* cardiac output; *GFR,* glomerular filtration rate; *NaCl,* sodium chloride.

AKI, the incidence of prerenal azotemia may be as frequent as 70%.[37] In contrast, in a classic study of hospital-acquired AKI, although hypoperfusion accounted for 42% of cases of AKI, only 41% of these cases of hypoperfusion were attributable to inadequate intravascular volume.[38] Although prerenal azotemia is ominous and typically accompanied by oliguria (<0.5 mL/kg/hr), it is reversible. At a critical tilting point, as conditions go beyond the compensatory mechanisms that maintain renal perfusion, ischemia leads to irreversible renal cell necrosis or ATN.[39] This represents the pure form of ischemic AKI. Other forms of ATN are due to toxins, including medications (e.g., aminoglycosides, cisplatinum), pigments (e.g., hemoglobin, myoglobin), and contrast dye. These forms of ATN do not involve the typical pattern of preceding prerenal azotemia with associated oliguria, since the insult is sudden. Importantly, most cases of perioperative AKI are the result of numerous renal insults, rather than being attributable to one pure source (Fig. 52-5). Thus patients with prerenal azotemia are likely at increased risk for toxic ATN.

Interruption of blood flow to the kidneys for more than 30 to 60 minutes results in ATN and irreversible cell damage. The kidneys receive 1000 to 1250 mL per minute of blood or 3 to 5 mL/min/g of tissue for the average adult, and this amount far exceeds what is needed to provide the kidney's intrinsic oxygen requirement. Intracortical blood flow may not be evenly distributed (see Fig. 52-3).[24] Because the renal cortex contains most of the glomeruli and depends on oxidative metabolism for energy, ischemic hypoxia injures the renal cortical structures, particularly the pars recta of the proximal tubules. As ischemia persists, the supply of glucose and substrates continues to decrease; glycogen is consumed, and the medulla, which depends to a great extent on glycolysis for its energy sources, becomes more adversely affected. Early cell changes are reversible, such as the swelling of cell organelles, especially the mitochondria. As ischemia progresses, a lack of adenosine triphosphate interferes with the sodium pump mechanism, water and sodium accumulate in the endoplasmic reticulum of tubular cells, and the cells begin to swell. Onset of tubular damage usually occurs within 25 minutes of ischemia as the microvilli of the proximal tubular cell brush borders begin to change. Within an hour, they slough off into the tubular lumen, and membrane bullae protrude into the straight portion of the proximal tubule. After a few hours, intratubular pressure rises, and tubular fluid passively backflows. Within 24 hours, obstructing casts appear in the distal tubular lumen. Even when RBF is completely restored after 60 to 120 minutes of ischemia, long-lasting vasoconstriction means that the GFR will not improve to baseline levels for a long time.[40]

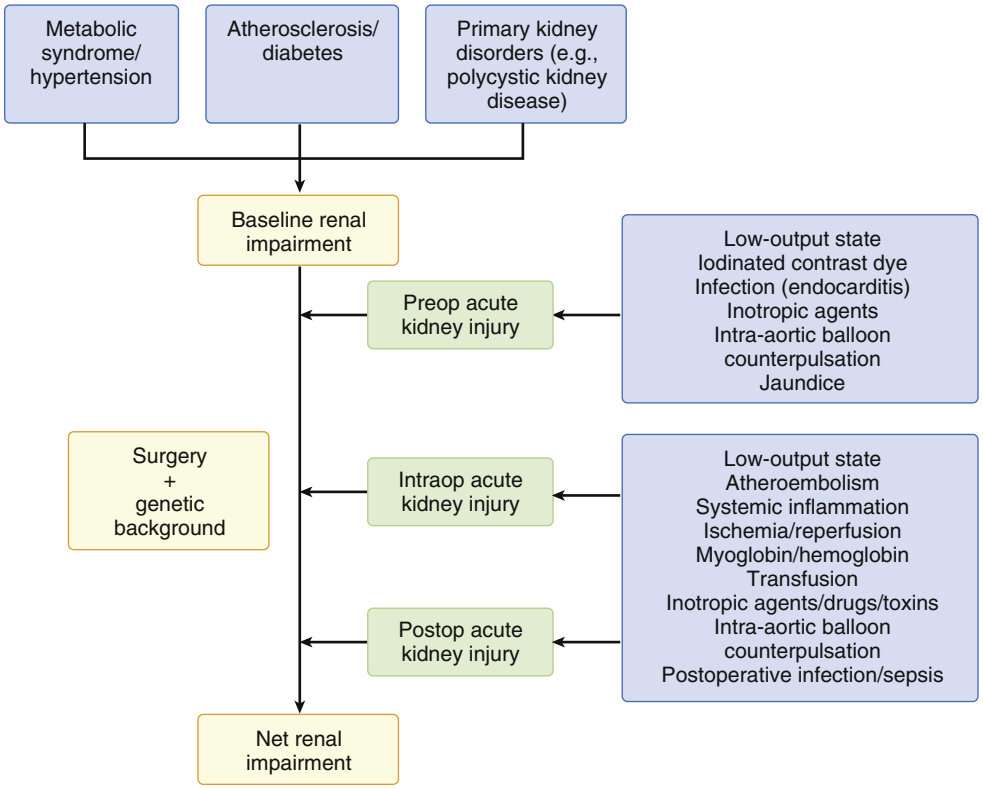

Figure 52-5. Perioperative clinical risk factors associated with postoperative kidney injury.

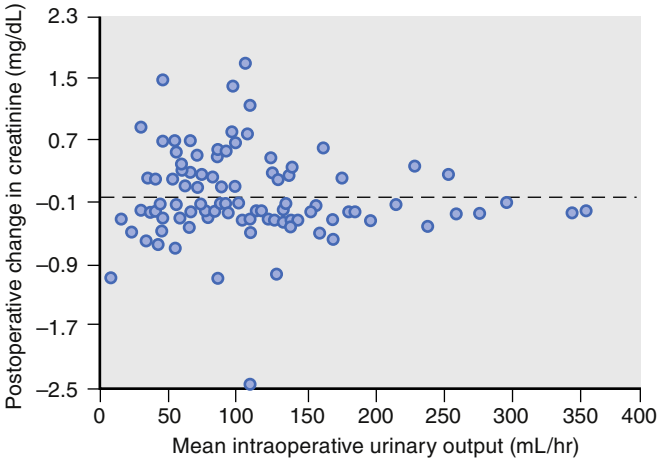

Figure 52-6. Low urine flow (<0.5 mL/kg/hr) is a marker in new diagnostic criteria for acute kidney injury (AKI) but may not be a meaningful assessment to make this diagnosis during the immediate perioperative period. In this study, intraoperative urine output does not correlate with postoperative change in serum creatinine after aortic surgery. *(From Alpert RA, Roizen MF, Hamilton WK, et al: Intraoperative urinary output does not predict postoperative renal function in patients undergoing abdominal aortic revascularization,* Surgery *95:707-711, 1984. Used with permission.)*

ANESTHESIA, SURGERY, AND NORMAL RENAL FUNCTION

Notably, the importance of oliguria (<0.5 mL/kg/hr) as a predictor of AKI is less well established in the perioperative setting than in other clinical settings (Fig. 52-6).[41,42] Anesthesia and surgery influence normal renal function primarily through changes in the GFR. Fluctuations in blood pressure have a major effect on RBF and glomerular filtration.[43-45] Anesthetic interventions, whether volatile anesthetics, intravenous drugs, or regional blocks, generally reduce arterial blood pressure and cardiac output, thereby diminishing RBF, leading to decreased glomerular filtration and urine formation.[46] Commonly used premedications can influence urine output. Narcotics and barbiturates, for example, cause a small decrease in the GFR and urine volume.

Surgical and anesthetic interventions may have autonomic consequences, such as increasing circulating catecholamines, which also reduce glomerular filtration by altering renal vascular resistance, and decreasing RBF. The normal physiologic function of the kidney includes a role of adrenergic receptors in modulating vasoconstrictor (alpha 1) and vasodilating (alpha 2) effects, respectively. Urine output may also be affected in the perioperative setting by changes in circulating ADH levels, especially during neurosurgical procedures (also see Chapter 70).

REGIONAL ANESTHESIA

Regional anesthetics and the kidneys interact in a complex manner that varies according to the underlying cardiovascular, renal, fluid, and electrolyte status of the patient (also see Chapters 56 and 57).[47] In general, epidural and spinal anesthesia reduce systemic and renal vascular sympathetic tone.[47] Spinal cord segments T4 through L1 contribute to the sympathetic innervation of the renal vasculature, which is mediated by sympathetic fibers from the celiac and renal plexus.[48,49] Autonomic blockade above the fourth thoracic level also blocks

cardioaccelerator sympathetic innervation to the heart. If neuraxial blockade reduces arterial blood pressure and cardiac output, then the RBF will be decreased with matching reductions in glomerular filtration and urine output. In studies of healthy volunteers undergoing epidural anesthesia with a T6 sensory block, Suleiman and colleagues[50] demonstrated that RBF is unchanged during the conditions of their study. Specifically, mean arterial pressure remained above 70 mm Hg, and RBF never decreased less than 6% of the baseline level.

Urine volume and free-water clearance may decrease during spinal anesthesia as a result of increased ADH secretion. Increased renal sympathomimetic activity decreases RBF through α-adrenergic mediation and increases renin release through β-adrenergic innervation directly or by interaction with the renal tubular macula densa and the baroreceptor reflex mechanism.[51] Thoracic epidural anesthesia increases RBF and urine output in animal models of endotoxic shock.[52]

Although controversial, intraoperative neuraxial blockade and postoperative epidural analgesia decrease rates of AKI. Rodgers and colleagues conducted a systematic review of 107 randomized clinical trials of intraoperative neuraxial blockade and demonstrated a 30% reduction in the odds of postoperative mortality.[53] This reduction was associated with decreases in the incidence of deep venous thrombosis, pulmonary embolism, transfusion, pneumonia, and respiratory depression, as well as renal failure, although the confidence limits for the renal failure estimates were very wide, in part due to the small number of cases of renal failure observed. Moraca and associates[54] conducted a meta-analysis and reported on the association of thoracic epidural anesthesia with improved surgical outcomes attributable, in part, to a reduction of perioperative morbidity, including blunting of stress response, attenuating infections, reduced ileus, reduced blood loss, and reduction in AKI.[54] Other studies have examined the impact of epidural anesthesia during cardiac surgery and have suggested a benefit with regards to renal failure, although the confidence intervals were wide[55] (also see Chapter 67). Unfortunately, renal failure was not an outcome of a recently published meta-analysis focused on epidural anesthesia during cardiac surgery.[56] Finally, with regards to postoperative analgesia, a recent Cochrane meta-analysis that focused on abdominal aortic surgery suggested a decreased incidence of perioperative AKI and other complications with epidural analgesia but no effect on postoperative mortality.[57]

EFFECTS OF INHALED ANESTHETICS

From an historic perspective, a nephrotoxic effect can be caused by older volatile inhaled anesthetics attributable to the liberation of inorganic fluoride when they are metabolized (also see Chapter 26).[58] Methoxyflurane (no longer clinically used) and enflurane when used for prolonged periods, lead to significant generation of inorganic fluoride.[40,58-60] Increased serum levels of inorganic fluoride were associated with polyuric renal insufficiency.[58,59] Approximately 100 published cases of renal failure and 20 renal-related deaths attest to the significance of methoxyflurane-related nephrotoxicity.[58]

Because sevoflurane metabolism is similar to enflurane in regards to the liberation of free fluoride ions,[61-63] does this anesthetic impair the ability of the kidneys to concentrate urine?[64] Methoxyflurane studies indicated that AKI was likely to occur with circulating fluoride levels more than 50 μm/L.[58] This presumed toxic threshold was extrapolated to the study of other volatile anesthetics. However, 43% of volunteers receiving sevoflurane had plasma fluoride levels that exceed 50 μm/L. Healthy patients receiving 9 minimum alveolar concentration (MAC) hours of sevoflurane anesthesia have serum fluoride levels averaging 36.6 ± 4.3 μm/L.[65] Relative to methoxyflurane, high fluoride levels with sevoflurane are short-lived, peaking 2 hours after the end of anesthesia and decreasing by 50% within 8 hours. Despite high fluoride levels with sevoflurane, volunteers have no impairment in their ability to concentrate urine in response to desmopressin, whereas 20% of volunteers receiving enflurane have transient concentrating deficits on day 1 but not day 5 after exposure.[65] To interpret these findings, investigators postulate that intrarenal production of fluoride ion may be more important for nephrotoxicity than circulating plasma fluoride levels.[63] The intrarenal metabolism of methoxyflurane is fourfold greater than that of sevoflurane.

Other explanations for the differences in the renal effects of volatile anesthetics were sought, including an evaluation of variation in nephrotoxic compounds generated when an inhaled anesthetic interacts with carbon dioxide absorbents. In breathing circuit systems at a high temperature and low flow rates, carbon dioxide absorbents degrade sevoflurane, creating fluoromethyl-2,2-difluoro-1-(trifluoroethyl) vinyl ether, also known as compound A. Metabolism of compound A occurs via conjugation in the liver with glutathione and then modification in the kidney by an enzyme (cysteine-S-conjugate β-lyase). Some compound A metabolites can cause renal injury, characterized by diuresis, glycosuria, proteinuria, and increased serum BUN and creatinine levels. AKI by this mechanism in experimental models is a function of the degree and duration of exposure to compound A,[66] with well-defined exposure thresholds in rats for injury (50 to 114 parts per million [ppm] for 3 hours) and death (331 for 3 hours, 203 for 6 hours, or 127 ppm for 12 hours).[67] However, a disparity exists between the results in rats and humans that may be due to differences in compound A processing; of the four recognized pathways for metabolism, three do not involve renal β-lyase or result in kidney toxicity. Humans have 10- to 30-fold less renal β-lyase enzyme activity compared with rats, which may account for the absence of kidney injury from sevoflurane in humans. One study[67] compared the safety of low-flow sevoflurane and isoflurane anesthesia in patients having prolonged surgeries (>6 hours). The average MAC hours in both groups was similar, and the average compound A concentration in the sevoflurane group was 20 ± 7 ppm. Markers of renal injury, including BUN, creatinine, *N*-acetyl-β-d-glucosaminidase (NAG), and alanine aminopeptidase, were similarly increased in all groups during the prolonged exposure to the volatile anesthetics.

The likely concentrations of compound A possible with sevoflurane during anesthesia have been studied

in human volunteers.[68] Fresh carbon dioxide absorbent was used, and 1.25 MAC sevoflurane was administered (without nitrous oxide) for 8 hours. Compound A levels approached 50 ppm, and 24-hour urine collections were analyzed for 3 consecutive days after exposure. Urinary glutathione S-transferase (GST) and other highly sensitive markers of tubular damage after nephrotoxic and ischemic insults were measured.[69] The investigators reported transient increases of urinary protein, albumin, glucose, α-GST, and π-GST in patients receiving sevoflurane. No such increases were observed after similar exposure to desflurane. A multicenter study[70] involving 73 elective surgical procedures lasting 2 to 8 hours compared the safety and efficacy of low flow (<2 L/min) sevoflurane to isoflurane. Fresh carbon dioxide absorbent was used for all cases, and nitrous oxide was not permitted. Sevoflurane use averaged 3.6 MAC hours, and compound A levels were as high as 223 ppm (mean 79 ± 54 ppm). No differences were found in urine albumin, glucose, protein, or osmolality between treatment groups. Moreover, within the sevoflurane group, no significant correlations were observed between compound A levels and BUN; creatinine; or urinary excretion of protein, glucose, NAG, α-GST, or π-GST.

Despite the fact that 7% to 15% of patients receiving sevoflurane may have (short-lived) circulating levels of fluoride in excess of 50 μm/L and/or significant exposure to compound A, adverse renal effects do not seem to occur.[58] Although the explanation for the apparent safety of sevoflurane in the presence of nephrotoxins is not completely understood, some have proposed that the source of methoxyflurane-related renal injury may be some other metabolic "villain" than fluoride or compound A that is unique to methoxyflurane metabolism, such as dichloroacetic acid.[71] Finally, potential benefits of sevoflurane to the kidney have been described. In a small study of patients undergoing cardiac surgery, preconditioning with sevoflurane decreased biochemical markers for renal (and myocardial) dysfunction.[72]

EFFECTS OF INTRAVENOUS ANESTHETICS

Propofol and dexmedetomidine may have antiinflammatory effects that are renoprotective. Propofol increases production of bone morphogenetic protein–7 (BMP-7), which suppresses the tumor necrosis factor (TNF) α–induced inflammatory cascade during sepsis-induced AKI,[73,74] as well as decreased injury during ischemia-reperfusion[75-77] and unilateral ureteral obstruction.[78] Similarly, in addition to altering RBF and sodium and water handling, the α_2-adrenoreceptor agonists such as dexmedetomidine may stimulate BMP-7 production. In a rat kidney renal tubular epithelial cell line exposed to lipopolysaccharide, dexmedetomidine increased the expression of BMP-7 and decreased the expression of inflammatory cytokines and histone deacetylases 2 and 5, resulting in improved cell survival.[79] In the same study, septic mice treated with dexmedetomidine had a longer survival time and a decreased incidence of AKI in a cecal-ligation and perforation model. Similar benefits have been observed in studies of ischemia-reperfusion injury in rats[80] and mice.[81] However, further studies in humans are needed to determine whether either of these anesthetics has renal benefits in the perioperative or critical care settings.

PERIOPERATIVE HEMODYNAMIC INSTABILITY AND RENAL FUNCTION

To comprehend the impact of perioperative hemodynamic instability on renal function, the complex pathogenesis of hemodynamically mediated AKI needs to be understood. Although an extreme reduction in RBF is necessary,[19] the unpredictable degree of AKI after hypotension suggests that it is not always sufficient. Even with decreased glomerular perfusion, a series of compensatory mechanisms can still preserve renal filtration.[58] Salt and water retention can restore intravascular volume and fractional tubular reabsorption. At a given level of cardiac output, intrarenal factors affect the ratio of renal-to-systemic vascular resistance, thereby influencing the fraction of cardiac output received by the kidneys. At the glomerular capillary, plasma is separated into a protein-free ultrafiltrate and a nonfiltered portion. Normally, the filtration fraction (i.e., relationship of glomerular filtration to renal plasma flow) is approximately 0.2. Initially, the filtration fraction is maintained by efferent arteriolar constriction. However, if unabated, the mechanisms that influence efferent arteriolar vasoconstriction may ultimately influence afferent arteriolar vasoconstriction. The resulting decrease in filtration fraction is the hallmark of postischemic AKI.[58] Ischemic tubular damage may be further exacerbated by an imbalance between oxygen supply and demand. Most vulnerable to the imbalance are the thick ascending tubular cells of the loop of Henle in the medulla.[30]

Cortical blood flow decreases in ischemic models of AKI.[82] Because 85% to 90% of RBF is normally distributed to cortical glomeruli, the finding of cortical pallor and RBF redistribution away from cortex suggests that redistribution may contribute to the functional lesions of AKI. In some cases, the return of perfusion to the cortex has correlated with a return of renal function.[82] The theory that intrarenal distribution of blood flow away from the outer cortex to the inner medulla decreases oxygen supply while increased tubular reabsorption of solute increases oxygen demand is further supported by studies of renal energetics during AKI.[83,84] A decrease in the glomerular filtration, and consequently in the energy requirement for tubular reabsorption, may be a mechanism by which the kidney reduces energy demands before energy supply is critically limited.

OTHER PERIOPERATIVE PERTURBATIONS AND RENAL FUNCTION

Several surgical interventions can affect RBF and, consequently, renal function. Whereas aortic cross-clamping above the renal arteries has obvious influence on glomerular filtration, infrarenal aortic cross-clamping and unclamping also have significant indirect effects on glomerular filtration and urine formation through changes in myocardial function, sympathetic activity, neuronal and hormonal activity (e.g., renin and angiotensin

production), intravascular volume, and systemic vascular resistance[85](also see Chapter 69). During standard cardiopulmonary bypass (CPB) surgery, cardiorenal relationships are approximately as expected; RBF decreases to 12% to 13% of total pump flow and is predicted by flow rate and perfusion pressure; however, only mean pressure correlates with urine output.[43,44] The intactness of myogenic and tubular-glomerular autoregulatory feedback has not been evaluated during CPB[22,23] (also see Chapter 67).

AKI after aortocoronary bypass surgery continues to be a devastating complication that is associated with multiorgan dysfunction, increased resource utilization, high cost, and increased mortality (see Chapters 67 and 69). Annually, approximately 800,000 patients worldwide undergo coronary artery bypass graft (CABG) surgery. In a recent multicenter observational study focused on AKI after cardiac surgery, 5% of participants developed AKI as defined by the need for acute dialysis or a doubling of serum creatinine from baseline.[4] The mechanism of perioperative AKI during cardiac surgery is multifactorial. Significant risk factors for AKI include underlying patient characteristics, such as age older than 75 years, history of diabetes, hypertension, pulse pressure, ventricular dysfunction, myocardial infarction, renal disease (also see Chapters 39 and 80), perioperative medication exposures (e.g., aprotinin, hetastarch), and surgical characteristics such as intraoperative use of multiple inotropes, insertion of intraaortic balloon pump, and extended duration of the CPB surgery.[86-90] Preoperative pulse pressure (systolic minus diastolic) more than 40 mm Hg has a clear relationship with renal risk—an odds ratio of 1.49 (confidence interval [CI], 1.17 to 1.89; $P = .001$) was added for every additional 20 mm Hg increment in pulse pressure.[86]

The role of CPB surgery in postoperative AKI remains controversial. In their comprehensive guidelines on AKI, KDIGO reviewed the literature on postoperative AKI between patients undergoing off-pump and on-pump coronary revascularization surgeries and ultimately recommended that "off-pump CABG surgery not be selected solely for the purpose of reducing perioperative AKI or need for RRT [renal replacement therapy]."[16] However, patients with chronic kidney disease, who are at the highest risk for AKI after CPB surgery, have often been excluded from randomized clinical trials of off-pump versus on-pump CABG. For example, in the Randomized On/Off Bypass (ROOBY) trial, in which 2303 patients were randomized to off-pump versus on-pump CABG, approximately 7.5% of patients had a preoperative serum creatinine level ≥1.5 mg/dL.[91]

However, a large observational study of 742,909 nonemergent, isolated CABG cases (including 158,561 off-pump cases) from the Society of Thoracic Surgery Database suggests a benefit to off-pump CABG in those with chronic kidney disease.[92] Propensity methods were used to adjust for patient- and center-level imbalances. The primary endpoint was death or dialysis. In those with lower estimated GFR (eGFR), the risk difference (i.e., number of patients with the outcome per 100 patients in those who underwent CPB minus the number with the outcome in those who underwent off-pump CABG) for the primary endpoint was 0.66 (95% CI, 0.45 to 0.87) for eGFR 30 to 59 mL/min/1.73 m^2 and 3.66 (95% CI, 2.14 to 5.18) for eGFR 15 to 29 mL/min/1.73 m^2. Both component endpoints followed the same trend. Highlighting the importance of chronic kidney disease as a risk factor for AKI after cardiac surgery, whereas slightly less than 1% of the overall cohort received dialysis after cardiac surgery, 2% of those with eGFR 30 to 59 mL/min/1.73m^2 and 12.5% of those with eGFR 15 to 29 mL/min/1.73m^2 required dialysis. The risk difference for dialysis alone in the same groups was 0.47 (95% CI, 0.31 to 0.62) and 2.79 (95% CI, 1.37 to 4.20) with on-pump versus off-pump CABG, respectively (Fig. 52-7). Thus, this study suggests that in those with advanced chronic kidney disease, there may be a benefit to off-pump surgery, but further studies are needed.

Finally, several genetic polymorphisms known to affect inflammation and vasoconstriction demonstrate strong associations with AKI after cardiac surgery.[93] Polymorphisms identified as relevant include the interleukin (IL)–6 572C and angiotensinogen 842C polymorphisms as a predictor of an approximately fourfold greater than the average peak creatinine rise after coronary revascularization. Such polymorphisms may have potential as a preoperative screening tool if validated in other populations and highlight the potential feasibility of such an approach. Thus in the future, the underlying genetic risk may also be assessed as a measure of the risk of perioperative AKI.

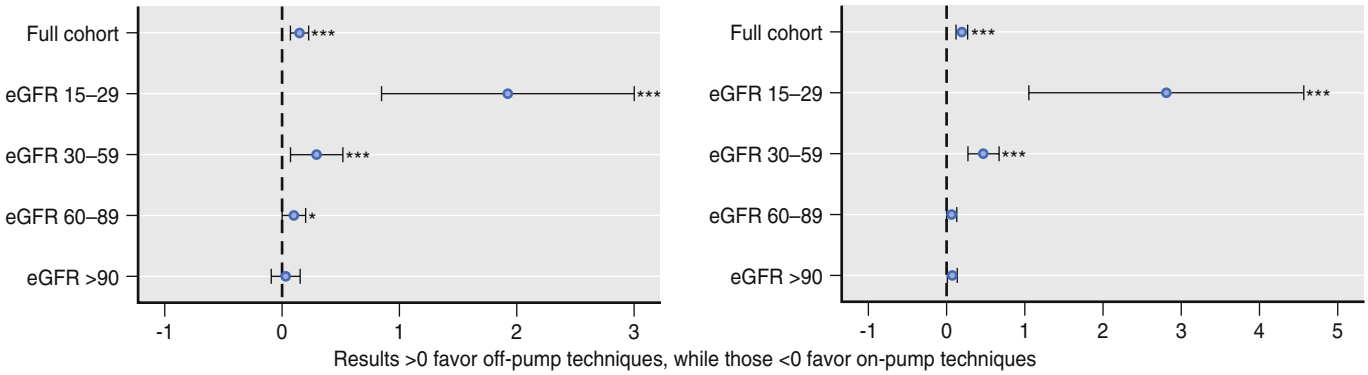

Figure 52-7. Estimates of adverse outcomes associated with on-pump versus off-pump coronary artery bypass grafting (CABG) by baseline estimated glomerular filtration rate (eGFR). For both mortality *(left panel)* and renal replacement therapy (RRT) *(right panel)*, off-pump CABG techniques appear to confer a benefit in those with lower eGFR. *P <0.05, **P <0.01, ***P <0.001. *(Redrawn from Chawla LS, Zhao Y, Lough FC, et al: Off-pump versus on-pump coronary artery bypass grafting outcomes stratified by preoperative renal function,* J Am Soc Nephrol *23:1389-1397, 2012.)*

MONITORS OF RENAL FUNCTION

In patients with perioperative AKI, one of the major challenges to optimal perioperative management and early intervention has been the inability to detect early onset, subtle AKI. Monitoring tools for traditional renal failure are typically insensitive until less than 40% of normal functioning nephrons remain (Fig. 52-8), which leaves only a small margin of renal function before symptoms are apparent.[39] Furthermore, late recognition of AKI allows little opportunity for the treatment of AKI.

Consensus criteria to define AKI are typically used in most studies of perioperative AKI. However, large blood volume loss and fluid shifts, which may artificially dilute serum creatinine, make these criteria sometimes questionable. Furthermore, the use of consensus urine output criteria in this context is unknown. Unlike the postoperative or critical care setting where renal monitoring can involve periodic evaluation of kidney function under relatively stable conditions, intraoperative renal monitoring involves a more brief unstable period, often involving significant blood loss, major fluid shifts, wide hemodynamic fluctuations, and even direct compromise to renal artery blood flow.

Therefore the anesthesia provider is likely the first monitor (i.e., in a sense) required for preserving renal function by recognizing and treating factors that may contribute to or exacerbate AKI; for example, the toxic effects of aminoglycosides and iodinated contrast materials are exacerbated by intravascular volume depletion. Furthermore, the anesthesia provider often relies on indirect variables, such as urine volume, to assess renal perfusion. Unfortunately, urine output does not reliably reflect glomerular filtration and renal function under intraoperative conditions. Even knowledge of RBF is not, in and of itself, particularly informative because increased flow mandates increased filtration and active transport demands, as well as increased oxygen delivery. A monitor of balanced supply and demand of regional renal perfusion, particularly in the renal medulla, would be an ideal, although currently unavailable, direct monitoring tool.

The best tools currently available intraoperatively are indirect hemodynamic monitors that can assist in optimizing conditions consistent with kidney well-being, such as ensuring adequate intravascular volume (i.e., preload), cardiac performance, and systemic perfusion. Serum chemistries and urinary indices may enable the assessment of adequate distribution of cardiac output to the kidneys themselves.

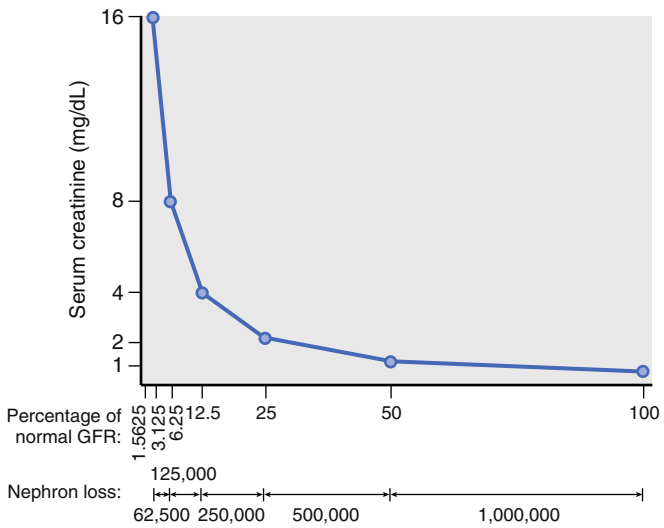

Figure 52-8. The inverse logarithmic relationship between serum creatinine concentration (*y* axis) and relative reductions in glomerular filtration rate (GFR) and approximate nephron loss (*x* axis) is shown. The nonlinear relationship means that the serum creatinine level is not significantly increased until a 75% reduction in GFR (e.g., 120 to 30 mL/min) occurs. *(Modified from Faber MD, Kupin WL, Krishna G, et al: The differential diagnosis of ARF. In Lazarus JM, Brenner BM, editors:* Acute renal failure*, ed 3. New York, 1993, Churchill Livingstone, p 133.)*

INDIRECT MARKERS OF OPTIMAL RENAL PERFUSION AND FUNCTION

Intravascular volume depletion, which commonly occurs in fasting patients undergoing surgery, is a risk factor for AKI. For example, the combination of diabetes mellitus and intravascular volume depletion increases the chance of developing AKI by 100-fold.[94] The most practical preoperative methods to assess volume status are with preoperative patient history and physical examination and by assessing changes in arterial blood pressure in response to changing conditions and dynamic maneuvers. For example, an awake patient normally does not have significant orthostatic changes in arterial blood pressure unless an autonomic or intravascular volume deficit exists. During anesthesia, a similarly dehydrated patient may demonstrate paradoxical arterial pulse changes with positive-pressure inspiration.

OXYGEN DELIVERY: BLOOD GAS, ACID-BASE BALANCE, AND HEMATOCRIT

Severe arterial hypoxemia to a partial arterial pressure of oxygen (Pao_2) value of less than 40 mm Hg is associated with decreased RBF and renal vasoconstriction.[95,96] Capnometry may be a useful monitor because hypercarbia has been associated with decreased RBF in patients requiring mechanical ventilation.[97] Inequalities in oxygen supply demand are exaggerated and medullary hypoxia is extreme during CPB, effects that last well beyond separation from circulatory support[69] (also see Chapter 67).

The effects of anemia on the kidney have been studied mostly in the context of CPB management. When crystalloid and colloid solutions are used to prime an extracorporeal circuit, the initiation of CPB surgery obligates an acute decrease of approximately 30% in oxygen-carrying capacity. Animal studies endorse moderate hemodilution (hematocrit 20% to 30%) as renoprotective during CPB surgery through a reduction of blood viscosity and improved regional blood flow.[98] However, although hematocrit values less than 20% during CPB surgery are commonly accepted clinically (extreme hemodilution), very low hematocrit values are linked with adverse outcomes, including AKI.[99-103] The solution may not be as simple as transfusion because blood transfusions themselves have

been linked to AKI. In a systematic review, Karkouti found 22 studies that examined the association between blood transfusions and AKI postcardiac surgery.[104] An independent association between transfusions and AKI was found in 18 of the 22 studies. The association of perioperative anemia with AKI was further examined in 14 studies, and 9 of the studies found an independent association of perioperative anemia with AKI. Proposed mechanisms for transfusion-associated AKI include exacerbation of inflammation and oxidative stress, which occur during the CPB surgery. The age of stored blood probably increases the risk of AKI (also see Chapter 61). Old blood may result in higher circulating levels of free hemoglobin and free iron. Finally, anemia might increase the risk of AKI and other organ injury by increasing the risk of tissue hypoxia and oxidative stress, as well as impaired iron metabolism. The Society of Thoracic Surgeons and the Society of Cardiovascular Anesthesiologists guidelines suggest that transfusion triggers (also see Chapter 61) should be lower during CPB surgery and that a transfusion trigger of 6 g/dL is reasonable, except in those at risk for end-organ ischemia, in whom a higher trigger may be reasonable.[105] However, many clinicians may not wish to wait for a hemoglobin level of 6 g/dL before giving a blood transfusion, especially intraoperatively.

SYSTEMIC PERFUSION: SYSTOLIC ARTERIAL AND PULSE PRESSURE

Large multicenter epidemiologic studies have identified a relationship between markers of abnormal central aortic compliance, such as preoperative isolated systolic hypertension (>160 mm Hg) and wide pulse pressure hypertension (>40 mm Hg),[86,106] and postoperative AKI and dialysis, in particular in patients undergoing cardiac surgery (also see Chapter 67). The systolic component of the arterial blood pressure number is determined by stroke volume and the rate of ventricular ejection, whereas the pulsatile component of arterial blood pressure is governed by the relationships among stroke volume, ventricular ejection, viscoelastic properties of large arteries, and peripheral vascular resistance. Pulse pressure is an index of the effects of large artery stiffness and the rate of pressure on propagation and reflection within the arterial tree. Early return of reflected arterial waves during late systolic rather than early diastolic pressure (from increased propagation velocity in stiff vessels) increases systolic blood pressure (i.e., afterload) and decreases diastolic blood pressure (i.e., perfusion pressure). Perfusion pressure and the risk of perioperative renal dysfunction are linked by the preexisting capacity of the vasculature to compensate for low pressure as it determines flow. Those with a predisposition to low flow attributable to abnormal central aortic compliance may represent patients who require higher pressure to maintain adequate flow and minimize renal risk compared with normotensive patients.

RBF during CPB is not autoregulated and varies with pump flow rates and arterial blood pressure.[44] However, CPB hypotension is not equivalent to hypotension with hemorrhagic shock or low cardiac output states, because a low pressure during CPB surgery is rarely associated with low flow. CPB flow rates and perfusion pressures were compared in a case-control analysis of three groups of patients with normal baseline renal function who postoperatively required dialysis (n = 44), sustained a renal injury without requiring dialysis (n = 51), or had no renal impairment (n = 48).[107] Usually, renal injury was associated with long bypass durations, low flows, and long periods with CPB pressure less than 60 mm Hg. A serious limitation of this study is the potential for confounding CPB variables and known renal risk factors. In contrast, several studies that accounted for known risk factors in evaluating perfusion management did not link low CPB blood pressure (with maintained flow) with postoperative AKI.[108-110]

RBF is affected by renal artery stenosis. In a retrospective study of 798 patients undergoing aortocoronary bypass whose cardiac catheterization procedures routinely included renal angiogram, Conlon and colleagues found that 18.7% of patients had at least 50% stenosis of one renal artery (nine patients had >95% renal artery stenosis bilaterally).[111] However, in a multivariable logistic regression analysis, no association of the presence or severity of renal artery stenosis was observed with postoperative AKI.

INTRAVASCULAR VOLUME STATUS: CENTRAL VENOUS PRESSURE, PULMONARY CAPILLARY WEDGE PRESSURE, LEFT ATRIAL PRESSURE, AND LEFT VENTRICULAR END-DIASTOLIC AREA

The decision to use any monitor should depend on the patient's functional cardiac reserve status and the extent of the proposed surgical insult. Although maintaining adequate cardiac output is necessary for maintaining adequate RBF, adequate flow may still not occur. Intravascular volume monitoring techniques must include caution to identify physiologic conditions that influence their validity as a reflection of preload in a particular patient (see Chapters 20, 23, and 44). Monitoring central venous pressure to assess preload involves assumptions about normal left and right ventricular function, pulmonary vascular resistance, and mitral, pulmonary, and tricuspid valve function. Similarly, monitoring pulmonary artery pressure or pulmonary capillary wedge pressure assumes normal left ventricular compliance, mitral valve function, and normal airway pressure.

Direct measurements of left atrial pressure may offer insight into the kidney pressure-flow relationship because left atrial hypotension is a powerful stimulus for renal vasoconstriction. Despite equivalent reductions in cardiac output and arterial blood pressure, RBF decreases significantly more when left atrial pressure is decreased (e.g., hemorrhagic shock), compared with left atrial pressure when it is increased (e.g., cardiogenic shock).[112] Left atrial pressure receptors modulate renal vasoconstriction through the release of ANP, a hormone secreted by the cardiac atria in response to intravascular volume expansion.[113] ANP acts on the arterial and venous systems, the adrenal glands, and the kidneys to reduce intravascular volume and decrease blood pressure.[33] Within the kidney, the hormone increases hydraulic pressure in the glomerular capillaries through afferent arteriolar dilation and efferent arteriolar vasoconstriction. ANP reduces arterial

blood pressure by relaxing smooth muscle and reducing sympathetic vascular stimulation and also inhibits renin and aldosterone secretion, causing renal vasodilation, natriuresis, and diuresis.[5]

Despite the direct relationship of left atrial pressure and renal vasoconstriction, static monitors of intravascular volume status are gradually being replaced by echocardiographic and dynamic monitors of intravascular volume status (see the next section on guided fluid optimization). Intraoperatively, one of the most direct ways to monitor intravascular volume may be by direct assessment of the left ventricular end-diastolic area with transesophageal echocardiography. Monitoring with invasive devices, such as pulmonary artery catheters, arterial cannulas, and transesophageal echocardiography, has not been demonstrated to reduce the incidence of AKI.

BLOOD FLOW: CARDIAC OUTPUT AND ESOPHAGEAL DOPPLER ULTRASONOGRAPHY–GUIDED FLUID OPTIMIZATION

The phrase *guided fluid optimization* has recently garnered significant interest as a step beyond traditional, somewhat unreliable guides to fluid administration (e.g., central venous pressure). The principle behind fluid optimization is to maximize tissue-oxygen delivery by achieving a maximum stroke volume. Intravascular fluid management is typically guided by the physiologic response to dynamic measures; proposed measures include systolic pressure variation, pulse pressure variation, continuous cardiac output monitoring, and esophageal Doppler ultrasonography fluid boluses.[114-117] Some maneuvers to assess fluid responsiveness may be feasible in the critical care setting but not in the perioperative setting (e.g., passive leg raise). Considering the improved outcomes in patients who are critically ill with the acute respiratory distress syndrome and are treated with a restrictive fluid management strategy, fluid restriction in the perioperative setting has gained attention. Yet, a meta-analysis of seven randomized clinical trials in the setting of intraabdominal surgery suggested a restrictive fluid strategy offered no benefit; however, there was also no evidence of harm, including AKI.[118] In some studies, excessive fluid restriction was associated with harm, including an increased risk of anastomotic breakdown and sepsis, and should clearly be avoided.[119] Although a systematic review of over 80 perioperative fluid management randomized trials concluded that the optimal amount of fluid to be administered for fluid replacement in elective surgical procedures is not clear, it recommended strict avoidance of fluid overload[120] (also see Chapter 59).

Others have described the disastrous and unpredictable occurrence of acute pulmonary edema related to postoperative fluid retention.[121] Thus evidence on which to base judgments of the importance of fluid management strategies on perioperative renal function is insufficient at present. However, balanced electrolyte solutions may be beneficial over hyperchloremic intravenous fluids.[122] Physiologically, hyperchloremia leads to renal vasoconstriction and a decrease in GFR, although the precise mechanism of this effect remains unknown.[123]

AUTOREGULATION AND DISTRIBUTION OF CARDIAC OUTPUT TO THE KIDNEYS

The fraction of cardiac output perfusing the kidneys depends on the ratio of renal vascular resistance to systemic vascular resistance.[39] In general, the response to renal hypoperfusion involves three major regulatory mechanisms that support renal function: (1) afferent arteriolar dilation increases the proportion of cardiac output that perfuses the kidney; (2) efferent arteriolar resistance increases the filtration fraction; and (3) hormonal and neural responses improve renal perfusion by increasing intravascular volume, thereby indirectly increasing cardiac output. The afferent arterioles react to reductions in perfusion pressure by relaxing their smooth muscle elements to decrease renal vascular resistance. Decreased solute delivery to the macula densa in the cortical portion of the thick ascending loop of Henle results in the relaxation of the juxtaposed afferent arteriolar smooth muscle cells, improving glomerular perfusion and filtration (also see Chapter 23).

The kidney produces vasodilator prostaglandins to counteract the effects of systemic vasoconstrictor hormones such as angiotensin II. In a state of low cardiac output when systemic blood pressure is preserved by the action of systemic vasopressors, RBF is not depressed because the effect of the vasopressors is blunted within the kidney.

A selective increase in efferent arteriolar resistance decreases glomerular plasma flow, thereby preserving GFR. Glomerular filtration is augmented because capillary pressure upstream from the site of vasoconstriction tends to rise. This mechanism enables the kidney to offer high organ vascular resistance to contribute to the maintenance of systemic blood pressure without compromising its function of filtration. Studies using specific inhibitors of angiotensin II have shown that efferent arteriolar resistance largely results from the action of angiotensin II.[124] At low concentrations, norepinephrine has a vasoconstricting effect on efferent arterioles, indicating that the adrenergic system may also be important for maintaining the renal compensatory response.[125]

Reductions in cardiac output are accompanied by the release of vasopressin and by increased activity of the sympathetic nervous system and the renin-angiotensin-aldosterone system. These regulatory mechanisms to preserve RBF conserve salt and water. The control of blood delivery to the kidney, the fraction of plasma filtered, and the amount of volume returned to the systemic circulation are determined by regulatory mechanisms within the kidney that attempt to preserve filtration function during compromised circulation.

One study reported the normal response to hemorrhage in otherwise healthy patients, describing a 30% reduction in RBF with a decrease in mean perfusion pressure from 80 to 60 mm Hg.[126] Changes known to occur at the initiation of CPB surgery include greater reduction in renal perfusion than systemic perfusion, loss of RBF autoregulation, and stress hormone and inflammatory responses known to be harmful to the kidney.[44,127] These effects may explain why the duration of CPB surgery independently predicts postcardiac surgery renal impairment. During experimental CPB surgery, medullary Po_2 decreases from typically low levels to unmeasurable levels.[69]

EXCESSIVE INTRAVASCULAR VOLUME AND THE ABDOMINAL COMPARTMENT SYNDROME

The abdominal compartment syndrome was first defined in 1985; since then, it has been progressively recognized as a common contributor to renal dysfunction in the setting of excessive intravascular volume.[128,129] Not surprisingly, excessive intravascular volume and mechanical ventilation with high airway pressures are significant contributors to the abdominal compartment syndrome. Abdominal compartment syndrome is defined as a sustained increase in intraabdominal pressures to greater than 20 mm Hg that causes organ dysfunction; in contrast, intraabdominal hypertension is typically defined as intraabdominal pressures ≥12 mm Hg without organ dysfunction. This increase in intraabdominal pressure decreases abdominal perfusion pressure (which is mean arterial pressure – intraabdominal pressure), and results in a functional prerenal state attributable to reduced renal perfusion.

The intraabdominal pressure can easily be measured using an indwelling Foley catheter and the same pressure tubing setup used for arterial line blood pressure monitoring.[130] The Foley catheter is clamped distal to the instillation port, and up to 25 mL of saline is instilled into the bladder. The transduced should be zeroed at the midaxillary line, and the pressure should be measured at end-expiration approximately 30 to 60 seconds after fluid is instilled into the bladder to allow for detrusor muscle relaxation. Of note, intraabdominal pressure may be chronically elevated to as high as 12 mm Hg in the obese adult but is not associated with end-organ dysfunction in this context (also see Chapter 71).[131] Prompt recognition of the abdominal compartment syndrome and treatment via decompression in the appropriate clinical context is critical.

LABORATORY TESTS OF SERUM AND URINE AS MARKERS OF RENAL FUNCTION

An ideal monitor for perioperative AKI recognition would be accurate, point-of-care, simple, brief, and inexpensive; in addition, it should have confirmed links with AKI-related outcomes (e.g., mortality). Because no such test currently exists, trends in repeated serum creatinine determinations (relative or absolute changes), alone or integrated into eGFR, are the clinical tools most often used for this purpose.[132] Although traditional tests are useful in identifying kidney failure, an inherent limitation of almost all currently available tools is the obligate delay between the *onset* of AKI and the *diagnosis* of AKI. One striking difference between the management of AKI and acute myocardial infarction (AMI) is the lack of early biomarkers for AKI to guide prompt recognition and intervention when tissue is threatened (i.e., AMI—troponin, creatine kinase–MB [CK-MB]). Thus significant ongoing efforts are testing the value of early AKI biomarkers. The following discussion is categorized into traditional diagnostic tools and the currently expanding field of early biomarkers for AKI.

TRADITIONAL BIOMARKERS OF ACUTE KIDNEY INJURY

Biomarkers are those used to estimate renal function (serum creatinine and GFR estimating equations and creatinine and urea clearance), those biomarkers used to recognize AKI (urine volume, serum BUN, and creatinine), and those used to distinguish the different causes of AKI (urine-specific gravity, urine osmolality, urine sodium level, fractional excretion of sodium (Fe_{Na}) and urea, and urinalysis). Because AKI represents a change in renal function, some of the estimates of renal function are also used to recognize AKI (e.g., serum creatinine). Another test frequently used to distinguish the causes of AKI is ultrasonography of the kidneys and urinary tract to rule out obstruction as a cause of AKI, noting that in individuals with two functioning kidneys, both kidneys must be obstructed for AKI to occur. Because ultrasonography is not a functional test *per se*, its use is not discussed further in this text. Although not routinely used in clinical practice, other functional measures include measured GFR using exogenous markers such as inulin, as well as RBF (Box 52-1). Finally, interest in cystatin C and other novel markers of GFR is increasing; therefore these are introduced in the section that discusses novel (early) biomarkers of AKI later in this chapter.

BOX 52-1 *Markers of Kidney Function*

- Serum creatinine
  - Analysis tools
    - Baseline-to-peak postoperative fractional change
    - Peak in-hospital postoperative
    - Baseline-to-peak maximum change
    - AKI definitions
    - STS definition
    - AKIN criteria
    - RIFLE criteria
    - KDIGO criteria
    - Modified contrast nephropathy criteria
- Creatinine clearance
  - Cockcroft-Gault estimating formula
    - 24-hour urine collection
    - Shorter (e.g., 2- or 4-hour) urine collection
- Glomerular filtration rate
  - Estimated glomerular filtration rate
    - MDRD equation
    - CKD-EPI equation
  - Direct measures
    - Insulin clearance
    - Iohexol clearance
- Urine volume
  - RIFLE, AKIN, KDIGO criteria
- Blood urea nitrogen
- Urine specific gravity
- Urine osmolality
- Urinary sodium
- Fractional excretion of sodium
- Renal blood flow

Functional measures of kidney health such as serum creatinine are essentially surrogates for glomerular filtration, which is governed by the following equation:

$$GFR = K_f \times (P_{GC} - P_{BC} - P_{PO})$$

where GFR is the rate at which fluid is filtered through the glomerular capillaries into the Bowman capsule, K_f is the glomerular filtration coefficient or the factor that considers the permeability and surface area of the glomerular basement membrane, P_{GC} is the glomerular capillary pressure, P_{BC} is the pressure in the Bowman capsule, and P_{PO} is the plasma oncotic pressure.

Acute changes in GFR and, consequently, in urine formation are commonly caused by changes in glomerular capillary pressure. For example, events that reduce plasma flow rates reduce the hydraulic pressure of glomerular capillaries and favor decreased ultrafiltration, whereas events that increase plasma flow rate have the opposite effect. In theory, varying concentrations of plasma proteins may influence oncotic pressure and influence GFR, with smaller plasma protein concentrations decreasing oncotic pressure and increasing GFR. The glomerular filtration coefficient is the product of glomerular capillary hydraulic permeability and total surface area available for filtration. Hydrostatic pressures are normally maintained higher in glomerular capillaries than in other capillary beds by a delicate balance of preglomerular and postglomerular vascular tone in arterioles. The permeability of the glomerular capillary wall is equal for substances with molecular masses up to 5000 to 6000 daltons (Da) and decreases to almost zero at 60,000 to 70,000 Da.[133] Metabolic wastes and essential nutrients are filtered freely, and larger proteins, such as albumin and immunoglobulin G (IgG), are filtered in trace amounts or not at all. The hope is that real-time GFR measurements will be possible in the future in the perioperative and critical care settings; such technology is being developed and tested in small and large animal models.[134-136]

Serum Creatinine Concentration

Despite all of its limitations, the serum creatinine concentration remains the most used clinical tool to assess renal function and to diagnose AKI. Serum creatinine is a cyclic anhydride of creatine, which is a small molecule (113 Da) that is continuously released during skeletal muscle protein catabolism. Muscle mass, which is smaller in women and declines with age, directly predicts creatinine release. Creatinine levels in body fluids (e.g., plasma, serum, urine) are also easy and inexpensive to measure. These properties have made serum creatinine a mainstay as a marker of steady-state changes in renal filtration.

However, because of its nonlinear relationship with changes in renal function (see Fig. 52-8), variability among individuals, and susceptibility to changes unrelated to changes in GFR (e.g., cimetidine, trimethoprim, N-acetylcysteine),[132,137,138] an increase of serum creatinine concentration is only somewhat reliable as a sign of renal dysfunction. GFR may be reduced by as much as 75% before increases reach abnormal levels attributable to the kinetics of creatinine accumulation.[139,140] Often the magnitude of the changes in serum creatinine may be more important than the absolute value. Because creatinine production is proportional to muscle mass, many chronically ill, malnourished, older patients have serum creatinine values in the normal range, despite reduced renal concentrating ability and GFR. Conversely, many critically ill patients at risk for developing AKI may have high metabolic rates because of hyperalimentation, sepsis, or posttraumatic states. Nonetheless, the serum creatinine concentration remains a useful; inexpensive; and, so far, unsurpassed clinical tool to reflect particularly *trends* of change in renal filtration function and to predict outcome, even during the perioperative period.

An inverse logarithmic relationship exists between GFR and serum creatinine concentration (see Fig. 52-8); that is, as GFR decreases, creatinine increases. Within the normal ranges, changes relative to baseline can represent significant changes in renal function. For example, a patient with a baseline serum creatinine level of 0.6 mg/dL who develops contrast nephropathy sufficient to reduce the GFR to 50% of baseline would have a serum creatinine level of approximately1.2 mg/dL, still in the normal range. Thus a trend in serum creatinine values is always more useful than a single serum creatinine measurement to evaluate renal function reserve, particularly when changes are anticipated.

Nephrologists and critical care physicians have focused on developing consensus criteria for AKI. Although the cardiac surgery literature has commonly defined AKI using the Society of Thoracic Surgeons' definition of at least a twofold creatinine rise to a value exceeding 2 mg/dL or new dialysis or both[141] and the contrast nephropathy literature has focused on creatinine rises exceeding 25% or 0.5 mg/dL (44 μmol/L), [a] major push to define AKI using the same criteria across all study types now exists (Table 52-1).

Additional methodologic concerns with the use of creatinine as a measure of renal function include the fact that creatinine distributes into total body water; when patients become volume overloaded, creatinine may become diluted, and AKI may be masked. AKI recognition may be delayed or entirely missed in the setting of excessive intravascular volume.[142,143] Furthermore, outcomes in those with AKI that is masked by excessive intravascular volume have very poor outcomes, with mortality rates similar to those with conventional AKI. In addition, creatinine generation rates may change under conditions of acute illness.[144,145] Despite these limitations, considering the low cost of the test and the ability to obtain frequent measurements, serum creatinine remains the best test of renal function currently available.

Creatinine and Urea Clearance

When monitoring renal function, the measure of interest is the GFR, which is slightly overestimated by creatinine clearance, since creatinine is partially secreted in the renal tubule. Since gold standard measurements of GFR including inulin and iothalamate clearance are expensive and cumbersome, these measurements are not routinely used in clinical practice. Creatinine clearance can be either estimated when creatinine is at steady state or directly measured. When creatinine is at steady state, the Cockcroft-Gault equation can be used to estimate creatinine

clearance based on patient gender, age (years), weight (kg), and serum creatinine (Cr) (mg/dL)[146]:

$$\text{Cockcroft – Gault eGFR (mL/min)} = [140\ (\text{age}) \times \text{weight (kg)}] \div (\text{Cr} \times 72) \times .85\ (\text{for females})$$

However, as described in the next section, under conditions where serum creatinine is at steady state, the Cockcroft-Gault equation has largely been superseded by more modern GFR estimating equations.

Precise measurements of creatinine clearance require the collection of timed urine samples using the following formula:

$$\text{GRR} - (\text{UV} \div \text{P})$$

where U is the urinary concentration of creatinine (mg/dL), V is the volume of urine (mL/min), and P is the plasma concentration (mg/dL). The major limitation in determining creatinine clearance is the necessity of accurately collecting urine. Although reasonable correlation between short-timed creatinine clearance measurements (as short as 2 hours) and 24-hour creatinine clearance has been reported for patients in ICUs[147] (Fig. 52-9), in general, the longer the urine collection period, the more accurate is the measurement. Nonetheless, short-timed clearance measurements may be useful to identify AKI before changes in serum creatinine[148] and as an assessment to guide therapy, including discontinuation of dialysis[149] and medication dosing. However, changing hydration of the patient and failing to record urine volume accurately may make such short-timed collections inaccurate.[150] The error in calculation of creatinine clearance can vary significantly, depending on the accuracy of urine collection, body weight, surface area, and normal day-to-day variations. Regardless, these direct measurements can be extremely useful for patients in whom a concern exists that eGFR equations may overestimate renal function. These individuals include older and critically ill patients who may have limited muscle mass, as well as those who are under conditions of acute stress and critical illness, during which emerging data have suggested that changes in creatinine generation may occur. Because creatinine is excreted by glomerular filtration and tubular secretion, as the GFR decreases the tubular secretion becomes a progressively more important fraction of creatinine excretion, such that creatinine clearance overestimates the GFR by 50% to 100% if the true GFR is less than 15 mL/min.

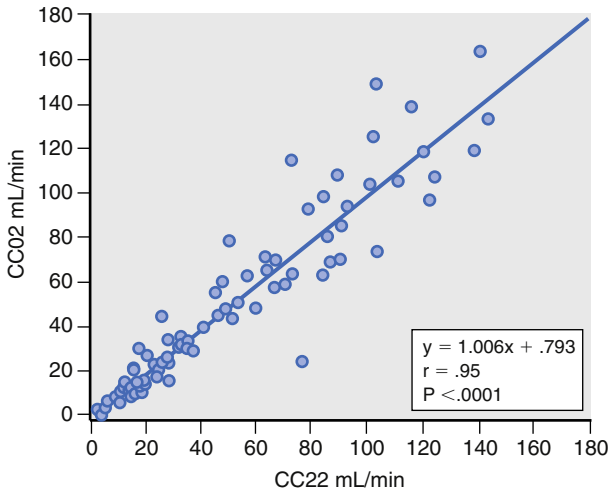

Figure 52-9. Correlation between the 2-hour creatinine clearance (CC02) and the 22-hour creatinine clearance (CC22). *(Modified from Sladen RN, Endo E, Harrison T: Two-hour versus 22-hour creatinine clearance in critically ill patients,* Anesthesiology *67:1013-1016, 1987.)*

Although urea is freely filtered at the glomerulus, it is also reabsorbed, and, as a result, measuring timed urea clearance underestimates GFR. Consequently, timed urea clearance measurements are not used with one exception: when GFR is low (less than 20 mL/min/1.73 m^2), the average of the timed urea and creatinine clearances is often used to estimate GFR, since the timed urea clearance underestimates clearance and the timed creatinine clearance overestimates clearance.

Glomerular Filtration Rate Estimating Equations Using Steady-State Creatinine

The Modification of Diet in Renal Disease (MDRD) GFR estimating formula uses several clinical variables to obtain estimates of GFR in a population with chronic kidney disease.[151] Several forms of this equation are available, but the one in widespread clinical use incorporates serum creatinine, age, gender, and race:

$$\text{GFR} = 186 \times [\text{serum Cr (mg/dL)}]^{-1.154} \times (\text{age})^{-0.203} \times 0.742\ (\text{for females}) \times 1.210\ (\text{for blacks})$$

This equation has been adopted by many clinical laboratories. However, two important caveats must be kept in mind when interpreting these results. First, interpretation of eGFR assumes that creatinine is at steady state; during an episode of AKI when the serum creatinine is rising, the eGFR will be inaccurate. In addition, because the equation was derived in a group of patients with chronic kidney disease, the equation is inaccurate when eGFR exceeds 60 mL/min/1.73 m^2 and is often reported out as >60 mL/min/1.73 m^2 rather than as an exact number.

The Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) equation is a more recent eGFR equation derived in both normal populations and those with chronic kidney disease[152]; this equation uses splines to allow for precise eGFR across a large range of values. This equation will likely replace the MDRD equation in the clinical laboratory setting over the next 5 to 10 years. Again, this equation cannot be used when serum creatinine is not at steady state.

Urine Volume

Although consistently recorded, intraoperative urine output remains a controversial perioperative marker of renal function. Whereas the presence of urine (regardless of amount) confirms blood flow to the kidney, many nonrenal factors directly and profoundly influence urine production. During surgery, patients are often hemodynamically unstable; decreased blood volume or cardiac output, fluctuating hormone levels (e.g., aldosterone, renin, ADH), nervous system reflexes, and increased

catecholamine concentrations added to the effects of general anesthesia can alter GFR. Although intraoperative urine output has been associated with subsequent AKI in some studies,[153] whether it is a reliable intraoperative sign of pending renal dysfunction is not clear, with several studies suggesting that intravascular volume resuscitation in the surgical setting may not improve urine output or affect rates of AKI.[41,154] For example, Alpert and colleagues observed patients who underwent oliguric aortic surgery (urine flow <0.125 mL/kg/hr) and were given additional crystalloid solution, intravenous mannitol, furosemide, or no intervention[41]; no correlation was found between intraoperative mean or the smallest hourly urine output and subsequent AKI (see Fig. 52-7).

In contrast to the intraoperative setting, significant prolonged preoperative or postoperative oliguria has been proposed as a diagnostic criterion for AKI, with urine output (<0.5 mL/kg/hr for longer than 6 hours) forming the basis for RIFLE, Stage R, and AKIN and KDIGO, Stage 1, AKI.[14-16] The kidney concentrates the ultrafiltrate so that at maximal concentration, a minimum of 400 to 500 mL of urine is required to clear the daily obligatory nitrogenous wastes. However, the urine output criteria for AKI have not been well validated in the clinical literature and remain controversial.[17] Furthermore, the lack of correlation of immediate perioperative oliguria with AKI has not been incorporated into these recent consensus statements, primarily developed by nephrologists and critical care physicians.[14-16]

Blood Urea Nitrogen

BUN is often measured as part of the assessment of renal function but is inherently problematic as a measure of renal function on its own. BUN is a protein degradation product and is consequently increased by high protein intake, blood in the gastrointestinal tract, and accelerated catabolism in traumatized or septic patients. Because urea is synthesized in the liver, hepatic dysfunction decreases urea production and therefore BUN concentration. It had been proposed that BUN/creatinine ratios could suggest whether AKI was due to prerenal causes or ATN, with BUN/creatinine ratios >20 consistent with prerenal azotemia; however, this criterion is nonspecific.

Urine Specific Gravity and Osmolality

Once AKI is diagnosed, a number of tests can be used to try to distinguish the cause of AKI. The distinction between prerenal azotemia and ATN is emphasized in this discussion. This distinction has clinical relevance since a patient with prerenal azotemia in the perioperative setting may require intravascular fluid administration, whereas avoiding excessive intravascular volumes may be important in the patient with established ATN. Nonetheless, an important caveat to this discussion is the fact that prerenal azotemia and ATN likely represent a spectrum of disease, rather than two distinct entities. Consequently, rigorous attempts to distinguish one disease from the other have been unsuccessful; perhaps, as a result, this distinction should not be made.[155] The tests proposed to distinguish prerenal azotemia from ATN have mostly been urine based and are more comprehensively reviewed by Perazella and Coca.[156]

Urine specific gravity reflects the mass of 1 mL of urine compared with 1 mL of distilled water. Normal values range between 1.001 and 1.035. In settings of poor perfusion or prerenal azotemia, urine specific gravity is high (e.g., 1.030), reflecting the kidney's ability to conserve sodium and water. With a loss of concentrating ability attributable to ATN, urine specific gravity resembles plasma osmolarity (e.g., 1.010). Unfortunately, when interfering substances that raise urine specific gravity (e.g., glucose, protein, contrast dye) are present in large amounts (Box 52-2), high urine specific gravity can provide misleading reassurance that the renal concentrating ability is preserved; depending on the nature of these agents, some will affect urine osmolality as well. Of note, the ability of the kidneys to concentrate urine is impaired in many older patients and many with chronic kidney disease.

Urine specific gravity is a surrogate for osmolality (normal range, 50 to 1000 mOsm/kg), a measure of the number of osmotically active particles in solution in the solvent phase. Theoretically, urine osmolality is physiologically superior to urine specific gravity as a test of renal function; however, the same substances and conditions that render urine specific gravity a nonspecific test can also affect the reliability of urine osmolality (see Box 52-2). Similar to urine-specific gravity, the sensitivity and specificity of urine osmolality as a test for predicting or distinguishing ATN from prerenal azotemia are clinically inadequate.[157]

Urinary Sodium Concentration

With decreasing perfusion, the normally functioning kidney conserves sodium and water. It is traditionally suggested that a urinary sodium level of less than 20 mEq is consistent with prerenal azotemia (since the normal kidney, under conditions of hypoperfusion, retains sodium) and that a level greater than 40 mEq indicates ATN.[157] However, the factors affecting urine sodium are numerous and include heterogeneity of nephrons, secretion of aldosterone, secretion of ADH, diuretic therapy, saline content of intravenous infusion solutions, sympathetic neural tone, and sodium-avid states (e.g., congestive heart failure, cirrhosis). Therefore urine sodium in isolation cannot be used to distinguish prerenal azotemia and ATN reliably.

Fractional Excretion of Sodium

Failure of avid sodium reuptake by the kidney in the setting of dehydration exhibits increased urine sodium

BOX 52-2 ***Substances and Conditions Affecting Urine-Specific Gravity and Urine Osmolality***

Antibiotics (e.g., carbenicillin)
Hormonal imbalances (e.g., diabetes insipidus)

and is the principle underpinning the utility of Fe_{Na} as a diagnostic tool. A sodium excretion value of less than 1%, compared with greater than 1%, suggests differentiation between prerenal azotemia and ATN, particularly in the presence of oliguria. The Fe_{Na} was first described by Espinel[158]; it represents the fraction of sodium excreted versus that filtered by the kidneys. Fe_{Na} is calculated as follows:

$$FE_{Na} = \frac{\text{Excreted Na}}{\text{Filtered Na} \times 100} = \frac{U_{Na}P_{Cr}}{(U_{Cr}P_{Na} \times 100)}$$

where P_{Cr} is the plasma creatinine level, P_{Na} is the plasma sodium level, U_{Cr} is the urinary creatinine level, and U_{Na} is the urinary sodium level. However, under conditions of normal GFR, Fe_{Na} is low, and generally the Fe_{Na} is useful only when oliguria is already present.[159] Fe_{Na} is affected by other factors, including, in particular, diuretic therapy. Some have proposed that the fractional excretion of urea can be useful in this context, with a fractional excretion of urea of <35% being consistent with prerenal azotemia, even in the setting of diuretic use.[159-161] However, a number of studies have not shown FE_{Urea} to be useful in distinguishing prerenal azotemia from ATN or transient versus persistent AKI.[162-164] Finally, Fe_{Na} may be low in the context of contrast nephropathy; therefore caution must be used when interpreting Fe_{Na} in this context.[165]

Urinalysis

Cells and cellular elements in the urine can provide important indications as to the cause of AKI. For example, dysmorphic red blood cells and red blood cell casts suggest a glomerulonephritis, whereas white blood cells and white blood cell casts suggest an interstitial nephritis. However, one must also consider nonglomerular causes for hematuria (urinary tract pathologic conditions including trauma or tumor) and pyuria (urinary tract infection, including pyelonephritis), if present. A urine test result that is positive for blood in the absence of red blood cells suggests the presence of free hemoglobin or myoglobin in the urine.

In contrast to hematuria and pyuria, the presence of renal tubular epithelial cells and granular or muddy brown casts are most suggestive of ATN, whereas hyaline casts may be consistent with a prerenal state or early ATN. Indeed, a simple scoring system that quantitates the number of renal tubular epithelial cells and granular casts has been proposed to differentiate ATN from prerenal azotemia with 76% sensitivity and 86% specificity.[166] Important caveats to this study include the fact that this was a single-institution study and all study participants underwent renal consultation and evaluation of urine microscopy by subspecialty consultants. Although additional studies are needed to validate the utility of such scoring systems for the diagnosis of AKI, these studies underscore the importance of the urine sediment in assessing the cause of AKI.

The presence of proteinuria on a routine dipstick examination may be normal, or it may suggest severe renal disease. In a concentrated urine sample, trace or 1+ proteinuria is a nonspecific finding, whereas 3+ or 4+ proteinuria suggests glomerular disease. The existence of glucosuria without hyperglycemia suggests proximal tubular damage.

Timed Clearance Measurements: Inulin, Iothalamate, and Others

Inulin, a polymer of fructose with a molecular mass of 5200 Da found in Jerusalem artichokes, dahlias, and chicory, has been used to measure GFR because it is filtered freely in the glomerulus, not reabsorbed or secreted, and is excreted in the urine. To assess inulin clearance, the clinician intravenously administers a priming dose of inulin, followed by a continuous infusion calculated to maintain constant blood concentrations. After an equilibration period (usually 1 hour), clearance measurements are obtained. Urine is collected (typically with a Foley catheter), and venous blood samples are obtained at the midpoint of each clearance period. The longer the clearance period, the less likely is the introduction of error from incomplete voiding. The standard formula for calculation of clearance is as follows:

$$C_I = (U_I V) \div P_I$$

where U_I and P_I are the urine and plasma concentrations of inulin, respectively, C_I is the rate of inulin clearance, and V is the urine flow rate. Other exogenously administered clearance markers include iohexol, iothalamate, and radiolabeled ethylenediaminetetraacetic acid (EDTA) and diethylenetriaminepentaacetic acid (DTPA); a detailed discussion of these markers and the pros and cons of measured and eGFR can be found in a recent review by Stevens and Levey.[132]

Renal Blood Flow

Although an extended period of renal artery clamping (e.g., 30 to 40 minutes) sufficient to cause blood flow to cease is also sufficient to cause ischemic AKI, it is simplistic to assume that moderate increases and decreases in RBF are good and bad for the kidney, respectively. Regional variations in perfusion result in a precarious balance between oxygen supply and demand in some renal tissues, particularly in the inner renal medulla. Notably, high levels of RBF also oblige high levels of oxygen demand to facilitate active transport of sodium and other solutes back into the circulation. Consequently, RBF is a very poor indicator of the adequacy of regional medullary perfusion and oxygen delivery. Furthermore, hypovolemia and AKI affect the distribution of RBF with renal arteriographic and xenon washout studies in patients with AKI showing a selected, profound reduction in RBF.[167] Thus clinically useful techniques to measure RBF must measure total RBF and the distribution of RBF; techniques include the clearance of para-aminohippurate, indicator dilution, renocortical tissue Po_2, radiolabeled tracers, Doppler ultrasonography, and external gas-washout techniques.[168] Owing to the risks and limitations associated with these techniques and the lack of clear utility of the diagnostic information, their clinical use has been limited.

However, if clinical utility could be demonstrated with the use of RBF measurements, then many noninvasive measures, including two-dimensional transesophageal echocardiography and renal arterial Doppler waveform images, primarily of the left kidney, could assess RBF to describe

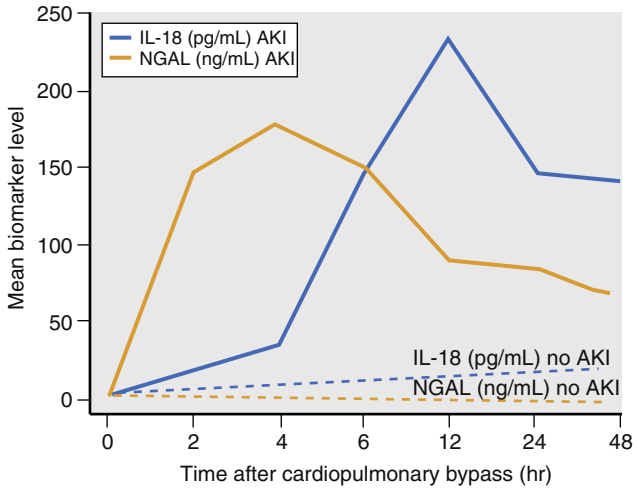

Figure 52-10. Pattern of early biomarkers for urinary interleukin (IL)-18 and neutrophil gelatinase–associated lipocalin (NGAL) after cardiopulmonary bypass (CPB) surgery in 55 patients with and without criteria for acute kidney injury (AKI) diagnosed 48 to 72 hours postoperatively (defined as a peak rise in serum creatinine concentration to >150% of baseline). *(From Parikh CR, Mishra J, Thiessen-Philbrook H, et al: Urinary IL-18 is an early predictive biomarker of acute kidney injury after cardiac surgery,* Kidney Int *70:199-203, 2006. Used with permission.)*

RBF changes qualitatively over time,[121] as well as contrast ultrasonography using sonicated microbubbles.[169] Finally, scintigraphic functional magnetic resonance imaging can characterize kidney physiologic abnormalities, including GFR, tubular concentration, transit, blood volume, perfusion, inflammation, and even tissue hypoxia, although this is likely to be impractical in the perioperative setting.[170,171]

NOVEL (EARLY) BIOMARKERS OF ACUTE KIDNEY INJURY

Limited progress in the care for AKI has fueled an enormous interest in new early biomarkers.[172-174] Although a few of the new tools represent attempts to find a substitute *ideal* creatinine-like substance to use in estimates of renal filtration (e.g., cystatin C), most markers take advantage of one of the three early consequences of AKI: (1) tubular cell damage, (2) tubular cell dysfunction, and (3) adaptive stress response of the kidney. The hope is that prompt biomarker information will allow timely AKI risk identification, surveillance (i.e., recognition of pre-AKI states such as prerenal azotemia), diagnosis, and prognosis. Some of the more promising biomarkers are presented in this text, including classes reflecting impaired renal filtration, tubular cell damage, tubular cell dysfunction, and adaptive responses of the kidney to stress (Box 52-3).

NEW FILTRATION-BASED MARKERS OF RENAL DYSFUNCTION

Of the most novel filtration-based markers of renal dysfunction, the most advanced is cystatin C, a member of the cystatin *superfamily* of cysteine-proteinase inhibitors that is produced by all nucleated cells at a constant rate. Cystatin C has been clinically available for longer than 15 years and can be rapidly determined. Similar to creatinine, cystatin C accumulates in the circulation with renal impairment and can be used as a marker of glomerular filtration. Urinary cystatin C has also been proposed as a marker of renal dysfunction; rather than as a marker of GFR, urinary cystatin C is due to proximal tubular injury and impaired metabolism. Serum cystatin C has theoretical advantages over creatinine, particularly as an indicator of mild chronic kidney disease and its sequelae.[175] Several GFR estimating equations have been proposed, based on cystatin C alone or cystatin C and creatinine,[176,177] but these are not in widespread use at present.

Although cystatin C outperformed creatinine in detecting AKI after cardiac surgery in some small studies,[178] this sensitivity has not consistently been the case (also see Chapter 67). Indeed, a recent large multicenter prospective observational study of AKI after cardiac surgery suggested that serum cystatin C was less, not more, sensitive for the detection of AKI. This study, conducted by the Translational Research Investigating Biomarker Endpoints in Acute Kidney Injury (TRIBE-AKI) Consortium, prospectively enrolled more than 1200 adults undergoing cardiac surgery and has rapidly advanced the field of novel biomarkers in this context. Of note, the subset of patients who

Liver fatty acid–binding protein
Insulinlike growth factor binding protein 7
Tissue inhibitor of metallo-proteinase 2

*New early biomarkers are being developed to provide information promptly to improve risk stratification, surveillance, diagnosis, and prognostic information concerning acute kidney injury.

had AKI by cystatin C and creatinine had more frequent risk of dialysis and death than those who had AKI by creatinine alone.[179] Conditions such as malignancy, human immunodeficiency viral infection, or corticosteroidal or thyroid hormone therapy are associated with increased serum levels without changes in renal function. Other novel markers of filtration include beta-trace protein and beta-2-microglobulin; these markers may be novel markers of mortality in the general population, compared with creatinine-based eGFR.[180] However, the additional utility of these markers in estimating GFR above and beyond creatinine and cystatin C is unknown.

BIOMARKERS REFLECTING RENAL TUBULAR CELL DAMAGE (TUBULAR ENZYMURIA)

Renal tubular cells contain enzymes that are highly specific to their location within the kidney and even tubule region. Under conditions of cellular stress, these enzymes are shed into the urine, making these potentially appealing markers of kidney dysfunction. These markers include α and π isomers of GST, which are cytosolic enzymes from proximal and distal tubular cells, respectively, and NAG, a proximal tubule lysosomal enzyme. General brush border injury is reflected by other markers including γ-glutamyl transpeptidase (γ-GT), alkaline phosphatase, and Ala-(Leu-Gly)-aminopeptidase. Of note, although enhanced urinary excretion of tubular enzymes can signal damaged tubular cells, it can also reflect an increased turnover of tubular cells or some other metabolic disturbance; thus the signals of early, irreversible disease may not always be distinguished from the noise of biologic variability, and the use of these markers should be applied with appropriate caution.

BIOMARKERS REFLECTING RENAL TUBULAR CELL DYSFUNCTION (TUBULAR PROTEINURIA)

When small proteins are filtered by the glomerulus, binding and endocytic reuptake in the proximal tubule normally returns these substances to the body through a megalin-mediated transport system. So-called tubular proteinuria results from functional impairment of this process and the escape of small proteins into the urine. Endogenous low–molecular-weight (LMW) proteins that are normally taken up in this way include β_2- and α_1-microglobulin, albumin, adenosine deaminase–binding protein, renal tubular epithelial antigen-1, retinol-binding protein, lysozyme, ribonuclease, IgG, transferrin, ceruloplasmin, lambda (λ) and kappa (κ) light chains, and urinary total protein. Appearance of any of these substances in the urine heralds abnormal proximal nephron function consistent with AKI. However, enthusiasm for LMW protein markers as perioperative tools to diagnose AKI has been reduced, particularly with cardiac surgery, by the confusion that can occur when an antifibrinolytic drug is used[181,182] (also see Chapter 67). Lysine and its analog (e.g., ε-aminocaproic acid, tranexamic acid) specifically block renal-binding sites, causing a profound but reversible inhibition of LMW protein reuptake[183] that is transient and apparently benign.

BIOMARKERS REFLECTING RENAL TUBULAR CELL RESPONSE TO STRESS

Examples of markers that assess the response of the kidney to stress include neutrophil gelatinase–associated lipocalin (NGAL), urinary IL-18, kidney injury molecule–1 (KIM-1), and liver fatty acid–binding protein (L-FABP). These have each been extensively reviewed in detail in recent literature.[172-174] Two markers of G1-cell cycle arrest have been shown to be upregulated in AKI.[184]

NGAL is a protein with a critical role in iron scavenging. A transcriptome-wide interrogation for genes induced very early after renal ischemia identified NGAL as a protein generated by ischemic renal tubular cells.[185] Administration of exogenous NGAL in animal models attenuates renal injury.[186] Enthusiasm for NGAL as a biomarker of AKI was fueled by a study in pediatric patients who underwent cardiac surgery, suggesting that plasma and urinary NGAL could predict AKI before elevations in serum creatinine[187] (Fig. 52-10). Although increased NGAL levels are associated with adverse outcomes,[188] studies in the adult perioperative literature have not consistently shown NGAL to predict AKI before elevations in serum creatinine. In a large biomarker study in the cardiac surgery field, the TRIBE-AKI consortium showed that plasma NGAL, not urinary NGAL, improved the prediction of a combined endpoint of dialysis and death over clinical risk factors, although the final model had only good discrimination, with an area under the receiver operating characteristic (ROC) curve of 0.75.[4] In the same study, plasma NGAL, not urinary NGAL, was also associated with subsequent AKI progression.[189]

Inflammation is a central aspect of the pathophysiologic processes of AKI. Cytokines and adhesion molecules mediate injury in the kidney, and levels of urinary cytokines such as IL-18 and platelet-activating factor have been assessed as early biomarkers of AKI. IL-18 is an inflammatory mediator of ischemic AKI in animals.[190] In human studies, a cross-sectional study comparing a variety of renal conditions with AKI found an increased urinary IL-18 level to be a good discriminator between patients with AKI and those with prerenal azotemia, urinary tract infections, chronic renal insufficiency, and nephrotic syndrome.[191] Similar to plasma NGAL, urinary IL-18 improved the prediction of adverse outcomes in the TRIBE-AKI study, with a modest improvement in the area under the ROC curve to 0.76, as well as AKI progression.[4,189] Other plasma and urinary cytokines, such as IL-6, are predictive of AKI, but not well developed.[192-194]

KIM-1 is a transmembrane protein expressed at low levels in a normal kidney that is significantly upregulated in proximal renal tubular cells in response to ischemic or nephrotoxic AKI.[195] In studies conducted by the Predictive Testing Safety Consortium, an academic-industrial partnership that has worked closely with the U.S. Food and Drug Administration (FDA) to develop novel biomarkers of kidney injury for use in the preclinical setting (in particular, as markers of drug toxicity), KIM-1 outperformed a number of traditional markers of kidney injury in a variety of preclinical models.[196] KIM-1 has also been associated with AKI in the TRIBE-AKI study.[196]

L-FABP is an intracellular protein that is shed by proximal tubule cells into the urine under conditions of cellular stress and has been proposed as a novel biomarker for both AKI and chronic kidney disease.[197] Studies in patients who are critically ill[198,199] and patients undergoing cardiac surgery[200,201] have suggested an association of L-FABP with AKI in both of these contexts; although, as for other biomarkers, it remains unclear how L-FABP will be clinically used to identify AKI before changes in serum creatinine are observed. One potential strategy may be to use a combination of clinical and biologic measures to identify patients at very high risk of AKI in the perioperative period, but more studies are needed.

Finally, cell cycle arrest has been implicated in models of AKI[202]; more recently, two proteins that induce cell cycle arrest, insulin-like growth factor–binding protein 7 and tissue inhibitor of metalloproteinases-2, have both been shown in a multicenter study to predict the development of KDIGO Stage 2 and 3 AKI in critically ill patients. In a validation cohort, these biomarkers had an impressive area under the ROC curve of 0.80 for subsequent AKI.[184] These two biomarkers are being actively developed for use in the clinical setting, although further studies are needed to confirm these findings and to determine the utility of these biomarkers in larger groups of patients at risk for AKI.

PREOPERATIVE EVALUATION OF RENAL FUNCTION

The greater the magnitude and duration of the surgical insult and the number of acute and chronic risk factors, the greater the likelihood of perioperative renal compromise and the need for preoperative identification of high-risk individuals (see Chapters 38 and 39). Common risk factors for AKI include intravascular volume depletion, aminoglycoside use, radiocontrast dye exposure, use of NSAIDs, septic shock, and pigmenturia. ACE inhibitors and ARBs, respectively, may contribute to intraoperative hypotension and may exacerbate AKI in the setting of impaired hemodynamics (volume depletion, NSAID use). Patients with preexisting renal insufficiency are clearly at increased risk for AKI and should be identified in the perioperative evaluation (also see Chapter 38). Chronic kidney disease affects more than 10% of the United States population. Common risk factors for chronic kidney disease include advanced age, diabetes, and hypertension. The potential value of understanding the genetic makeup of patients has yet to be fully explored and is likely to be important (see earlier discussion). Additional key determinants of postoperative renal function include maintenance of appropriate intravascular volume and normal myocardial function.[13]

Urinalysis provides qualitative information that must be cautiously interpreted (see "Laboratory Tests of Serum and Urine as Markers of Renal Function"). In particular, urinalysis can identify patients with chronic kidney disease with relatively preserved GFR but with significant proteinuria. Other urinary indices, if abnormal, may indicate urinary tract infection, urinary tract pathologic abnormality, or intrinsic kidney disease and must be interpreted in the clinical context of a given patient.

Serum creatinine levels offer rapid eGFR. The incidence and severity of AKI are usually more frequent when the preoperative serum creatinine level is more than 2 mg/dL[38]; however, an isolated serum creatinine measurement is an unreliable indicator of GFR when renal function is changing. The measurement of creatinine clearance may constitute the best overall indicator of GFR, although this index also has its limitations.

SUMMARY

In patients with or at risk for developing AKI, perioperative management continues to be challenging. Numerous factors contribute to the heterogeneous condition referred to as perioperative *AKI*, but insults collectively combine through ischemic and toxic mechanisms. The recent research efforts directed to the investigation of AKI will likely lead to rapid developments in the field of renal function monitoring, including early biomarker tests or panels of tests that aid in predicting risk factors, identifying patients with conditions that precede AKI, such as prerenal azotemia, and determining the diagnosis and prognosis of AKI. The major hope is that improvements in monitoring will translate into better prevention, treatment, and outcome from AKI, something that has been absent over the past half century since the problem of perioperative AKI was first described. Meanwhile, serum creatinine continues to be the mainstay of most renal function monitoring strategies.

Chapter 53

Neuromuscular Monitoring

JØRGEN VIBY-MOGENSEN • CASPER CLAUDIUS

Key Points

- Good evidence-based practice dictates that clinicians always quantitate the extent of neuromuscular block by objective monitoring.
- The neuromuscular block should be adjusted to ensure optimal surgical conditions. In most procedures, one or two responses to train-of-four (TOF) stimulation will suffice.
- Adequate recovery of postoperative neuromuscular function cannot be guaranteed without objective neuromuscular monitoring.
- Objective neuromuscular monitoring is essential for management of neuromuscular blockade intraoperatively and its reversal for postoperative care. Muscle relaxants should not be given in the intensive care unit (see Chapters 34, 35, and 101) without proper monitoring.
- It is impossible to exclude with certainty clinically significant residual neuromuscular block by clinical evaluation of recovery of neuromuscular function.
- Residual postoperative neuromuscular block causes decreased chemoreceptor sensitivity to hypoxia, functional impairment of the pharyngeal and upper esophageal muscles, impaired ability to maintain an open upper airway, and an increased risk of hypoxemic events, as well as the development of postoperative pulmonary complications.
- Absence of tactile fade in the response to TOF stimulation, tetanic stimulation, and double-burst stimulation does not exclude significant residual block.
- To exclude clinically significant residual neuromuscular block, the TOF ratio must exceed 0.9 when measured mechanically or electromyographically and 1.0 when measured acceleromyographically.
- Antagonism of the neuromuscular block with a cholinesterase inhibitor should not be initiated before at least two to four responses to TOF stimulation are observed.
- Antagonism of the neuromuscular block achieved by rocuronium and vecuronium can be initiated at all levels of block with the selective relaxant binding agent, sugammadex.
- If sufficient recovery (TOF ≥ 0.9-1.0) has not been documented objectively at the end of the surgical procedure, the neuromuscular block should be antagonized with neostigmine or sugammadex. Minority opinion is that even with a TOF greater than 0.9, neostigmine or sugammadex should still be given.

Clinically significant residual neuromuscular block (i.e., paralysis) cannot be excluded using clinical criteria only and can persist postoperatively.[1,2] Objective monitoring of the degree of neuromuscular block during and after anesthesia reduces the incidence of residual neuromuscular block and should be part of standard monitoring equipment.[3-9]

In awake patients, muscle power can be evaluated by tests of voluntary muscle strength, but this is impossible during anesthesia and recovery from anesthesia. Instead, the clinician must use clinical tests to assess muscle power directly and to estimate neuromuscular function indirectly (muscle tone; feel of the anesthesia bag as an indirect measure of pulmonary compliance, tidal volume, and inspiratory force). All these tests, however, are influenced by factors other than the degree of neuromuscular block; therefore, whenever more precise information regarding the status of neuromuscular functioning is desired, the response of muscle to nerve stimulation should be assessed. This procedure also takes into account the considerable variation in individual response and sensitivity to muscle relaxants.

This chapter reviews the basic principles of neuromuscular monitoring and the requirements for effective use of nerve stimulators for peripheral nerve stimulation. It also describes the response to nerve stimulation

during depolarizing (phase I and phase II) and nondepolarizing neuromuscular block. Finally, methods of evaluating evoked neuromuscular responses with and without the availability of recording equipment are discussed.

TYPES OF PERIPHERAL NERVE STIMULATION

Neuromuscular function is monitored by evaluating the muscular response to supramaximal stimulation of a peripheral motor nerve. Two types of stimulation can be used: electrical and magnetic. Electrical nerve stimulation is by far the most commonly used method in clinical practice, and it is described in detail in this chapter. In theory, magnetic nerve stimulation has several advantages over electrical nerve stimulation.[10,11] It is less painful and does not require physical contact with the body; however, the equipment required is bulky and heavy, it cannot be used for train-of-four (TOF) stimulation, and it is difficult to achieve supramaximal stimulation with this method. As a result, magnetic nerve stimulation is seldom used in clinical anesthesia.

PRINCIPLES OF PERIPHERAL NERVE STIMULATION

Whatever method is used for neuromuscular monitoring, the clinician must be familiar with the two terms, supramaximal stimulation and calibration.

SUPRAMAXIMAL STIMULATION

The reaction of a single muscle fiber to a stimulus follows an all-or-none pattern. In contrast, the response (the force of contraction) of the whole muscle depends on the number of muscle fibers activated. If a nerve is stimulated with sufficient intensity, all fibers supplied by the nerve will react, and the maximum response will be triggered. After administration of a neuromuscular blocking drug, the response of the muscle decreases in parallel with the number of fibers blocked. The reduction in response during constant stimulation reflects the degree of neuromuscular block.

For the preceding principles to be in effect, the stimulus must be truly maximal throughout the period of monitoring; therefore, the electrical stimulus applied is usually at least 15% to 20% greater than that necessary for a maximal response. For this reason, the stimulus is said to be supramaximal; however, supramaximal electrical stimulation can be painful, which is not a concern during anesthesia, but during recovery the patient may be awake enough to experience the discomfort of nerve stimulation. Therefore, some researchers advocate stimulation with submaximal current during recovery. Although several investigations indicate that testing of neuromuscular function can be reliably performed postoperatively with submaximal stimulation,[12,13] the accuracy of such monitoring is unacceptable with low current.[14]

CALIBRATION

A device used for objective monitoring of the neuromuscular function should be calibrated before the neuromuscular blocking drug is administered. Calibration adjusts the gain of the device to ensure that the observed response to supramaximal stimulation is within the measurement window of the device and as close as possible to the "100% control response." The calibration procedure varies with the type of device used, but most often it is done with 1.0 Hz single-twitch stimulation. It is especially important to calibrate when the onset and recovery of the neuromuscular block is established with single-twitch stimulation.

In the TOF mode of nerve stimulation, calibration is considered less important because all four responses are amplified equally. Consequently, the TOF ratio is rarely influenced by calibration; however, in patients with very weak or strong responses to nerve stimulation, one or more responses to TOF stimulation might be out of the recording window, and the displayed TOF response might be incorrect. In some devices, supramaximal stimulation is established concurrently with the calibration procedure.

PATTERNS OF NERVE STIMULATION

For evaluation of neuromuscular function, the most commonly used patterns of electrical nerve stimulation are single-twitch, TOF, and tetanic. Other patterns, such as posttetanic count (PTC) and double-burst stimulation (DBS) can be valuable in certain clinical situations that are described later.

SINGLE-TWITCH STIMULATION

In the single-twitch mode of stimulation, single supramaximal electrical stimuli are applied to a peripheral motor nerve at frequencies ranging from 1.0 Hz (once every second) to 0.1 Hz (once every 10 seconds; Fig. 53-1). The response to single-twitch stimulation depends on the frequency at which the individual stimuli are applied. If the rate of delivery is increased to greater than 0.15 Hz, the evoked response will gradually decrease and stabilize at a lower level. As a result, a frequency of 0.1 Hz is generally used. Because 1-Hz stimulation shortens the time necessary to determine supramaximal stimulation, this frequency is sometimes used during induction of anesthesia; however, the apparent time of onset and length of neuromuscular block depend on the pattern and duration of stimulation. Therefore, results obtained with 1-Hz single-twitch stimulation cannot be compared with results obtained using, for example, 0.1-Hz single-twitch stimulation or TOF stimulation.[15]

TRAIN-OF-FOUR STIMULATION

Train-of-four nerve stimulation pattern, as introduced by Ali and associates[16,17] during the early 1970s, consists of four supramaximal stimuli given every 0.5 seconds (2 Hz; Fig. 53-2). When used continuously, each set (train) of

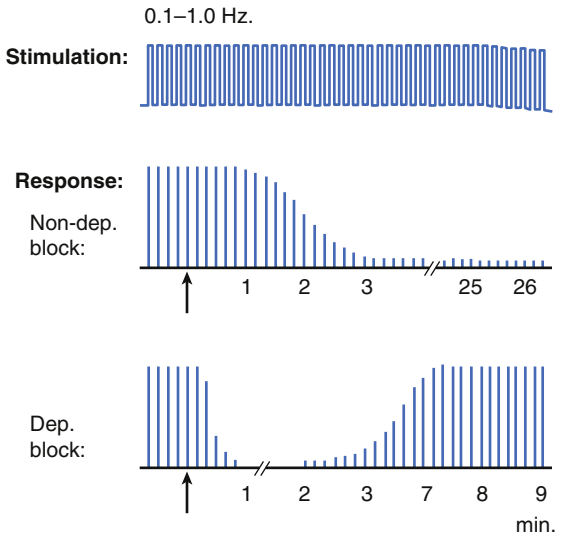

Figure 53-1. Pattern of electrical stimulation and evoked muscle responses to single-twitch nerve stimulation (at frequencies of 0.1 to 1.0 Hz) after injection of nondepolarizing (Non-dep.) and depolarizing (Dep.) neuromuscular blocking drugs (*arrows*). Note that except for the difference in time factors, no differences in the strength of the evoked responses exist between the two types of block.

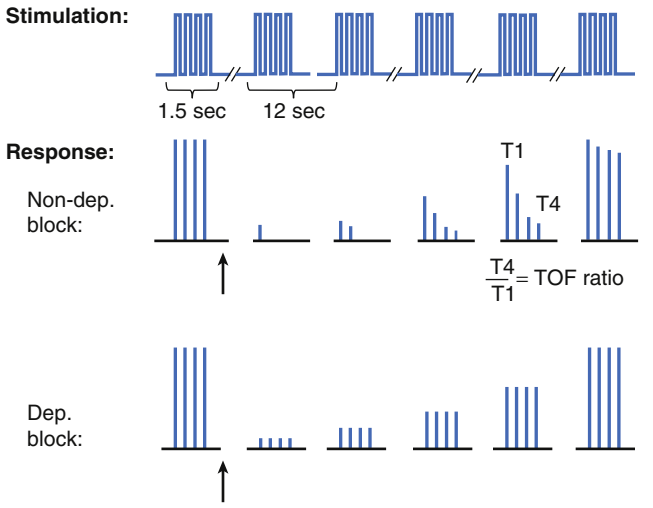

Figure 53-2. Pattern of electrical stimulation and evoked muscle responses to train-of-four (TOF) nerve stimulation before and after injection of nondepolarizing (Non-dep.) and depolarizing (Dep.) neuromuscular blocking drugs (*arrows*).

four stimuli is typically repeated every tenth to twentieth second. Each stimulus in the train causes the muscle to contract, and the "fade" in the train of responses provides the basis for evaluation; that is, dividing the amplitude of the fourth response by the amplitude of the first response provides the TOF ratio. In the control response (the response obtained before the administration of a muscle relaxant), all four responses are ideally the same: the TOF ratio is 1.0. During a partial nondepolarizing block, the ratio decreases (fades) and is inversely proportional to the degree of block. During a partial depolarizing block, no fade occurs in the TOF response; ideally, the TOF ratio is approximately 1.0. Fade in the TOF response after injection of succinylcholine signifies the development of a phase II block (discussed later in the section on depolarizing neuromuscular block).

The advantages of TOF stimulation are most apparent during a nondepolarizing neuromuscular block because the degree of block can be read directly from the TOF response even though a preoperative value is lacking. In addition, TOF stimulation has some advantages over double-burst stimulation and tetanic stimulation; it is less painful and, unlike tetanic stimulation, does not generally influence subsequent monitoring of the degree of neuromuscular block.

TETANIC STIMULATION

Tetanic stimulation consists of high-frequency delivery of electrical stimuli (e.g., 30, 50, or 100 Hz). The most commonly used pattern in clinical practice is 50-Hz stimulation given for 5 seconds, although some investigators have advocated the use of 50-, 100-, and even 200-Hz stimulation for 1 second. In normal neuromuscular transmission or during a depolarizing block, the muscle response to 50-Hz tetanic stimulation for 5 seconds is

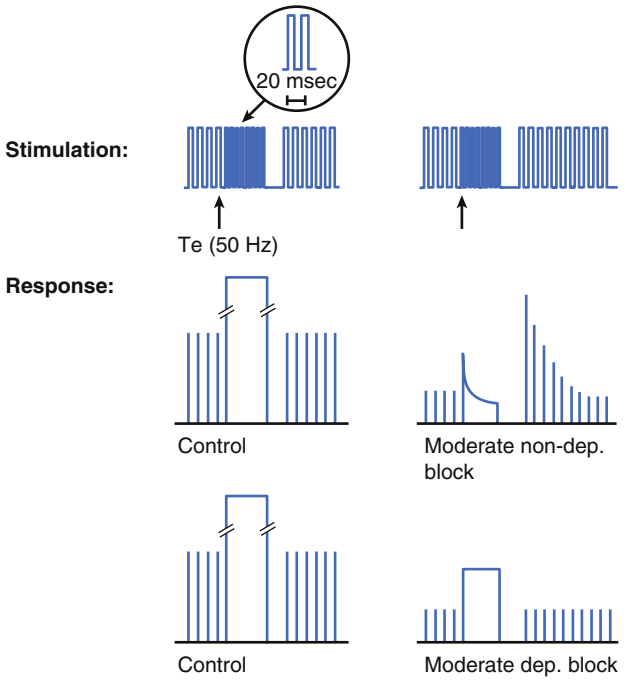

Figure 53-3. Pattern of stimulation and evoked muscle responses to tetanic (50 Hz) nerve stimulation for 5 seconds (Te) and posttetanic twitch stimulation (1.0 Hz; *arrows*). Stimulation was applied before the injection of neuromuscular blocking drugs and during moderate nondepolarizing (non-dep.) and depolarizing (dep.) blocks. Note the fade in the response to tetanic stimulation, plus the posttetanic facilitation of transmission during nondepolarizing block. During depolarizing block, the tetanic response is well sustained, and no posttetanic facilitation of transmission occurs.

sustained. On the other hand, during a nondepolarizing block and a phase II block after the injection of succinylcholine, the response is not sustained (i.e., fade occurs; Fig. 53-3).

Fade in response to tetanic stimulation is normally considered a presynaptic event (see Chapter 18); the traditional explanation is that at the start of tetanic

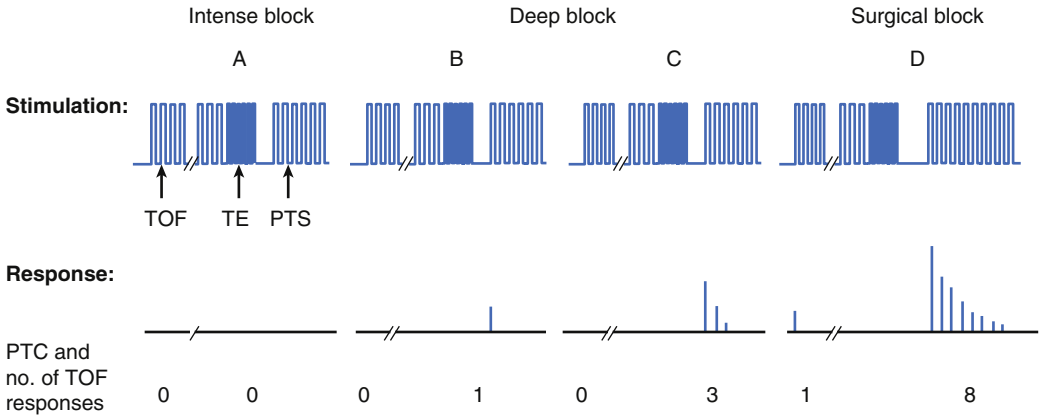

Figure 53-4. Pattern of electrical stimulation and evoked muscle responses to train-of-four (TOF) nerve stimulation, 50-Hz tetanic nerve stimulation for 5 seconds (TE), and 1.0-Hz posttetanic twitch stimulation (PTS) during four different levels of nondepolarizing neuromuscular block. During intense block of peripheral muscles (**A**), no response to any of the forms of stimulation occurs. During less pronounced block (deep block, **B** and **C**), there is still no response to TOF stimulation, but posttetanic facilitation of transmission is present. During surgical block (**D**), the first response to TOF appears and posttetanic facilitation increases further. The posttetanic count (see text) is 1 during very deep block (**B**), 3 during less deep block (**C**), and 8 during surgical (or moderate) block (**D**).

stimulation, large amounts of acetylcholine are released from immediately available stores in the nerve terminal. As these stores become depleted, the rate of acetylcholine release decreases until equilibrium between mobilization and synthesis of acetylcholine is achieved. Despite this equilibrium, the muscle response to tetanic nerve stimulation is maintained (given normal neuromuscular transmission) because the acetylcholine released is many times greater than the amount necessary to evoke a response. When the "margin of safety"[18] at the postsynaptic membrane (i.e., the number of free cholinergic receptors) is reduced by nondepolarizing neuromuscular blocking drugs, a typical reduction in twitch height is seen with a fade during, for example, repetitive stimulation. In addition to this postsynaptic block, nondepolarizing neuromuscular blocking drugs can also block presynaptic neuronal subtype acetylcholine receptors, thereby leading to impaired mobilization of acetylcholine within the nerve terminal (see Chapter 18).[19] This effect substantially contributes to fade in the response to tetanic (and TOF) stimulation. Although the degree of fade depends primarily on the degree of neuromuscular block, fade also depends on the frequency (Hz), the length (seconds) of stimulation, and on how often tetanic stimuli are applied. Unless these variables are kept constant, results from different studies using tetanic stimulation cannot be compared.

During partial nondepolarizing block, tetanic nerve stimulation is followed by a posttetanic, slight increase in twitch tension called *posttetanic facilitation* (see Fig. 53-3). This event occurs because the increase in mobilization and synthesis of acetylcholine caused by tetanic stimulation continues for some time after discontinuation of stimulation. The degree and duration of posttetanic facilitation depend on the degree of neuromuscular block, with posttetanic facilitation usually disappearing within 60 seconds of tetanic stimulation. Posttetanic facilitation is evident in electromyographic, kinemyographic, acceleromyographic, and mechanomyographic recordings during partial nondepolarizing neuromuscular block. In contrast, posttetanic twitch potentiation, which sometimes occurs in mechanical recordings before any neuromuscular blocking drug has been given, is a muscular phenomenon that is not accompanied by an increase in the compound muscle action potential.

Tetanic stimulation is extremely painful, which limits its use in unanesthetized patients. Furthermore, especially in the late phase of neuromuscular recovery, tetanic stimulation can produce lasting antagonism of neuromuscular block in the stimulated muscle such that the response of the tested site may no longer be representative of other muscle groups.[20] Traditionally, tetanic stimulation is used to evaluate residual neuromuscular block. Except in connection with the technique of PTC, tetanic stimulation has little use in everyday clinical anesthesia. If the response to nerve stimulation is recorded, all the information required can be obtained from the response to TOF nerve stimulation. In contrast, if the response to nerve stimulation is evaluated only visually or by tactile evaluation,[21,22] even experienced observers are unable to judge the response of tetanic stimulation with sufficient certainty to exclude residual neuromuscular block.

POSTTETANIC COUNT STIMULATION

Injection of a nondepolarizing neuromuscular blocking drug in a dose sufficient to ensure smooth tracheal intubation causes intense neuromuscular block of peripheral muscles. Because there is no response to TOF and single-twitch stimulation under these conditions, these modes of stimulation cannot be used to determine the degree of block. However, an intense neuromuscular block of the peripheral muscles can be monitored by applying tetanic stimulation (50 Hz for 5 seconds) and observing the posttetanic response to single-twitch stimulation given at 1 Hz starting 3 seconds after the end of tetanic stimulation.[23] During intense block, there is no response to either tetanic or posttetanic stimulation (Fig. 53-4). As the period of very intense

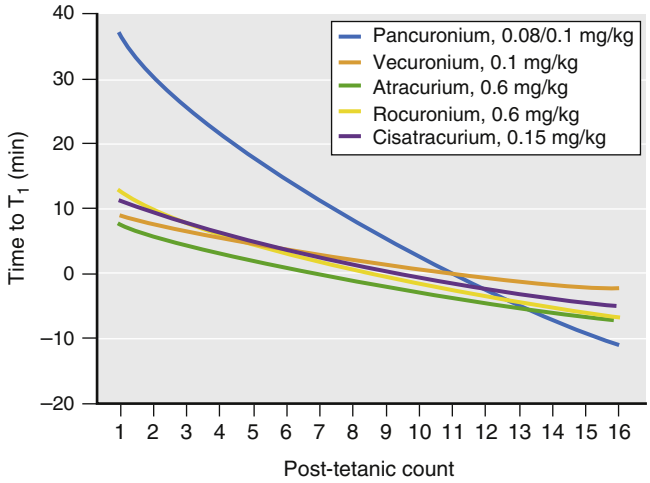

Figure 53-5. Relationship between the posttetanic count and time when onset of train-of-four (T_1) is likely to be elicited for various neuromuscular blocking agents. *(From El-Orbany MI, Joseph JN, Salem MR: The relationship of post-tetanic count and train-of-four responses during recovery from intense cisatracurium-induced neuromuscular block,* Anesth Analg *97:80, 2003.)*

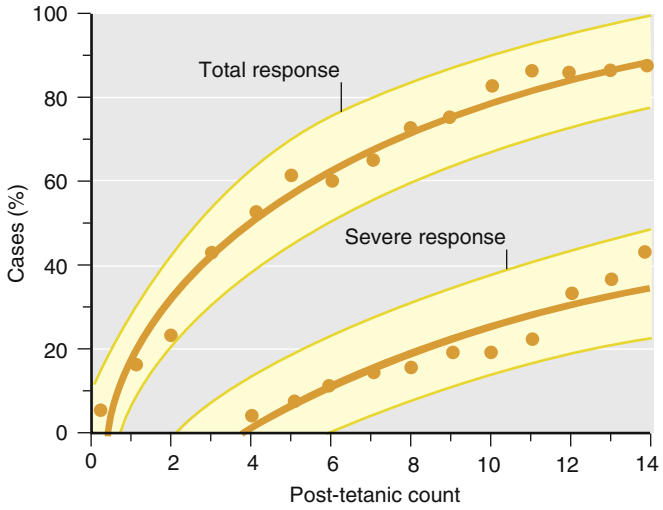

Figure 53-6. Relationship between the rate of muscle response to stimulation of the tracheal carina and the degree of neuromuscular block of peripheral muscles, as evaluated by posttetanic count (PTC). The subjects were 25 patients who were anesthetized with thiopental, nitrous oxide, and fentanyl and given vecuronium (0.1 mg/kg) for tracheal intubation. For comparison, the first response to train-of-four stimulation usually occurs when the PTC is approximately 10 (range, 6 to 16). The carina was stimulated with a soft sterile rubber suction catheter introduced via the endotracheal tube. The total response consisted of mild responses plus severe responses. A mild response was said to occur if stimulation of the carina induced only slight bucking that did not interfere with surgery. A severe response was said to occur if stimulation elicited bucking that interfered with surgery and required intervention. Elimination of severe responses requires an intense neuromuscular block; PTC must be less than 2 to 3, and elimination of all reactions requires that PTC be 0. *(From Fernando PUE, et al: Relationship between post-tetanic count and response to carinal stimulation during vecuronium-induced neuromuscular block.* Acta Anaesthesiol Scand *31:593, 1987. Copyright 1987, Munksgaard International Publishers, Ltd. Copenhagen, Denmark.)*

neuromuscular block dissipates, the first response to posttetanic twitch stimulation occurs and is followed by a gradual return of posttetanic twitches until the first response to TOF stimulation reappears. For a given neuromuscular blocking drug, the time until return of the first response to TOF stimulation is related to the number of posttetanic twitch responses present at a given time (i.e., the PTC; Fig. 53-5).[23-27]

The PTC method is mainly used to assess the degree of neuromuscular block when there is no reaction to single-twitch or TOF nerve stimulation. However, PTC can also be used whenever sudden movements must be eliminated (e.g., during surgery in the airways or ophthalmic surgery). A specific clinical example of the value of PTC occurs in ophthalmic surgery (see Chapter 84). The necessary level of block at the adductor pollicis muscle to ensure paralysis of the diaphragm depends on the type of anesthesia. To ensure elimination of any bucking or coughing in response to tracheobronchial stimulation, a neuromuscular block must be intense (i.e., no response to TOF or PTC stimulation) (Fig. 53-6).[24-28]

When using the new selective relaxant binding drug, sugammadex for reversing a rocuronium-induced or vecuronium-induced deep or intense block (discussed later), the necessary dose of sugammadex depends on the level of block (see Chapter 35). In this situation, PTC can be used to quantitate the degree of block.

The response to PTC stimulation depends primarily on the degree of neuromuscular block. It also depends on the frequency and duration of tetanic stimulation, the length of time between the end of tetanic stimulation and the first posttetanic stimulus, the frequency of the single-twitch stimulation, and probably the duration of single-twitch stimulation before tetanic stimulation. When the PTC method is used, these variables should be kept constant. In addition, because of interference between PTC stimulation and the actual neuromuscular block within the monitored hand, tetanic stimulation should ideally not be performed more often than every 6 minutes.[23]

DOUBLE-BURST STIMULATION

DBS consists of two short bursts of 50-Hz tetanic stimulation separated by 750 msec, with a 0.2-msec duration of each square wave impulse in the burst (Fig. 53-7). Although the number of impulses in each burst can vary, DBS with three impulses in each of the two tetanic bursts ($DBS_{3,3}$) is most commonly used.[29-31]

In nonparalyzed muscle, the response to $DBS_{3,3}$ is two short muscle contractions of equal strength. In a partially paralyzed muscle, the second response is weaker than the first and corresponds to the typical TOF fade (see Fig 53-7). When measured mechanically, the TOF ratio correlates closely with the $DBS_{3,3}$ ratio. DBS was developed with the specific aim of improving manual (tactile) detection of residual block under clinical conditions,[30] or during recovery and immediately after surgery; tactile evaluation of the response to $DBS_{3,3}$ is superior to tactile evaluation of the response to TOF stimulation.[31,32] However, as shown in Figure 53-8, absence of fade in the manually evaluated response to $DBS_{3,3}$ (and TOF) does

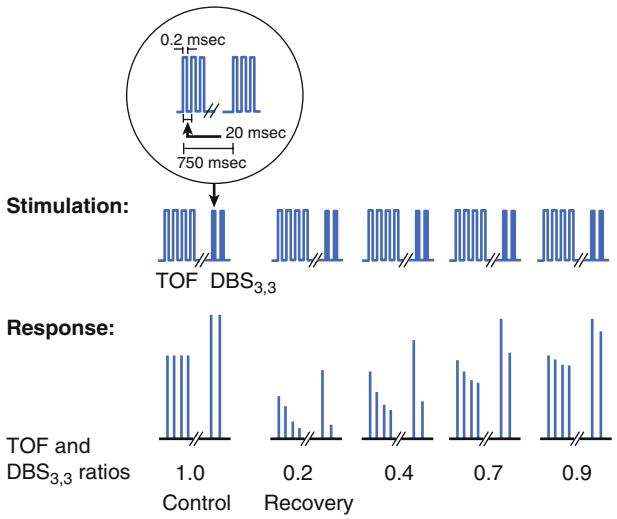

Figure 53-7. Pattern of electrical stimulation and evoked muscle responses to train-of-four (TOF) nerve stimulation and double-burst nerve stimulation (i.e., three impulses in each of two tetanic bursts, $DBS_{3,3}$) before injection of muscle relaxants (control) and during recovery from nondepolarizing neuromuscular block. The TOF ratio is the amplitude of the fourth response to TOF divided by the amplitude of the first response. The $DBS_{3,3}$ ratio is the amplitude of the second response to $DBS_{3,3}$ divided by the amplitude of the first response. (See text for further explanation.)

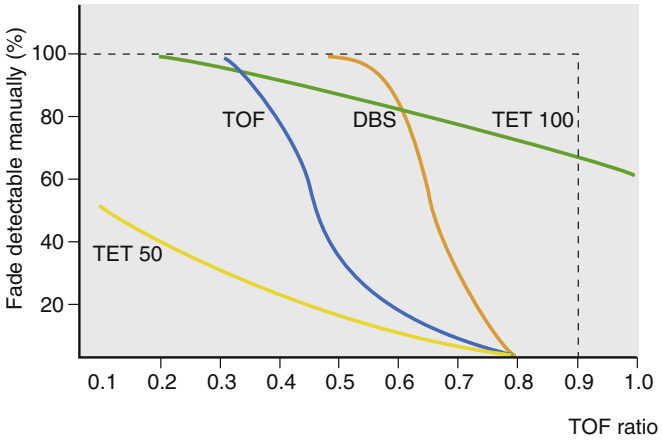

Figure 53-8. Fade detectable by feel in the response to train-of-four (TOF), double-burst stimulation ($DBS_{3,3}$), and 50- and 100-Hz tetanic stimulation (TET 50 and TET 100) in relation to the true TOF ratio, as measured mechanically. The axis indicates the percentage of instances in which fade can be detected at a given TOF ratio.[22,29,31] It appears that it is not possible to exclude residual neuromuscular block by any of the methods. (See text for further explanation.)

not exclude residual neuromuscular block.[33] Accordingly, $DBS_{3,3}$ cannot replace objective monitoring. On the other hand, when objective monitoring is not possible, residual neuromuscular block corresponding to a TOF less than 0.6 or lower can be detected using this method.

THE NERVE STIMULATOR

Although many nerve stimulators are commercially available, not all meet the basic requirements for clinical use. The stimulus should produce a monophasic and rectangular waveform, and the length of the pulse should not exceed 0.2 to 0.3 msec. A pulse exceeding 0.5 msec may stimulate the muscle directly or cause repetitive firing. Stimulation at a constant current is preferable to stimulation at a constant voltage because current is the determinant of nerve stimulation. Furthermore, for safety reasons, the nerve stimulator should be battery operated, include a battery check, and be able to generate 60 to 70 mA, but not more than 80 mA. Many commercially available stimulators can deliver just 25 to 50 mA and provide a constant current only when skin resistance ranges from 0 to 2.5 kΩ. These limitations are a disadvantage; during cooling, skin resistance can increase to approximately 5 kΩ, which can cause the current delivered to the nerve to decrease below the supramaximal level and lead to a decrease in the response to stimulation and possible misjudgment in the degree of block used. Ideally, the nerve stimulator should have a built-in warning system or a current level display that alerts the user when the selected current is not delivered to the nerve. The polarity of the electrodes should be indicated, and the apparatus should be capable of delivering the following modes of stimulation: TOF (as both a single train and in a repetitive mode, with TOF stimulation being given every 10 to 20 seconds), single-twitch stimulation at 0.1 and 1.0 Hz, and tetanic stimulation at 50 Hz. In addition, the stimulator should have a built-in time constant system to facilitate PTC. The tetanic stimulus should last 5 seconds and be followed 3 seconds later by the first posttetanic stimulus. If the nerve stimulator does not allow objective measurement of the response to TOF stimulation, at least one DBS mode should be available, preferably $DBS_{3,3}$. Single-twitch, 1-Hz stimulation is particularly useful in assessing the level of supramaximal stimulation. Tetanus at 100 or 200 Hz is rarely indicated because 50-Hz tetanic stimulation is similar to maximal voluntary muscle contraction. Furthermore, in contrast to 100- and 200-Hz stimulation, 50-Hz tetanic stimulation does not cause fatigue (fade) in nonparalyzed muscle.

STIMULATING ELECTRODES

Electrical impulses are transmitted from stimulator to nerve by means of surface or needle electrodes, the former being the more commonly used in clinical anesthesia. Normally, disposable pregelled silver or silver chloride surface electrodes are used. The actual conducting area should be small, approximately 7 to 11 mm in diameter (Fig. 53-9). Otherwise, the current produced in the underlying nerve may not be adequate.[34] The skin should always be cleansed properly and preferably rubbed with an abrasive before application of the electrodes. When a supramaximal response cannot be obtained with surface electrodes, needle electrodes can be used in a few exceptional cases. Although specially coated needle electrodes are commercially available, ordinary steel injection needles often suffice. A sterile technique should be used, and the needles should be placed subcutaneously to avoid direct injury to the underlying nerve.

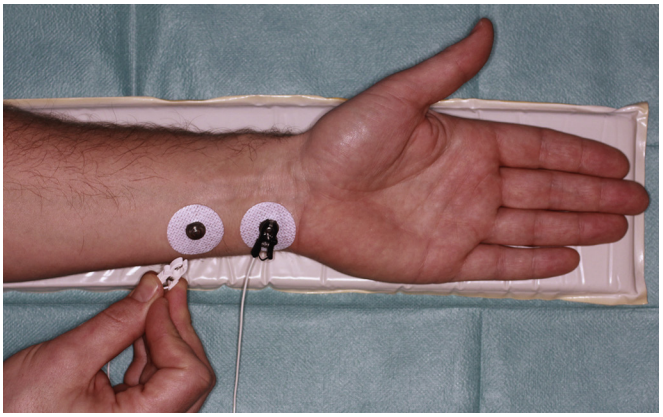

Figure 53-9. Stimulating electrodes with the appropriate contact area in the correct position over the ulnar nerve of the left forearm.

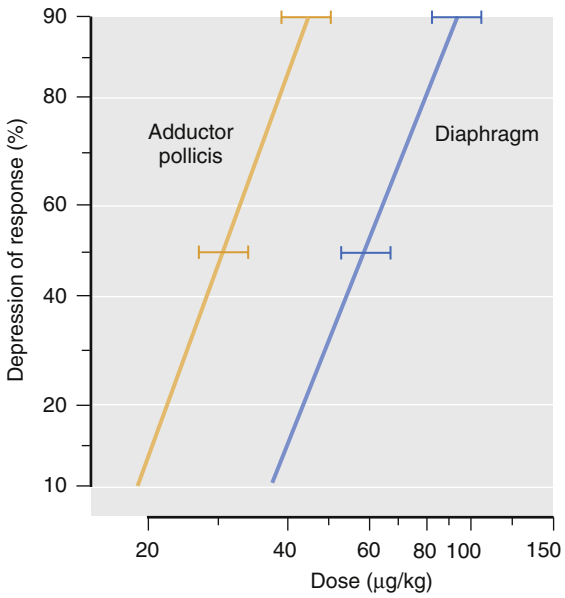

Figure 53-10. The mean cumulative dose-response curve for pancuronium in two muscles shows that the diaphragm requires approximately twice as much pancuronium as the adductor pollicis muscle for the same amount of neuromuscular block. The depression in muscle response to the first stimulus in train-of-four nerve stimulation (probit scale) was plotted against dose (log scale). The force of contraction of the adductor pollicis was measured on a force-displacement transducer; response of the diaphragm was measured electromyographically. *(From Donati F, Antzaka C, Bevan DR: Potency of pancuronium at the diaphragm and the adductor pollicis muscle in humans,* Anesthesiology *65:1, 1986.)*

SITES OF NERVE STIMULATION AND DIFFERENT MUSCLE RESPONSES

In principle, any superficially located peripheral motor nerve can be stimulated. In clinical anesthesia, the ulnar nerve is the most popular site; the median, posterior tibial, common peroneal, and facial nerves are also sometimes used. For stimulation of the ulnar nerve, the electrodes are best applied to the volar side of the wrist (see Fig. 53-9). The distal electrode should be placed approximately 1 cm proximal to the point at which the proximal flexion crease of the wrist crosses the radial side of the tendon to the flexor carpi ulnaris muscle. The proximal electrode should preferably be placed so that the distance between the centers of the two electrodes is 3 to 6 cm (see Fig. 53-9). With this placement of the electrodes, electrical stimulation normally elicits only finger flexion and thumb adduction. If one electrode is placed over the ulnar groove at the elbow, thumb adduction is often pronounced because of stimulation of the flexor carpi ulnaris muscle. When this latter placement of electrodes (sometimes preferred in small children) is used, the active negative electrode should be at the wrist to ensure maximal response. Polarity of the electrodes is less crucial when both electrodes are close to each other at the volar side of the wrist; however, placement of the negative electrode distally normally elicits the greatest neuromuscular response.[35] When the temporal branch of the facial nerve is stimulated, the negative electrode should be placed over the nerve, and the positive electrode should be placed somewhere else over the forehead.

Because different muscle groups have different sensitivities to neuromuscular blocking drugs, results obtained for one muscle cannot be automatically extrapolated to other muscles. The diaphragm is among the most resistant of all muscles to both depolarizing[36] and nondepolarizing neuromuscular blocking drugs.[37] In general, the diaphragm requires 1.4- to 2.0-fold as much muscle relaxant as the adductor pollicis muscle for an identical degree of block (Fig. 53-10).[37] Also of clinical significance is that onset time is normally shorter for the diaphragm than for the adductor pollicis muscle, and the diaphragm recovers from paralysis more quickly than the peripheral muscles (Fig. 53-11).[38] The other respiratory muscles are less resistant than the diaphragm, as are the larynx and the corrugator supercilii muscles.[39-41] Most sensitive are the abdominal muscles, the orbicularis oculi muscle, the peripheral muscles of the limbs, and the geniohyoid, masseter, and upper airway muscles.[42-45] From a clinical point of view, the response of the corrugator supercilii to facial nerve stimulation reflects the extent of neuromuscular block of the laryngeal adductor muscles and abdominal muscles better than the response of the adductor pollicis to ulnar nerve stimulation.[41,46] Furthermore, the upper airway muscles seem to be more sensitive than the peripheral muscles.[42,43] Although some investigations using acceleromyography have indicated small differences in the response to TOF nerve stimulation in the hand (adductor pollicis muscle) compared to the leg (flexor hallucis brevis muscle), these differences are probably of little clinical significance.[47,48] When comparing different sites of stimulation, there might be large differences between contralateral limbs (e.g., arm-to-arm variation of ± 20%).[49,50]

Although the precise source of these differences is unknown, possible explanations may be variations in acetylcholine receptor density, acetylcholine release, acetylcholinesterase activity, fiber composition, innervation ratio (number of neuromuscular junctions), blood flow, and muscle temperature.

Evolution of twitch height (mean ± SD) of the diaphragm (*blue circles*) and the adductor pollicis muscle (*yellow circles*) in 10 anesthetized patients after the administration of atracurium (0.6 mg/kg). *(From Pansard J-L, Chauvin M, Lebrault C, et al: Effect of an intubating dose of succinylcholine and atracurium on the diaphragm and the adductor pollicis muscle in humans,* Anesthesiology *67:326, 1987.)*

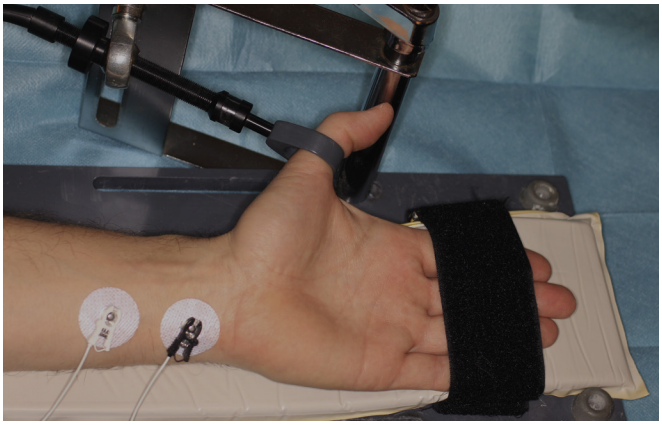

Figure 53-12. The setup for mechanomyography. The response to nerve stimulation is measured using a force transducer (TD-100; Biometer, Odense, Denmark) placed at the proximal phalanx of the thumb.

RECORDING OF EVOKED RESPONSES

Five methods are available for clinical monitoring of neuromuscular function: evoked mechanical response of the muscle (mechanomyography [MMG]), evoked electrical response of the muscle (electromyography [EMG]), acceleration of the muscle response (acceleromyography [AMG]), evoked electrical response in a piezoelectric film sensor attached to the muscle (kinemyography [KMG]) and measurement of low-frequency sounds evoked by the muscle contraction (phonomyography [PMG]). The five methods are described below. For further information on recording evoked responses, the reader is referred to guidelines for good clinical research practice in pharmacodynamic studies of neuromuscular blocking drugs.[34] The only objective monitors currently available are based on AMG, EMG, and KMG. The use of computer-guided administration of neuromuscular blocking drugs and "closed loop control" systems has been suggested, but no systems are commercially available.[51,52]

MECHANOMYOGRAPHY

For correct and reproducible measurement of evoked tension, the muscle contraction needs to be isometric. In clinical anesthesia, this condition is most easily achieved by measuring the force of contraction of the thumb after the application of a resting tension of 200 to 300 g (a preload) to the thumb. When the ulnar nerve is stimulated, the thumb (the adductor pollicis muscle) acts on a force-displacement transducer (Fig. 53-12). The force of contraction is then converted into an electrical signal, which is amplified, displayed, and recorded. The arm and hand should be rigidly fixed, and care should be taken to prevent overloading of the transducer. In addition, the transducer should be placed in correct relation to the thumb (i.e., the thumb should always apply tension along the length of the transducer). It is important to remember that the response to nerve stimulation depends on the frequency with which the individual stimuli are applied and that the time used to achieve a stable control response may influence subsequent determination of the onset time and duration of block.[34] Generally, the reaction to supramaximal stimulation increases during the first 8 to 12 minutes after commencement of the stimulation (staircase phenomenon). Therefore, in clinical studies, recording of the control response (before injection of muscle relaxant) should not be made until the response has stabilized for 8 to 12 minutes or a 2- or 5-second 50-Hz tetanic stimulation has been given.[53] Even then, twitch response often recovers to 110% to 150% of the control response after paralysis with succinylcholine. This increase in response, possibly caused by a change in the contractile response of the muscle, normally disappears within 15 to 25 minutes.

Although there are numerous methods for mechanical recording of evoked mechanical responses, not all meet the criteria outlined. Mechanomyography is recognized as the gold standard of neuromuscular monitoring.[34] Despite this status, there is no commercially available neuromuscular monitor for daily clinical use based on this principle.

ELECTROMYOGRAPHY

Evoked EMG records the compound action potentials produced by stimulation of a peripheral nerve. The compound action potential is a high-speed event that for many years could be detected only by means of a preamplifier and a storage oscilloscope. Modern neuromuscular transmission analyzers are able to make online electronic analyses and graphic presentations of the EMG response.

The evoked EMG response is most often obtained from muscles innervated by the ulnar or the median nerves. Stimulating electrodes are applied as in force measurements. Although both surface and needle electrodes can be used for recording, no advantage is obtained by using the latter. Most often, the evoked EMG response is obtained from the thenar or hypothenar eminence of the hand or from the first dorsal interosseous muscle of the hand, preferably with the active electrode over the motor

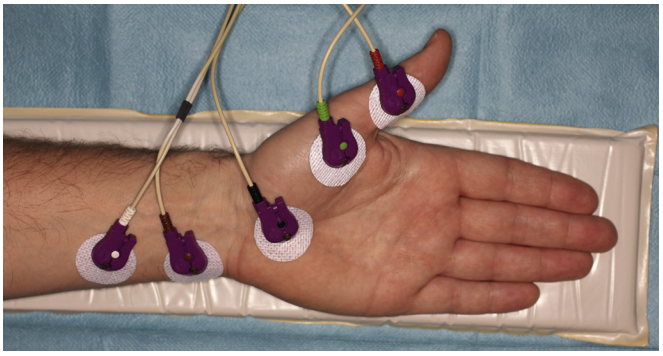

Figure 53-13. The setup for electromyography (NMT ElectroSensor, Datex-Ohmeda, Helsinki, Finland) for recording the compound action potential from the adductor pollicis muscle.

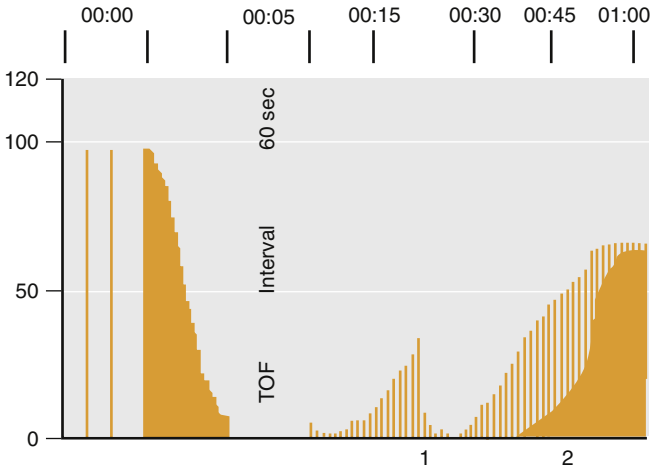

Figure 53-14. Evoked electromyographic printout from a Relaxograph (Datex-Ohmeda, Helsinki, Finland). Initially, single-twitch stimulation was given at 0.1 Hz, and vecuronium (70 μg/kg) was administered intravenously for tracheal intubation. After approximately 5 minutes, the mode of stimulation was changed to train-of-four (TOF) stimulation every 60 seconds. At a twitch height (first twitch in the TOF response) of approximately 30% of control (marker 1), 1 mg of vecuronium was given intravenously. At marker 2, 1 mg of neostigmine was given intravenously, preceded by 2 mg of glycopyrrolate. The printout also illustrates the common problem of failure of the electromyographic response to return to the control level. *(Courtesy Datex-Ohmeda, Helsinki, Finland.)*

point of the muscle (Fig. 53-13). The signal picked up by the analyzer is processed by an amplifier, a rectifier, and an electronic integrator. The results are displayed either as a percentage of control or as a TOF ratio.

Two new sites for recording the EMG response have been introduced: the larynx and the diaphragm.[54,55] Using a noninvasive disposable laryngeal electrode attached to the tracheal tube and placed between the vocal cords, it is possible to monitor the onset of neuromuscular block in the laryngeal muscles. However, the method is mainly of interest in clinical research when investigating onset times of the laryngeal muscles. In paravertebral surface diaphragmatic EMG, the recording electrodes are placed on the right of vertebrae T12/L1 or L1/L2 for monitoring the response of the right diaphragmatic crux to transcutaneous stimulation of the right phrenic nerve at the neck.[54-57] As is the case with surface laryngeal EMG, surface diaphragmatic EMG is mainly of interest in clinical research.

Evoked electrical and mechanical responses represent different physiologic events. Evoked EMG records changes in the electrical activity of one or more muscles, whereas evoked MMG records changes associated with excitation-contraction coupling and contraction of the muscle as well. For these reasons, the results obtained with these methods may differ.[57,58] Although evoked EMG responses generally correlate well with evoked mechanical responses,[30] marked differences can occur, especially in the response to succinylcholine and in the TOF ratio during recovery from a nondepolarizing block.[30,57,59]

In theory, recording of evoked EMG responses has several advantages over recording of evoked mechanical responses. Equipment for measuring-evoked EMG responses is easier to set up, the response reflects only factors influencing neuromuscular transmission, and the response can be obtained from muscles not accessible to mechanical recording. However, evoked EMG does entail some difficulties. Although high-quality recordings are possible in most patients, the results are not always reliable. For one thing, improper placement of electrodes can result in inadequate pickup of the compound EMG signal. If the neuromuscular transmission analyzer does not allow observation of the actual waveform of the compound EMG, determining optimal placement of the electrodes is difficult. Another source of unreliable results may be that fixation of the hand with a preload on the thumb might be more important than is generally appreciated,[30] inasmuch as changes in the position of the electrodes in relation to the muscle can affect the EMG response. In addition, direct muscle stimulation sometimes occurs. If muscles close to the stimulating electrodes are stimulated directly, the recording electrodes can pick up an electrical signal even though neuromuscular transmission is completely blocked. Another difficulty is that the EMG response often does not return to the control value. Whether this situation is the result of technical problems, inadequate fixation of the hand, or changes in temperature is unknown (Fig. 53-14). Finally, the evoked EMG response is highly sensitive to electrical interference, such as that caused by diathermy.

ACCELEROMYOGRAPHY

The technique of AMG is based on Newton's second law: Force = Mass × Acceleration.[60] If mass is constant, acceleration is directly proportional to force. Accordingly, after nerve stimulation, one can measure not only the evoked force but also acceleration of the thumb.

AMG uses a piezoelectric ceramic wafer with electrodes on both sides. Exposure of the electrode to a force generates an electrical voltage proportional to acceleration of the electrode. Consequently, when an accelerometer is fixed to the thumb and the ulnar nerve is stimulated, an electrical signal is produced whenever the thumb moves. This signal can be analyzed in a specially designed analyzer[61] or displayed on a recording system. At least two detached monitors are commercially available, based on the same transducer: the TOF-Watch (Biometer, Odense, Denmark) and the Infinity Trident NMT SmartPod (Dräger, Lübeck, Germany; Fig. 53-15).

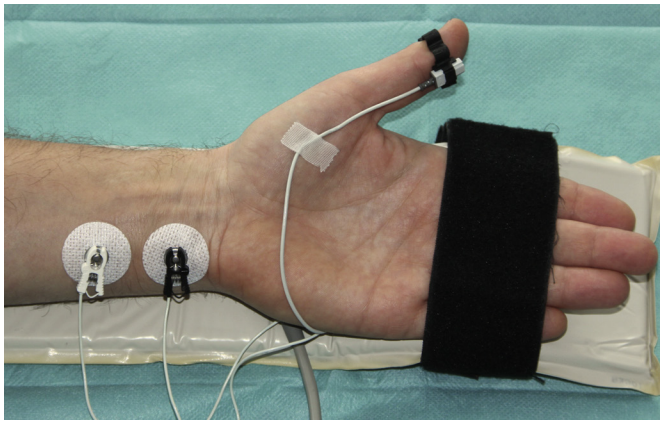

Figure 53-15. The setup of acceleromyography without preload (TOF Watch, Biometer, Odense, Denmark). The response to nerve stimulation is measured with a small piezoelectric acceleration transducer placed distally on the volar site of the thumb.

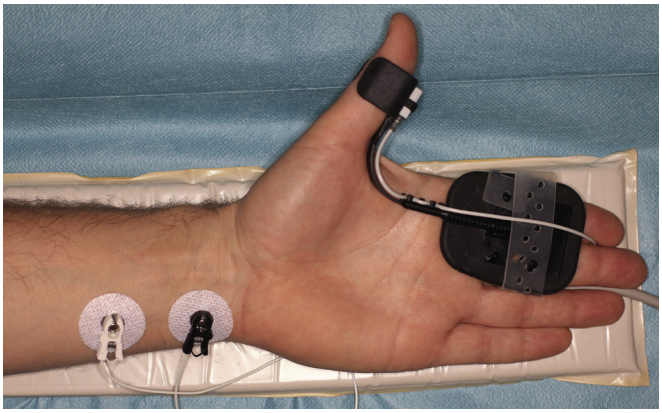

Figure 53-16. The setup of acceleromyography with preload (TOF Watch with Hand Adapter, Biometer, Odense, Denmark). The piezoelectric acceleration transducer is placed in the Hand Adapter. The stretching wing ensures that the thumb does not touch the palm of the hand.

AMG is a simple method of analyzing neuromuscular function, both in the operating room and in the intensive care unit. Although good correlation exists between the TOF ratio measured by this method and the TOF ratio measured with a force-displacement transducer or EMG,[60,62,63] measurements made via AMG are not directly comparable with results obtained by the other two methods.[63-69] When AMG is used with a free-moving thumb, as originally suggested,[60] wide limits of agreements in twitch height (T1) and TOF ratio and differences in the onset and recovery course of block between AMG and MMG have been found. Moreover, the AMG control TOF ratio is consistently higher than when measured with a force-displacement transducer. In accordance with this, several studies have indicated that when using AMG, the TOF ratio indicative of sufficient postoperative neuromuscular recovery is 1.0 rather than 0.90, as when measured by MMG or EMG in the adductor pollicis muscle.[2,22,68,70,71] In contrast to MMG and EMG, the control baseline TOF value before administration of a neuromuscular blocking drug is most often 1.1 to 1.2 when measured with AMG, and in some patients is as high as 1.4. A high control baseline value probably indicates that the TOF ratio necessary for excluding residual curarization is equally higher. For instance, in a patient with a high control baseline value (e.g., TOF = 1.2), it is to be expected that a higher TOF ratio during recovery is necessary to exclude residual block compared with a patient with a low control baseline value (e.g., TOF = 0.95). It is generally accepted that the TOF ratio should be at least 0.90 to exclude clinically significant residual paralysis; using the preceding example, a TOF ratio of 1.08 (90% of 1.2) would represent safe recovery in the first patient, whereas a TOF ratio of 0.86 (90% of 0.95) would suffice in the other patient. To overcome such problems, it has been suggested to refer the actually obtained TOF ratios during recovery to the baseline control TOF ratio (normalization).[22,67,72-75] Currently, no commercially available monitors can "normalize" the TOF ratio automatically. Intuitively, for excluding residual block using AMG, a TOF ratio of at least 1.0 should be targeted to exclude residual block.[22,67,68,73]

One reason for the wide limits of agreement between AMG and MMG is probably and paradoxically connected with one of the originally claimed advantages of the method, that fixation of the hand could be reduced to a minimum as long as the thumb could move freely.[60] In clinical practice, it is often not possible to ensure that the thumb can move freely and that the position of the hand does not change during the surgical procedure. The evoked response can therefore vary considerably. Several solutions have been proposed, but the use of an elastic preload on the thumb improves the precision without compromising the agreement between results obtained with AMG and MMG (Fig. 53-16).[67,68] Several studies have indicated that objective monitoring with AMG reduces and almost eliminates the problem of postoperative residual neuromuscular block.[67,76-80]

When the thumb is not available for monitoring during surgery, some clinicians prefer to monitor the AMG response of the orbicularis oculi or the corrugator supercilii in response to facial nerve stimulation.[46] However, neuromuscular monitoring of both sites with AMG is subject to large uncertainty regarding the extent of paralysis, and it cannot be recommended for routine monitoring. It provides only a rough estimate of the degree of block of the peripheral muscles.[81,82]

PIEZOELECTRIC NEUROMUSCULAR MONITORS

The technique of the piezoelectric monitor is based on the principle that stretching or bending a flexible piezoelectric film (e.g., one attached to the thumb) in response to nerve stimulation generates a voltage that is proportional to the amount of stretching or bending.[83,84] At least one device based on this principle is available commercially in two sizes (adult and pediatric): the NMT MechanoSensor (Datex-Ohmeda, Helsinki, Finland; Fig. 53-17).

Few studies have evaluated the function of these monitors.[83-85] Limited data indicate not only a good relationship between results obtained with PZEMG, AMG, and MMG, but also wide limits of agreement between

the methods. Therefore, although PZEMG may be a valuable clinical tool, the values obtained in an individual patient with this method can vary from those obtained with MMG or AMG.

PHONOMYOGRAPHY

Phonomyography (acoustic myography) is an interesting new method of monitoring neuromuscular function, but it is not yet commercially available.[49,86-91] Contraction of skeletal muscles generates intrinsic low-frequency sounds, which can be recorded with special microphones. This method has been evaluated for clinical and research purposes. Several reports indicate good correlation between evoked acoustic responses and those obtained with more traditional methods of recording, such as MMG, EMG, and AMG. However, it is uncertain whether PMG will ever be used for monitoring neuromuscular block during routine anesthesia. What does make PMG interesting, however, is that in theory the method can be applied not only to the adductor pollicis muscle, but also to other muscles of interest such as the diaphragm, larynx, and eye muscles. In addition, the ease of application is attractive.

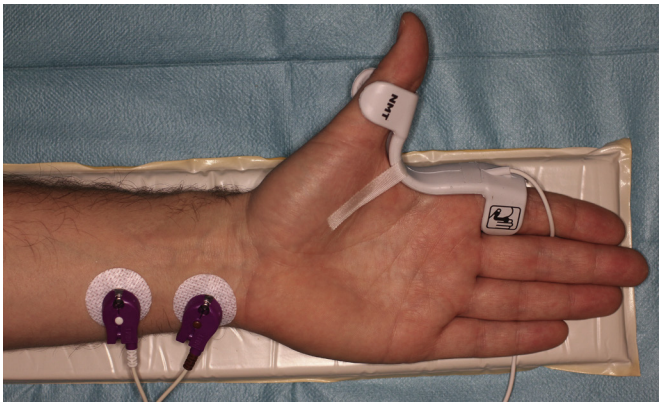

Figure 53-17. The setup of kinemyography (NMT MechanoSensor, Datex-Ohmeda, Helsinki, Finland). The response to nerve stimulation is measured by the bending of a small piezoelectric sensor positioned between the index finger and the thumb.

EVALUATION OF RECORDED EVOKED RESPONSES

Nerve stimulation in clinical anesthesia is usually synonymous with TOF nerve stimulation. Therefore, the recorded response to this form of stimulation is used to explain how to evaluate the degree of neuromuscular block during clinical anesthesia.

NONDEPOLARIZING NEUROMUSCULAR BLOCK

After injection of a nondepolarizing neuromuscular blocking drug in a dose sufficient for smooth tracheal intubation, TOF recording demonstrates four phases, or levels, of neuromuscular block: intense block, deep block, moderate or surgical block, and recovery (Fig. 53-18).

Intense Neuromuscular Block

Intense or profound neuromuscular block occurs within 3 to 6 minutes of injection of an intubating dose of a nondepolarizing muscle relaxant, depending on the drug and the dose given. This phase is also called the "period of no response" because no response to any pattern of nerve stimulation occurs. The length of this period varies, again depending primarily on the duration of action of the muscle relaxant and the dose given. The sensitivity of the patient to the drug also affects the period of no response. An intense block cannot be antagonized with a cholinesterase inhibitor (e.g., neostigmine), and only a high dose of sugammadex (16 mg/kg) can antagonize an intense block caused by rocuronium or vecuronium.[92,93]

Deep Neuromuscular Block

Intense neuromuscular block is followed by a period of deep neuromuscular block, characterized by absence of

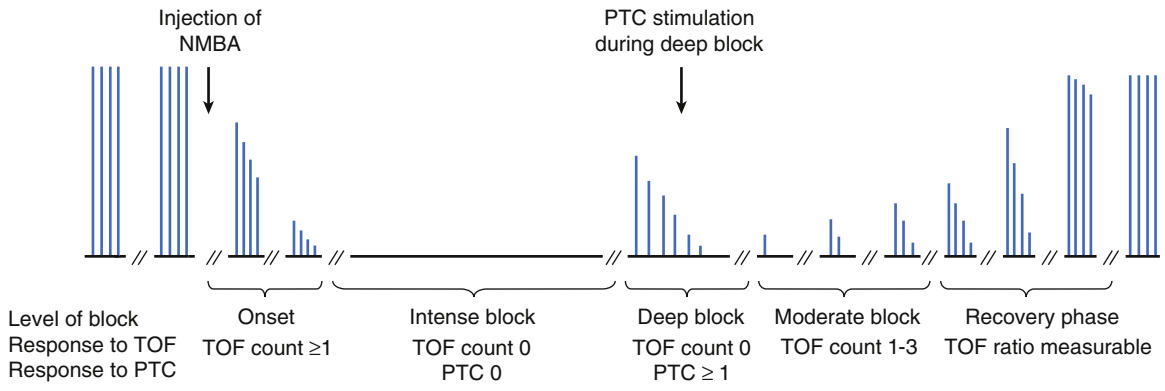

Figure 53-18. Levels of block after a normal intubating dose of a nondepolarizing neuromuscular blocking agent (NMBA) as classified by posttetanic count (PTC) and train-of-four (TOF) stimulation. During intense (profound) block, there are no responses to either TOF or PTC stimulation. During deep block, there is response to PTC but not to TOF stimulation. Intense (profound) block and deep block together constitute the "period of no response to TOF stimulation." Reappearance of the response to TOF stimulation heralds the start of moderate block. Finally, when all four responses to TOF stimulation are present and a TOF ratio can be measured, the recovery period has started. *(From Fuchs-Buder T, et al: Good clinical research practice in pharmacodynamic studies of neuromuscular blocking agents II: The Stockholm revision,* Acta Anaesthesiol *Scand 51:789, 2007.)*

response to TOF stimulation, but with the presence of posttetanic twitches (i.e., PTC ≥ 1; compare with Figure 53-4). Although prediction of the duration of a deep neuromuscular block is difficult, correlation usually exists between PTC stimulation and the time until reappearance of the first response to TOF stimulation (see Fig. 53-5). Attempts to reverse a deep neuromuscular block with neostigmine is usually impossible (see Chapter 35). However, a deep neuromuscular block caused by rocuronium or vecuronium can be antagonized completely within a few minutes using a dose of sugammadex of 4 mg/kg.[94-96]

Moderate or Surgical Neuromuscular Block

Moderate or surgical neuromuscular block begins when the first response to TOF stimulation appears. This phase is characterized by a gradual return of the four responses to TOF stimulation. Furthermore, good correlation exists between the degree of neuromuscular block and the number of responses to TOF stimulation. When only one response is detectable, the degree of neuromuscular block (the depression in twitch tension) is 90% to 95%. When the fourth response reappears, neuromuscular block is usually 60% to 85%.[97,98] The presence of one or two responses in the TOF pattern normally indicates sufficient relaxation for most surgical procedures. During light anesthesia, however, patients may move, buck, or cough; therefore, a deeper block (or a deeper level of anesthesia) may be necessary when elimination of sudden movements or facilitation of surgery is necessary. The deep neuromuscular block can then be evaluated with PTC (see Fig. 53-6).[23]

Antagonism of neuromuscular block with neostigmine should usually not be attempted when the block is intense or deep. Even if some reversal occurs, it will often be inadequate, regardless of the dose of neostigmine administered.[99] Furthermore, after the administration of large doses of muscle relaxants, reversal of the block with neostigmine to clinically normal activity is not always possible if only one TOF response is present. In general, antagonism with neostigmine should not be initiated before at least two to four responses are observed. Even then, sufficient recovery cannot be guaranteed unless documented using objective monitoring (see Chapter 35).[100,101]

Antagonism of moderate block induced by rocuronium and vecuronium can be achieved with a small dose of sugammadex (2 mg/kg) within a few minutes.[102-104] However, the reappearance of neuromuscular blockade has been reported by anesthesiologists from Japan[105] when the 2 mg/kg dose has been used. They did not monitor the degree of neuromuscular blockade. Did the reappearance of neuromuscular blockade occur because of inadequate monitoring or too small a dose of sugammadex? Even with proper monitoring, these results suggest that a dose larger than 2 mg/kg should be used.[106] Although the antagonism of neuromuscular block from sugammadex seems to be fast and predictable, objective monitoring should still be used until the TOF ratio is 0.9 to 1.0.

Recovery from Neuromuscular Block

Return of the fourth response in the TOF heralds the recovery phase. During neuromuscular recovery, a reasonably good correlation exists between the actual TOF ratio and clinical observation, but the relationship between the TOF ratio and signs and symptoms of residual block varies greatly among patients.[80,99] When the TOF ratio is 0.4 or less, the patient is generally unable to lift the head or arm. Tidal volume may be normal, but vital capacity and inspiratory force is reduced. When the ratio is 0.6, most patients are able to lift their head for 3 seconds, open their eyes widely, and stick out their tongue, but vital capacity and inspiratory force are often still reduced. At a TOF ratio of 0.7 to 0.75, the patient can normally cough sufficiently and lift the head for at least 5 seconds, but grip strength may still be as low as about 60% of control.[107] When the ratio is 0.8 and higher, vital capacity and inspiratory force are normal.[17,108-110] The patient may, however, still have diplopia, blurred vision, and facial weakness (Table 53-1).[80,107]

The TOF ratio must exceed 0.90 when recorded with MMG or EMG, and 1.0 when using AMG to exclude clinically important residual neuromuscular block.[30,44,67,68,70,111-116] Moderate degrees of neuromuscular block can impair carotid body chemosensitivity to hypoxia with absent ventilatory response to arterial desaturation.[111,112,114,116] Moreover, residual block (TOF < 0.90) is associated with functional impairment of the pharyngeal and upper esophageal muscles, which most probably predisposes to regurgitation and aspiration of gastric contents.[44] Eikermann and colleagues[117] have documented that partial neuromuscular block, even to a degree that does not evoke dyspnea or oxygen desaturation, can decrease inspiratory upper airway volume and can evoke partial inspiratory airway collapse.[117] Also, residual block (TOF < 0.70) caused by the long-acting muscle relaxant pancuronium is a significant risk factor for the development of postoperative pulmonary complications (Table 53-2 and Fig. 53-19).[113] Intraoperative neuromuscular monitoring reduces the risk of residual neuromuscular block and results in fewer patients with hypoxemic events or airway obstruction in the postanesthesia care unit.[79] Even in volunteers without sedation or impaired consciousness, a TOF ratio of 0.90 or less

TOF < 0.70	59	10	16.9†	24	1	4.2

*Results from a prospective, randomized, and blinded study of postoperative pulmonary complications (POPC) in a total of 691 adult patients undergoing abdominal, gynecologic, or orthopedic surgery and receiving either pancuronium, atracurium, or vecuronium.[82] In 4 of the 46 patients with POPC (1 in the pancuronium group and 3 in the atracurium and vecuronium groups), the train-of-four (TOF) ratio was not available. Because there were no significant differences in the two groups of patients given the intermediate-acting muscle relaxants, the data from these groups are pooled.
†$p < 0.02$ versus patients in the same group with a train-of-four ratio of 0.70 or greater.

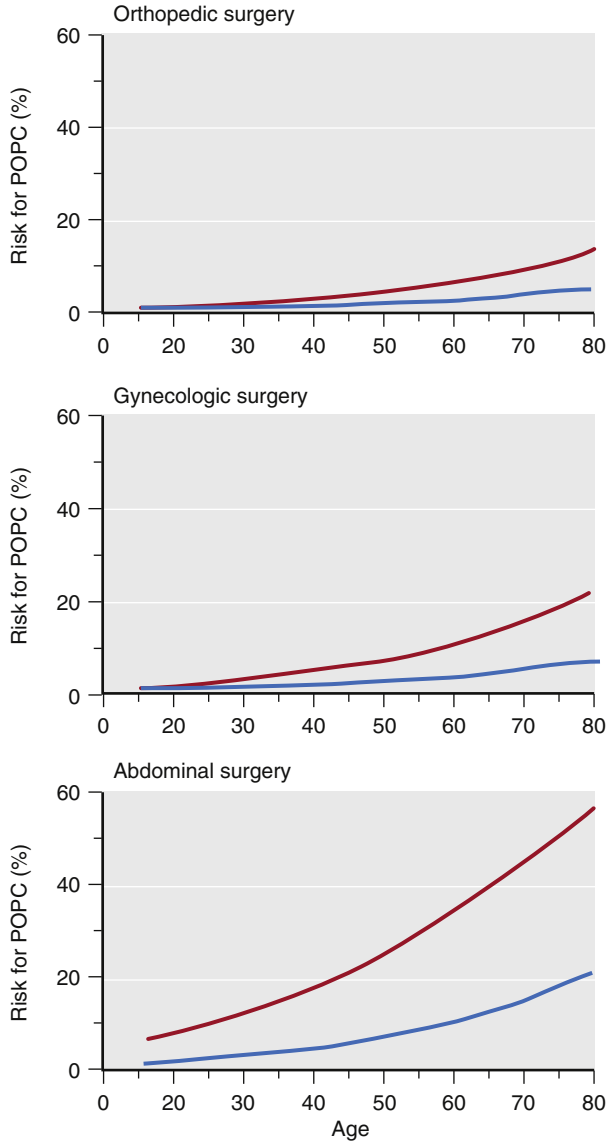

Figure 53-19. Predicted probabilities of a postoperative pulmonary complication (POPC) in different age groups in orthopedic, gynecologic, and major abdominal surgery with duration of anesthesia of less than 200 minutes. The *red lines* represent patients with residual neuromuscular block (train-of-four [TOF] < 0.70) after the administration of pancuronium; the *blue lines* represent patients with a TOF of 0.70 or greater after the administration of pancuronium, as well as all patients after the administration of atracurium and vecuronium, independent of the TOF ratio at the end of anesthesia.[113]

can impair the ability to maintain the airway.[76,107,118] Even small degrees of residual block are unpleasant for patients causing symptoms, such as general weakness and blurred vision.[80] In summary, adequate recovery of neuromuscular function requires the return of an MMG or EMG TOF ratio to at least 0.90, and an AMG TOF ratio to at least 1.0 (or normalized to 0.90),[74] which cannot be guaranteed without objective neuromuscular monitoring.[77,78,80,119-122]

DEPOLARIZING NEUROMUSCULAR BLOCK (PHASE I AND II BLOCKS)

Patients with normal plasma cholinesterase activity who are given a moderate dose of succinylcholine (0.5 to 1.5 mg/kg) undergo a typical depolarizing neuromuscular block (phase I block; i.e., the response to TOF or tetanic stimulation does not fade, and no posttetanic facilitation of transmission occurs). In contrast, some patients with genetically determined abnormal plasma cholinesterase activity who are given the same dose of succinylcholine undergo a nondepolarizing-like block characterized by fade in the response to TOF and tetanic stimulation and the occurrence of posttetanic facilitation of transmission (Fig. 53-20). This type of block is called a *phase II block* (dual, mixed, or desensitizing block). In addition, phase II blocks sometimes occur in genetically normal patients after repetitive bolus doses or a prolonged infusion of succinylcholine.

From a therapeutic point of view, a phase II block in normal patients must be differentiated from a phase II block in patients with abnormal cholinesterase activity. In healthy patients, a phase II block can be antagonized by administering a cholinesterase inhibitor a few minutes after discontinuation of succinylcholine. In patients with abnormal genotypes, however, the effect of intravenous injection of a cholinesterase inhibitor (e.g., neostigmine) is unpredictable because it inhibits acetylcholinesterase and plasma-cholinesterase. For example, neostigmine can potentiate the block dramatically, temporarily improve neuromuscular transmission, and then potentiate the block or partially reverse the block, all depending on the time elapsed since administration of succinylcholine and the dose of neostigmine given. Therefore, unless the cholinesterase genotype is known to be normal, antagonism of a phase II block with a cholinesterase inhibitor should be undertaken with extreme caution. Even if

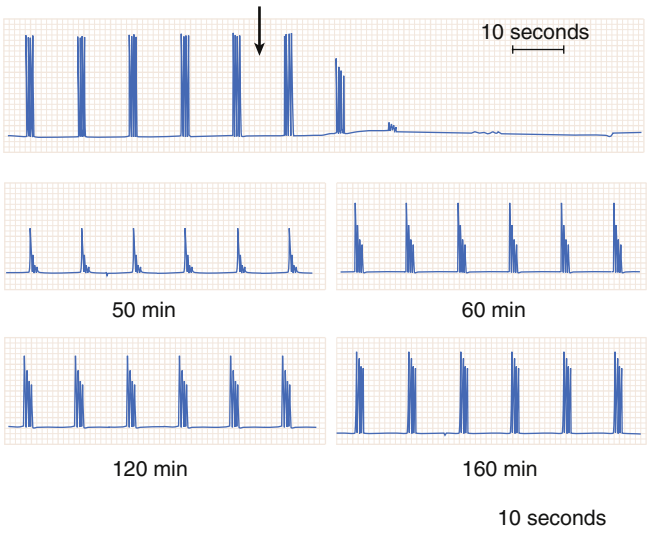

Figure 53-20. Typical recording of the mechanical response to train-of-four ulnar nerve stimulation after injection of 1 mg/kg of succinylcholine (*arrow*) in a patient with genetically determined abnormal plasma cholinesterase activity. The prolonged duration of action and the pronounced fade in the response indicate a phase II block.

neuromuscular function improves promptly, patient surveillance should continue for at least 1 hour.

USE OF NERVE STIMULATORS IN DAILY CLINICAL PRACTICE

Whenever a neuromuscular blocking drug is administered to a patient, objective monitoring of the evoked response using recording equipment is the best way to evaluate the neuromuscular block. However, tactile or visual evaluation are still the most common forms of clinical neuromuscular monitoring, not least when recording equipment is not available or considered unreliable. The following is a description of how to use nerve stimulators with or without recording equipment (objective monitoring).

PREPARATIONS BEFORE INDUCTION OF ANESTHESIA AND ADMINISTRATION OF THE NEUROMUSCULAR BLOCKING AGENT

First, for supramaximal stimulation, careful cleansing of the skin and proper placement and fixation of electrodes are essential. When the ulnar nerve is used for nerve stimulation, one should take advantage of the fact that the nerve follows the artery by placing the electrodes above the pulse. This placement gives the best response (see Fig. 53-9). Second, every effort should be taken to prevent central cooling, as well as cooling of the extremity being evaluated. Both central and local surface cooling of the adductor pollicis muscle can reduce twitch tension and the TOF ratio.[123-125] Peripheral cooling can affect nerve conduction, decrease the rate of release of acetylcholine and muscle contractility, increase skin impedance, and reduce blood flow to the muscles, thus decreasing the rate of removal of muscle relaxant from the neuromuscular junction. These factors might account for the occasional and pronounced difference in muscle response between a cold extremity and the contralateral warm extremity.[126]

USE OF A NERVE STIMULATOR DURING INDUCTION OF ANESTHESIA

The nerve stimulator should be attached to the patient before induction of anesthesia, but should not be turned on until after the patient is unconscious.

Single-twitch stimulation at 1 Hz can be used initially when seeking supramaximal stimulation. However, after supramaximal stimulation has been ensured and before the muscle relaxant is injected, the recording equipment (when using objective monitoring) should be calibrated to ensure that the response is in the measurement window and the response to 1 Hz stimulation is set to 100%. Currently, all commercially available devices have an automatic calibration modus. Without calibration, the recorded response to nerve stimulation might differ significantly from the visual or tactile response throughout all levels of neuromuscular block; therefore, the mode of stimulation should be changed to TOF (or 0.1-Hz twitch stimulation). When the response to this stimulation is observed (the control response), the neuromuscular blocking drug is injected. Although the trachea is often intubated when the response to TOF stimulation disappears, postponement of this procedure for 30 to 90 seconds, depending on the muscle relaxant used, usually produces better conditions.

When possible, the response to nerve stimulation should be evaluated at the thumb (rather than at the fifth finger). Direct stimulation of the muscle often causes subtle movement of the fifth finger when no response is present at the thumb. Finally, the different sensitivities of various muscle groups to neuromuscular blocking drugs should always be kept in mind.

USE OF A NERVE STIMULATOR DURING SURGERY

If tracheal intubation is facilitated by the administration of succinylcholine, no more muscle relaxant should be given until the response to nerve stimulation reappears or the patient shows other signs of returning neuromuscular function. If plasma cholinesterase activity is normal, the muscle response to TOF nerve stimulation reappears within 4 to 8 minutes.

When a nondepolarizing neuromuscular drug is used for tracheal intubation, a longer-lasting period of intense block usually follows. During this period of no response to TOF and single-twitch stimulation, the time until the return of response to TOF stimulation can be evaluated by PTC (see Fig. 53-5 and Fig. 53-21).

For most surgical procedures requiring muscle relaxation, it is not necessary to have an intense block, provided that the patient is adequately anesthetized. If a nondepolarizing relaxant is used, a moderate level of neuromuscular block with one or two of the responses to TOF stimulation is sufficient. However, because the respiratory muscles (including the diaphragm) are less sensitive to neuromuscular blocking drugs than the peripheral

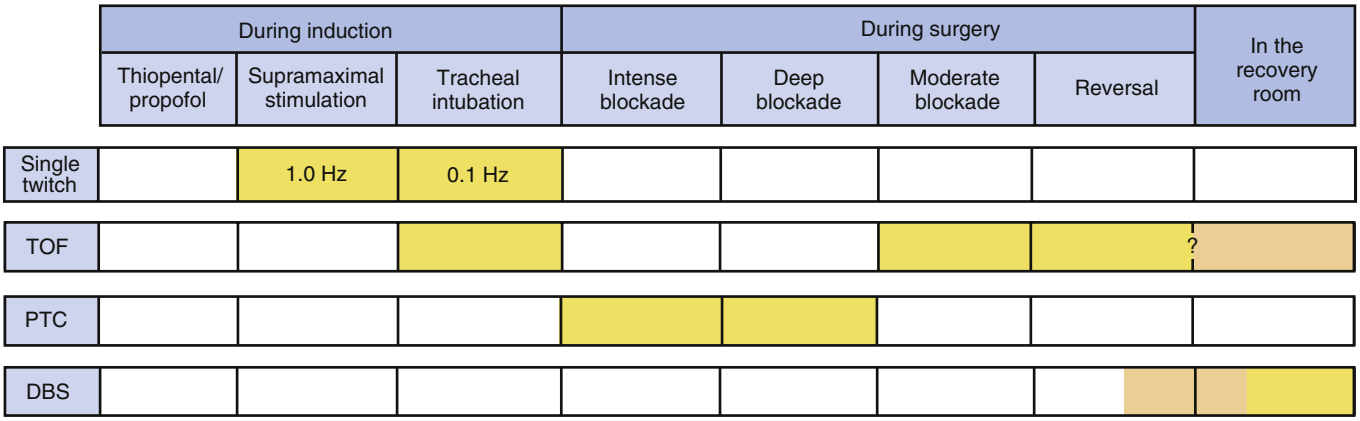

Figure 53-21. Diagram showing when the different modes of electrical nerve stimulation can be used during clinical anesthesia. *Dark areas* indicate appropriate use and *light areas*, less effective use. Modes of nerve stimulation are train-of-four (TOF) stimulation; posttetanic count (PTC); double-burst stimulation (DBS); and the question mark (?), indicating that TOF is less useful in the recovery room unless measured with mechanomyography, electromyography, or acceleromyography. (See text for further explanation.)

muscles are, the patient may breathe, hiccup, or even cough at this depth of block. Moreover, tonus of the diaphragm might impede the surgical conditions. To ensure paralysis of the diaphragm, neuromuscular block of the peripheral muscles must be so intense that the PTC is zero at the thumb.

The disadvantages of sustaining a deep or intense neuromuscular block is that the risk of awareness most probably is increased (see Chapters 13 and 50). When muscles are completely paralyzed, the patient cannot signal awareness with voluntary or involuntary movements. Another disadvantage of a deep or intense block is that the neuromuscular block cannot readily be reversed by neostigmine. Only sugammadex can reverse a deep or intense neuromuscular block (if caused by rocuronium or vecuronium; see Chapter 35).

USE OF A NERVE STIMULATOR DURING REVERSAL OF NEUROMUSCULAR BLOCK

Antagonism of nondepolarizing neuromuscular block is most often facilitated with a cholinesterase inhibitor, such as neostigmine, or with the selective relaxant binding agent sugammadex when the neuromuscular block is achieved using rocuronium or vecuronium.

Antagonism with neostigmine should not be initiated before at least two to four responses to TOF stimulation are present or before there are obvious clinical signs of returning neuromuscular function. Reversal of neuromuscular block will not be hastened and can possibly be delayed by giving neostigmine when no response to peripheral nerve stimulation is present. Moreover, even when there are two to four responses to TOF stimulation, the reversal is slow and insufficient in some patients. With a large dose of neostigmine (e.g., 5 mg/70 kg) the median time to achieve a TOF ratio of 0.90 is 15 to 20 minutes, and it will take approximately 90 to 120 minutes to achieve a TOF ratio of 0.90 in 95% of the patients after an intermediate-acting neuromuscular blocking drug (e.g., rocuronium). Conversely, a large dose of neostigmine after full recovery might give a paradoxical block with decreasing TOF ratio.[127-131]

When rocuronium or vecuronium is used, the selective relaxant binding drug, sugammadex can be used for reversal[102,103] (see Chapter 35). Sugammadex encapsulates rocuronium and vecuronium with a high affinity, thereby antagonizing the neuromuscular blocking effect. Three different doses of sugammadex are recommended according to the level of block. A large dose (16 mg/kg) is given during intense block (no response to PTC stimulation),[92,93] a medium dose (4 mg/kg) during deep block (two or more responses to PTC),[94-96] and a low dose (2 mg/kg) during moderate block (two or more responses to TOF stimulation).[102-104] In most patients, all levels of neuromuscular block are reversed within 2 to 5 minutes. However, residual neuromuscular block can be excluded only with objective monitoring (TOF ratio, 0.9 to 1.0).[132]

As previously described, a recent observational study from Japan also placed emphasis on the relative relationship between a dose of sugammadex and monitoring of neuromuscular blockade.[105] Basically, Kotake and colleagues[105] observed reappearance of neuromuscular block after administration of an average dose of 2.7 mg/kg of sugammadex. The accompanying editorial by Naguib and colleagues[106] placed prime importance on the lack of monitoring as the problem. They also lamented the frequent incidence of not using neuromuscular monitoring during anesthesia. The emphasis on monitoring is important and correct, but incomplete. In this editor's (R. D. Miller) opinion, a larger dose of sugammadex should be given. However, Naguib and colleagues[106] state that this recommendation would double the cost of the reversal drug. Should we not give a proper dose of sugammadex in the interest of decreasing the incidence of residual neuromuscular block? The fact that these two publications are being referenced twice within this chapter indicates their importance.

During recovery of neuromuscular function, when all four responses to TOF stimulation can be felt, an estimation of the TOF ratio can be attempted. However, manual (tactile) evaluation of the response to TOF stimulation (see Fig. 53-8) is not sensitive enough to exclude the possibility of residual neuromuscular block.[22,29,119,133] Greater sensitivity is achieved with $DBS_{3,3}$, but even absence of manual

BOX 53-1 *Clinical Tests of Postoperative Neuromuscular Recovery*

Unreliable

- Sustained eye opening
- Protrusion of the tongue
- Arm lift to the opposite shoulder
- Normal tidal volume
- Normal or nearly normal vital capacity
- Maximum inspiratory pressure less than 40 to 50 cm H_2O

More reliable, but still not excluding residual neuromuscular block

- Sustained head lift for 5 seconds
- Sustained leg lift for 5 seconds
- Sustained handgrip for 5 seconds
- Sustained "tongue depressor test"
- Maximum inspiratory pressure 40 to 50 cm H_2O or greater

fade in the $DBS_{3,3}$ response does not exclude clinically significant residual block.[22,32] Moreover, some patients might suffer from residual block, even after recovery to a TOF ratio of 0.9 to 1.0.[76,80] Therefore, manual evaluation of responses to nerve stimulation should always be considered in relation to reliable clinical signs and symptoms of residual neuromuscular block (Box 53-1).

WHEN TO USE A PERIPHERAL NERVE STIMULATOR

In clinical practice, significant residual block can be excluded with certainty only if an objective method of neuromuscular monitoring is used.[77,78] Therefore, good evidence-based practice dictates that clinicians should always quantitate the extent of neuromuscular recovery by objective monitoring.[3-9] Only a TOF ratio of 0.90 to 1.00 that is measured by objective monitoring ensures a low risk of clinically significant residual block.

However, in many departments clinicians do not have access to equipment for measuring the degree of block.[134] How then to evaluate and, as far as possible, exclude a clinically significant postoperative block? First, long-acting neuromuscular blocking drugs should not be used. Second, the tactile response to TOF nerve stimulation should be evaluated during surgery. Third, if possible, total twitch suppression should be avoided. The neuromuscular block should be managed so that there are always one or two tactile TOF responses. Fourth, the block should be antagonized at the end of the procedure, preferably with sugammadex if rocuronium or vecuronium have been used. When using neostigmine, reversal should not be initiated before at least two to four responses to TOF stimulation are present. Fifth, during recovery, tactile evaluation of the response to DBS is preferable to tactile evaluation of the response to TOF stimulation because it is easier to manually assess fade in the DBS than in the TOF response. Sixth, the clinician should recognize that the absence of tactile fade in both the TOF and DBS responses does not exclude significant residual block. Finally, reliable clinical signs and symptoms of residual block (see Box 53-1) should be considered in relation to the response to nerve stimulation. Figure 53-22 shows how to minimize the risk of residual block with or without objective monitoring.[135]

In view of the uncertainty connected with the use of clinical tests of postoperative neuromuscular recovery and tactile evaluation of the response to nerve stimulation, all patients receiving neuromuscular blocking drugs should be monitored with an objective monitor (also see Chapter 35). Whether the functioning of such a neuromuscular transmission analyzer is based on EMG, MMG, AMG, PZEMG, or PMG is not crucial, as long as the apparatus is used appropriately.

Chapter 54

Temperature Regulation and Monitoring

DANIEL I. SESSLER

KEY POINTS

- General anesthetics decrease the thresholds (triggering core temperatures) for vasoconstriction and shivering by 2° C to 3° C.
- Anesthetic-induced impairment of thermoregulatory control, combined with a cool operating room environment, makes most patients hypothermic.
- The major initial cause of hypothermia in most patients is core-to-peripheral redistribution of body heat.
- Neuraxial anesthesia impairs both central and peripheral thermoregulatory control and is associated with substantial hypothermia.
- Large randomized trials have proved that even mild hypothermia (i.e., 1.5° C to 2.0° C) causes adverse outcomes, including a threefold increase in morbid myocardial outcomes, a threefold increase in wound infection risk, coagulopathy and need for allogeneic transfusion, prolonged recovery, and prolonged hospitalization.
- Body temperature should be monitored in patients having surgery lasting more than 30 minutes, and core temperature should be maintained at 36° C or higher whenever possible. Forced-air warming currently offers the best combination of high efficacy, low cost, and remarkable safety.

Mammals and birds are homeothermic, requiring a nearly constant internal body temperature. When internal temperature deviates significantly from normal, metabolic functions usually deteriorate, and death may result. The thermoregulatory system usually maintains core body temperature within a few tenths of a degree centigrade of "normal," which is approximately 37° C in humans. Anesthetic-induced inhibition of thermoregulation combines with exposure to a cold operating room environment to make most unwarmed patients hypothermic.

Major outcome studies have shown that mild hypothermia (≈1° C to 2° C) (1) triples the incidence of morbid cardiac outcomes, (2) triples the incidence of surgical wound infections, (3) increases surgical blood loss and the need for allogeneic transfusions by approximately 20%, and (4) prolongs postanesthesia recovery and the duration of hospitalization. An understanding of normal and anesthetic-influenced thermoregulation will facilitate prevention and management of these and numerous other temperature-related complications.

NORMAL THERMOREGULATION

Thermoregulation is similar to many other physiologic control systems in that the brain uses negative and positive feedback to minimize perturbations from preset, "normal" values. Since 1912, animals have been known to regulate body temperature poorly when the hypothalamus is destroyed. The importance of thermal input from the skin surface was recognized in the late 1950s, when investigators observed that mice placed in a cold environment shivered *before* decreasing their hypothalamic temperatures.

In the early 1960s, physiologists reported active thermoregulation in response to isolated warming and cooling at sites other than the hypothalamus or skin surface, including extrahypothalamic portions of the brain, deep abdominal tissues, and the spinal cord. Thus, thermoregulation is based on multiple, redundant signals from nearly every type of tissue. The processing of thermoregulatory information occurs in three phases: *afferent thermal sensing*, *central regulation*, and *efferent responses*.

AFFERENT INPUT

Temperature information is obtained from thermally sensitive cells throughout the body. Cold-sensitive cells are anatomically and physiologically distinct from those that detect warmth. Warm receptors increase their firing rates when temperature increases, whereas cold receptors do so when temperature decreases. Cutaneous warm receptors rarely depolarize at normal skin temperatures and probably are important only during heat stress. The actual sensors appear to be a class of transient receptor potential (TRP) protein receptors.[1]

Cold signals travel primarily via Aδ nerve fibers and warm information by unmyelinated C fibers, although some overlap occurs.[2] The C fibers also detect and convey pain sensation, and that is why intense heat cannot be distinguished from sharp pain. Most ascending thermal information traverses the spinothalamic tracts in the anterior spinal cord, but no single spinal tract is critical for conveying thermal information. Consequently, the entire anterior cord must be destroyed to ablate thermoregulatory responses.

The hypothalamus, other parts of the brain, the spinal cord, the deep abdominal and thoracic tissues, and the skin surface each contribute roughly 20% of the total thermal input to the central regulatory system.[3]

CENTRAL CONTROL

Temperature is regulated by central structures (primarily the hypothalamus) that compare integrated thermal inputs from the skin surface, neuraxis, and deep tissues with *threshold* temperatures for each thermoregulatory response. Although integrated by the hypothalamus, most thermal information is "preprocessed" in the spinal cord and other parts of the central nervous system. This hierarchic arrangement presumably developed when the evolving thermoregulatory control system co-opted previously existing mechanisms (e.g., shivering from muscles previously used for posture and locomotion). It is likely that some thermoregulatory responses can be mounted by the spinal cord alone.[4] For example, animals and patients with high spinal cord transections regulate temperature better than would be expected.

The slope of response intensity versus core temperature defines the *gain* of a thermoregulatory response. Response intensity no longer increasing with further deviation in core temperature identifies the *maximum intensity*. This system of thresholds and gains is a model for a thermoregulatory system that is further complicated by interactions between other regulatory responses (i.e., vascular volume control) and time-dependent effects.

How the body determines absolute threshold temperatures is unknown, but the mechanism appears to be mediated by norepinephrine, dopamine, 5-hydroxytryptamine, acetylcholine, prostaglandin E_1, and neuropeptides. The thresholds vary daily in both sexes (circadian rhythm) and monthly in women by approximately 0.5° C. Exercise, food intake, infection, hypothyroidism and hyperthyroidism, anesthetic and other drugs (including alcohol, sedatives, and nicotine), and cold and warm adaptation alter threshold temperatures.

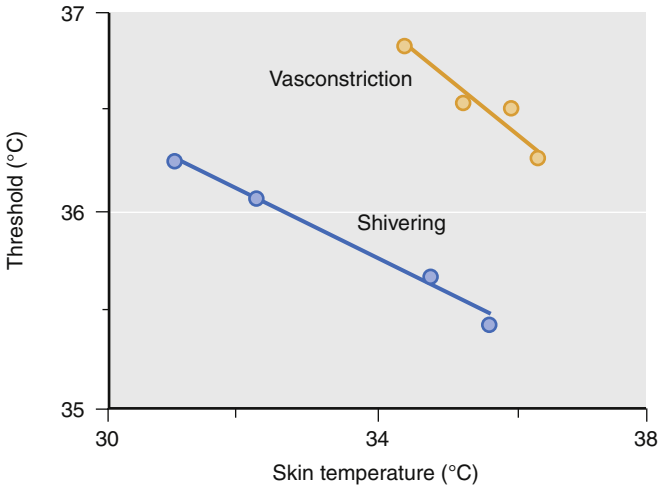

Figure 54-1. A linear relationship exists between mean skin temperature and the core temperature triggering vasoconstriction and shivering. Skin temperature contributes approximately 20% to control of each thermoregulatory defense. *(From Cheng C, Matsukawa T, Sessler DI, et al: Increasing mean skin temperature linearly reduces the core-temperature thresholds for vasoconstriction and shivering in humans,* Anesthesiology *82:1160-1168, 1995.)*

Control of autonomic responses is approximately 80% determined by thermal input from core structures (Fig. 54-1).[5,6] In contrast, a large fraction of the input controlling behavioral responses is derived from the skin surface. The *interthreshold range* (core temperatures *not* triggering autonomic thermoregulatory responses) is a few tenths of a degree centigrade.[7] This range is bounded by the sweating threshold at its upper end and by vasoconstriction at the lower end. Because energy cost and nutrients are conserved without excessive autonomic control within this range, some animals such as camels and desert rats use this strategy extensively, thus allowing core temperature changes up to 10° C each day. However, most mammals—including humans—normally regulate core temperature tightly.

Both sweating and vasoconstriction thresholds are 0.3° C to 0.5° C higher in women than in men, even during the follicular phase of the monthly cycle (first 10 days).[8] Differences are even greater during the luteal phase.[9] Although central thermoregulatory control is apparently intact even in premature infants,[10] thermoregulatory control may be impaired in older adults.[11]

EFFERENT RESPONSES

The body responds to thermal perturbations (body temperatures differing from the appropriate threshold) via effector mechanisms that increase metabolic heat production or alter environmental heat loss. Each thermoregulatory effector has its own threshold and gain, so an orderly progression of responses and response intensities occurs in proportion to need. In general, energy-efficient effectors such as vasoconstriction are maximized before metabolically costly responses such as shivering are initiated. Figure 54-2 shows the normal values for the major autonomic response thresholds.

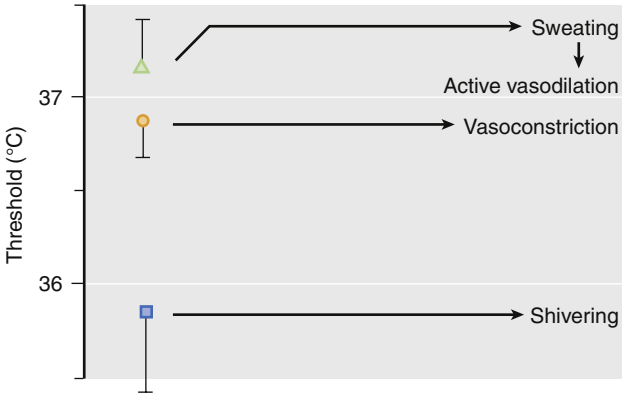

Figure 54-2. A core temperature lower than the thresholds for response to cold provokes vasoconstriction, nonshivering thermogenesis, and shivering. Core temperature exceeding the hyperthermic thresholds produces active vasodilation and sweating. No thermoregulatory responses are initiated when core temperature is between the sweating and vasoconstriction thresholds; these temperatures identify the interthreshold range. The interthreshold range in humans is usually only approximately 0.2° C. *(Threshold data from Lopez M, Sessler DI, Walter K, et al: Rate and gender dependence of the sweating, vasoconstriction, and shivering thresholds in humans,* Anesthesiology *80:780-788, 1994.)*

Effectors determine the ambient temperature range that the body will tolerate while maintaining a normal core temperature. When specific effector mechanisms are inhibited (e.g., when shivering is prevented by administration of muscle relaxants), the tolerable range is decreased. Still, temperature will remain normal unless other effectors cannot compensate for the imposed stress. Quantitatively, *behavioral regulation* is the most important effector mechanism. Behavioral compensations include dressing appropriately, modifying environmental temperature, assuming positions that appose skin surfaces, and moving voluntarily.

Infants regulate their temperatures remarkably well. In contrast, advanced age, infirmity, or medications can diminish the efficacy of thermoregulatory responses and increase the risk of hypothermia. For example, decreased muscle mass, neuromuscular diseases, and muscle relaxants all inhibit shivering and thereby increase the minimum tolerable ambient temperature. Similarly, anticholinergic drugs inhibit sweating,[12] and this decreases the maximum tolerable temperature.

Cutaneous vasoconstriction is the most consistently used autonomic effector mechanism. Metabolic heat is lost primarily via convection and radiation from the skin surface, and vasoconstriction reduces this loss. Total digital skin blood flow is divided into nutritional (mostly capillary) and thermoregulatory (mostly arteriovenous shunt) components.[13] The arteriovenous shunts are anatomically and functionally distinct from the capillaries supplying nutritional blood to the skin (hence vasoconstriction does not compromise the needs of peripheral tissues). Shunts are typically 100 μm in diameter, which means that one shunt can convey 10,000-fold as much blood as a comparable length of capillary 10 μm in diameter.

Control of blood flow through the arteriovenous shunts tends to be "on" or "off." In other words, the gain of this response is high with digital flow increasing from trivial to maximal levels over core temperature changes of only a few tenths of a degree centigrade. Local α-adrenergic sympathetic nerves mediate constriction in the thermoregulatory arteriovenous shunts, and flow is minimally affected by *circulating* catecholamines. Roughly 10% of cardiac output traverses arteriovenous shunts; consequently, shunt vasoconstriction increases mean arterial pressure approximately 15 mm Hg.[14]

Nonshivering thermogenesis increases metabolic heat production (measured as whole-body oxygen consumption) without producing mechanical work. It doubles heat production in infants,[15] but increases it only slightly in adults.[16] The intensity of nonshivering thermogenesis increases in linear proportion to the difference between mean body temperature and its threshold. Skeletal muscle and brown fat tissue are the major sources of nonshivering heat in adults. The metabolic rate in both tissues is controlled primarily by norepinephrine release from adrenergic nerve terminals and is further mediated locally by an uncoupling protein.[17]

Sustained shivering augments metabolic heat production by 50% to 100% in adults. This increase is small compared with that produced by exercise (which can, at least briefly, increase metabolism by 500%) and is thus surprisingly ineffective. Shivering does not occur in newborn infants and probably is not fully effective until children are several years old. The rapid tremor (≤250 Hz) and unsynchronized muscular activity of thermogenic shivering suggest no central oscillator. However, superimposed on the fast activity is usually a slow (four to eight cycles/minute), synchronous "waxing-and-waning" pattern that presumably is centrally mediated.[18]

Sweating is mediated by postganglionic, cholinergic nerves.[19] It thus is an active process that is prevented by nerve block or atropine administration.[20] Even untrained individuals can sweat up to 1 L/hour, and athletes can sweat at twice that rate. Sweating is the only mechanism by which the body can dissipate heat in an environment exceeding core temperature. Fortunately, the process is remarkably effective, dissipating 0.58 kcal/g of evaporated sweat.

Active vasodilation is apparently mediated by nitric oxide.[21,22] Because active vasodilation requires intact sweat gland function, it also is largely inhibited by nerve block. During extreme heat stress, blood flow through the top millimeter of skin can reach 7.5 L/minute—equaling the entire resting cardiac output.[23] The threshold for active vasodilation usually is similar to the sweating threshold, but the gain may be less. Consequently, maximum cutaneous vasodilation usually is delayed until core temperature is clearly higher than that provoking maximum sweating intensity.

THERMOREGULATION DURING GENERAL ANESTHESIA

Behavioral regulation is not relevant during general anesthesia because patients are unconscious and frequently paralyzed. All general anesthetics tested thus far markedly impair normal autonomic thermoregulatory control. Anesthetic-induced impairment has a specific form: warm-response thresholds are elevated slightly, whereas cold-response

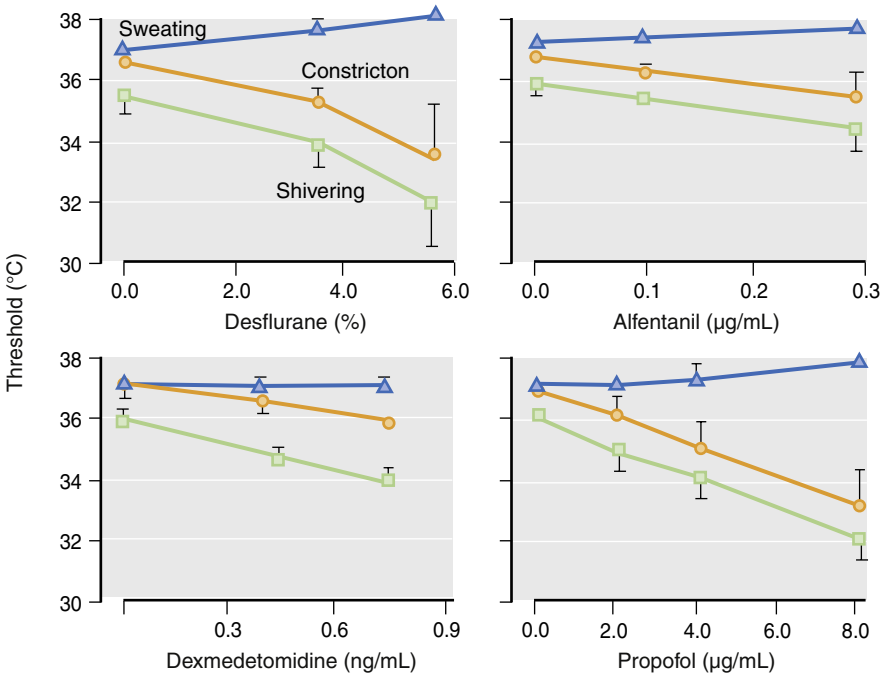

Figure 54-3. The major autonomic thermoregulatory response thresholds in volunteers given desflurane, alfentanil, dexmedetomidine, or propofol. All the anesthetics slightly increase the sweating threshold (triggering core temperature) while markedly and synchronously decreasing the vasoconstriction and shivering thresholds. Standard deviation bars smaller than the data markers have been deleted. *(Data from references 24 to 27.)*

thresholds are markedly reduced. Consequently, the interthreshold range is increased from its normal values near 0.3° C to approximately 2° C to 4° C.[24-28] The gain and maximum intensity of some responses remain normal, [8] whereas other responses are reduced by general anesthesia.[29,30]

RESPONSE THRESHOLDS

Propofol,[24] alfentanil,[25] and dexmedetomidine[26] all produce a slight, linear increase in the sweating threshold combined with a marked and linear decrease in the vasoconstriction and shivering thresholds. Isoflurane[28] and desflurane[27] also slightly increase the sweating threshold; however, they decrease the cold-response thresholds nonlinearly. Consequently, the volatile anesthetics inhibit vasoconstriction and shivering less than propofol at low concentrations, but more than propofol at typical anesthetic doses. In all cases (except after meperidine[31] and nefopam[32] administration), vasoconstriction and shivering decrease synchronously and maintain their normal approximate 1° C difference.

The dose-dependent response thresholds for four anesthetic drugs are shown in Figure 54-3. The combination of increased sweating thresholds and reduced vasoconstriction thresholds increases the interthreshold range approximately 20-fold, from its normal value near 0.2° C to approximately 2° C to 4° C. Temperatures within this range do *not* trigger thermoregulatory defenses; by definition, patients are poikilothermic within this temperature range.

Isoflurane,[28] desflurane,[27,29] enflurane,[33] halothane,[34] and the combination of nitrous oxide and fentanyl[35] decrease the vasoconstriction threshold 2° C to 4° C from its normal value near approximately 37° C. The dose dependence is nonlinear (i.e., greater concentrations produce disproportionate threshold reductions). The shivering thresholds decrease synchronously. In contrast, these drugs increase the sweating threshold only slightly.

Clonidine synchronously decreases cold-response thresholds,[36] while slightly increasing the sweating threshold.[37] Nitrous oxide decreases the vasoconstriction[38] and shivering[39] thresholds less than equipotent concentrations of volatile anesthetics. In contrast, midazolam only slightly impairs thermoregulatory control.[40,41] Painful stimulation slightly increases vasoconstriction thresholds[33]; consequently, thresholds are somewhat lower when surgical pain is prevented by simultaneous local or regional anesthesia.

RESPONSES IN INFANTS AND OLDER ADULTS

Thermoregulatory vasoconstriction is comparably impaired in infants, children, and adults given isoflurane[42] or halothane[43] (Fig. 54-4). In contrast, the vasoconstriction threshold is approximately 1° C less in patients 60 to 80 years old than in those between 30 and 50 years old (Fig. 54-5).[44,45]

Nonshivering thermogenesis does not occur in anesthetized adults.[46] This finding is unsurprising because this response is not particularly important in unanesthetized adults.[16] In contrast to adult humans, nonshivering thermogenesis is an important thermoregulatory response in animals and human infants. However, nonshivering thermogenesis in animals is inhibited by volatile anesthetics,[47] and it fails to increase the metabolic rate in infants anesthetized with propofol (Fig. 54-6).[48]

GAIN AND MAXIMUM RESPONSE INTENSITY

Both the gain and maximum intensity of sweating remain normal during isoflurane[8] and enflurane anesthesia.[49] However, the gain of arteriovenous shunt vasoconstriction is reduced threefold during desflurane anesthesia

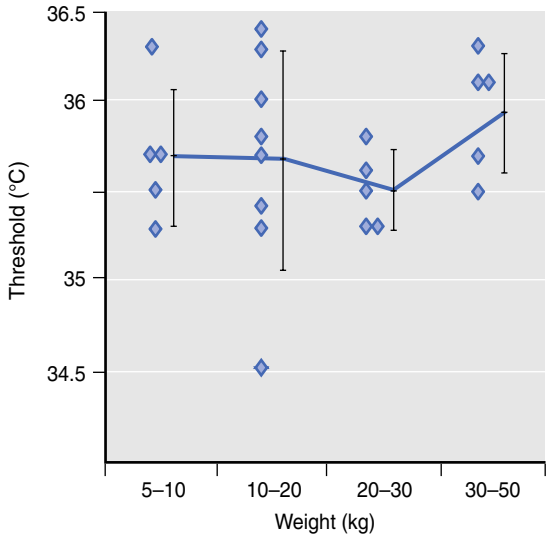

Figure 54-4. The core thermoregulatory threshold in 23 healthy children and infants undergoing abdominal surgery with halothane anesthesia. Differences among the groups are not statistically significant. Results are presented as means ± SDs. *(From Bissonnette B, Sessler DI: Thermoregulatory thresholds for vasoconstriction in pediatric patients anesthetized with halothane or halothane and caudal bupivacaine,* Anesthesiology *76:387-392, 1992.)*

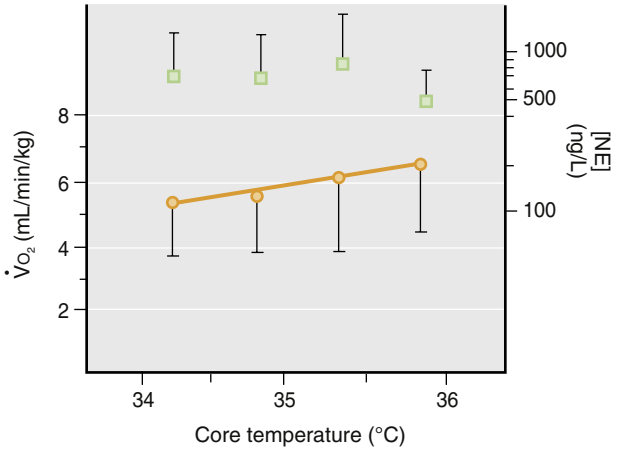

Figure 54-6. Progressive reduction in core temperature did not trigger an increase in oxygen consumption ($\dot{V}O_2$) that may indicate nonshivering thermogenesis. Instead, hypothermia decreased systemic VO_2: $\dot{V}O_2$ = 0.83 (Core Temperature) – 23.3; r^2 = 0.92. Intraoperative plasma norepinephrine (NE) concentrations were variable, but they did not change significantly as a function of core temperature (squares). Data are presented as means ± SD. *(From Plattner O, Semsroth M, Sessler DI, et al: Lack of nonshivering thermogenesis in infants anesthetized with fentanyl and propofol,* Anesthesiology *86: 772-777, 1997.)*

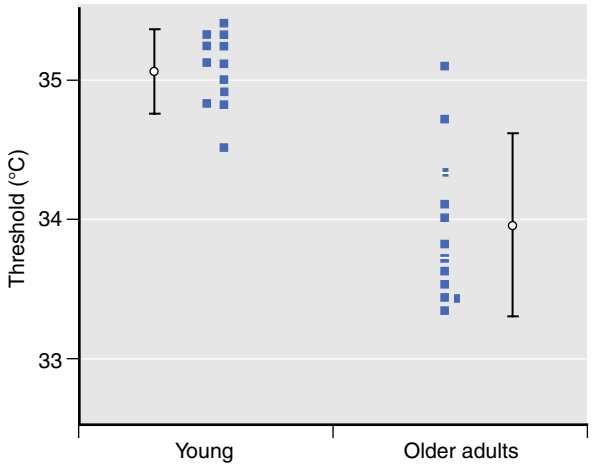

Figure 54-5. The vasoconstriction threshold was significantly less in the older adults (33.9 ± 0.6° C) than in younger patients (35.1 ± 0.3° C) during 60% nitrous oxide and isoflurane (0.75% end-tidal concentration). *Filled squares* indicate the vasoconstriction threshold in each patient; *open circles* show the mean and standard deviation in each group. *(From Kurz A, Plattner O, Sessler DI, et al: The threshold for thermoregulatory vasoconstriction during nitrous oxide/isoflurane anesthesia is lower in elderly than young patients,* Anesthesiology *79:465-469, 1993.)*

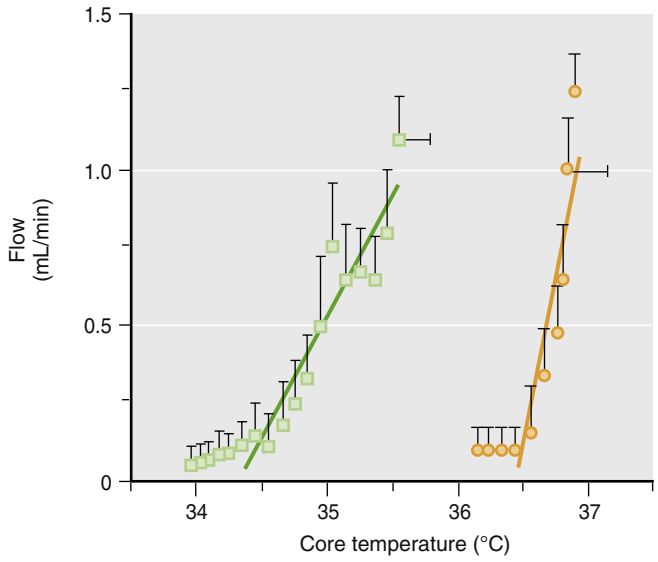

Figure 54-7. Finger blood flow without (*circles*) and with (*squares*) desflurane administration. Values were computed relative to the thresholds (finger flow = 1.0 mL/min) in each subject. Flows of exactly 1.0 mL/min are not shown because flows in each individual were averaged over 0.1° C or 0.05° C increments; each data point thus includes both higher and lower flows. The horizontal standard deviation bars indicate variability in the thresholds among the volunteers; although errors bars are shown only at a flow near 1.0 mL/min, the same temperature variability applies to each data point. The slopes of the flow versus core temperature relationships (1.0 to ≈0.15 mL/min) were determined using linear regression. These slopes defined the gain of vasoconstriction with and without desflurane anesthesia. Gain was reduced by a factor of three, from 2.4 to 0.8 mL/min/°C^{-1} ($P < 0.01$). *(From Kurz A, Xiong J, Sessler DI, et al: Desflurane reduces the gain of thermoregulatory arterio-venous shunt vasoconstriction in humans,* Anesthesiology *83:1212-1219, 1995.)*

(Fig. 54-7),[29] even though the maximum vasoconstriction intensity remains normal.[50]

Shivering is rare during surgical doses of general anesthesia. This finding is consistent with the shivering threshold being roughly 1° C less than the vasoconstriction threshold.[24-28] (Vasoconstriction usually prevents additional hypothermia,[51] so even unwarmed patients rarely become cold enough to shiver.) Nonetheless, shivering can be induced by sufficient active cooling.

Gain and maximum shivering intensity remain normal during both meperidine and alfentanil administration.[52]

Gain also remains nearly intact during nitrous oxide administration, although maximum intensity is reduced.[53] Isoflurane changes the macroscopic pattern of shivering to such an extent that it is no longer possible to determine gain easily. The drug does, however, reduce maximum shivering intensity.[30]

Sweating is the best preserved major thermoregulatory defense during anesthesia. Not only is the threshold only slightly increased, but the gain and maximum intensity remain normal. In contrast, the thresholds for vasoconstriction and shivering are markedly reduced, and furthermore, the efficacy of these responses is diminished even after being activated.

DEVELOPMENT OF HYPOTHERMIA DURING GENERAL ANESTHESIA

Inadvertent hypothermia is by far the most common perioperative thermal disturbance during anesthesia. Hypothermia results from a combination of anesthetic-impaired thermoregulation and exposure to a cold operating room environment. Of these two causes, however, impaired thermoregulation is much more important.

HEAT TRANSFER

Heat can be transferred from a patient to the environment four ways: (1) radiation, (2) conduction, (3) convection, and (4) evaporation. Among these, radiation and convection contribute most to perioperative heat loss.

All surfaces with a temperature higher than absolute zero radiate heat; similarly, all surfaces absorb radiative heat from surrounding surfaces. Heat transfer via this mechanism is proportional to the difference of the fourth power of the absolute temperature difference between the surfaces. It is likely that radiation is the major type of heat loss in most surgical patients.[54]

Conductive heat loss is proportional to the temperature difference between two adjacent surfaces and the strength of the thermal insulation separating them. In general, conductive losses are negligible during surgery because patients usually directly contact only the foam pad (an excellent thermal insulator) covering most operating room tables.

Conductive loss of heat directly to air molecules is limited by development of a layer of still air adjacent to the skin that serves as an insulator. When this layer is disturbed by air currents, the insulative properties diminish substantially, thereby increasing heat loss. This increase is termed convection and is proportional to the square root of air speed; this is the basis of the familiar "wind chill" factor. Air speed in operating rooms—even those with high rates of air turnover—typically is only approximately 20 cm/second, which only slightly increases loss compared with still air. Nonetheless, convective loss usually is the second most important mechanism by which heat is transferred from patients to the environment. Presumably, convective loss increases substantially in operating rooms equipped to provide laminar flow. However, the actual augmentation has not been quantified and may be less than expected from the increase in air speed because surgical draping provides considerable thermal insulation.

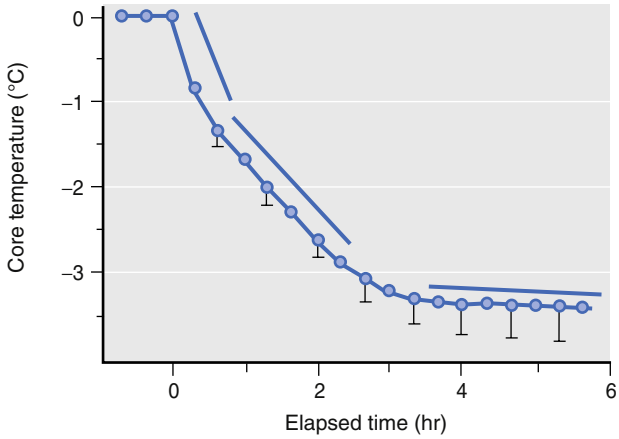

Figure 54-8. Hypothermia during general anesthesia develops with a characteristic pattern. An initial rapid decrease in core temperature results from a core-to-peripheral redistribution of body heat. This is followed by a slow, linear reduction in core temperature that results simply from heat loss exceeding heat production. Finally, core temperature stabilizes and subsequently remains virtually unchanged. This plateau phase may be a passive thermal steady state, or it may result when sufficient hypothermia triggers thermoregulatory vasoconstriction. Results are presented as means ± SDs.

Sweating increases cutaneous evaporative loss immensely, but is rare during anesthesia. In the absence of sweating, evaporative loss from the skin surface is less than 10% of metabolic heat production in adults. In contrast, infants lose a higher fraction of their metabolic heat from transpiration of water through thin skin. The problem becomes especially acute in premature infants, who may lose one fifth of their metabolic heat production via transcutaneous evaporation.[55] Simple thermodynamic calculations and clinical measurements indicate that only trivial amounts of heat are lost from the respiratory system.[56] Evaporation inside surgical wounds may contribute substantially to total heat loss,[57] but this has never been quantified in humans.

PATTERNS OF INTRAOPERATIVE HYPOTHERMIA

Hypothermia during general anesthesia develops with a characteristic pattern. An initial rapid decrease in core temperature is followed by a slow, linear reduction in core temperature. Finally, core temperature stabilizes and subsequently remains virtually unchanged (Fig. 54-8). Each section of this typical pattern has a different etiology.

Volatile anesthetics cause vasodilation via a direct peripheral action.[58] More importantly, they also inhibit tonic thermoregulatory vasoconstriction, resulting in arteriovenous shunt dilation.[24-28] Nonetheless, anesthetic-induced vasodilation increases cutaneous heat loss only slightly.[59] Anesthetics reduce the metabolic rate 20% to 30%.[60] However, even the combination of increased heat loss and reduced heat production is insufficient to explain the 0.5° C to 1.5° C decrease in core temperature usually observed during the first hour of anesthesia.

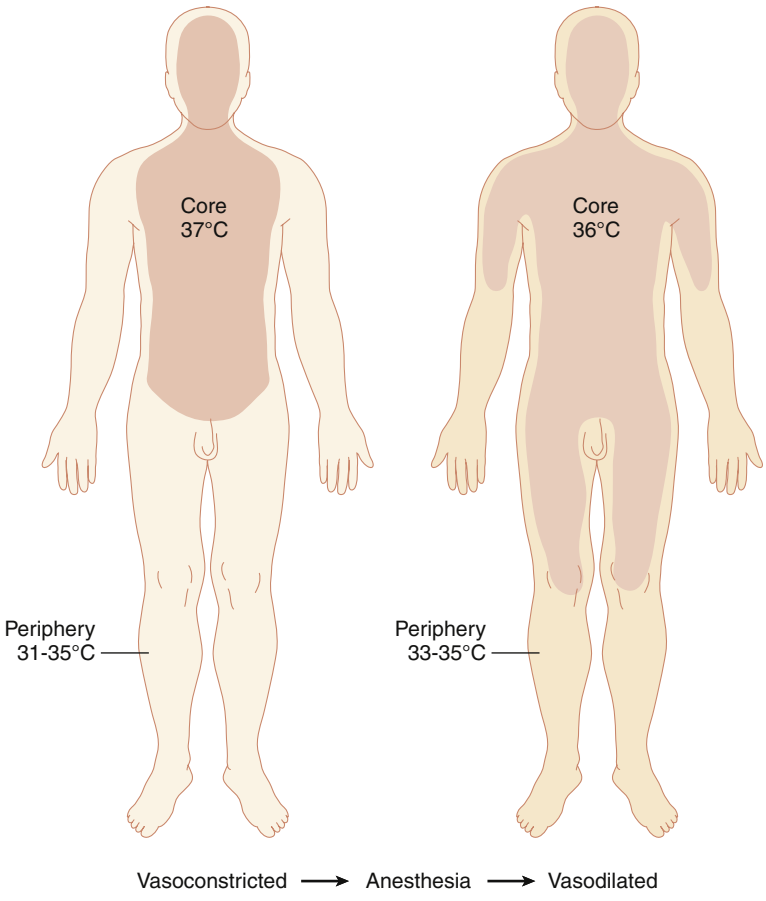

Figure 54-9. A drawing illustrating internal redistribution of body heat following induction of general anesthesia. Hypothermia following induction of spinal or epidural anesthesia results similarly, but redistribution is restricted to the legs.

The key to understanding the initial decrease in core temperature is to appreciate that body heat is not normally evenly distributed. Core temperature represents only approximately half the body mass (mostly the trunk and head); the remaining mass is typically 2° C to 4° C cooler than the core. This core-to-peripheral tissue temperature gradient is normally maintained by tonic thermoregulatory vasoconstriction. Anesthetic-induced vasodilation, however, allows core heat to flow peripherally. This flow warms the arms and legs, but it does so at the expense of the core (Figs. 54-9 and 54-10).[61] The extent to which redistribution reduces core temperature depends on the core-to-peripheral tissue temperature gradient at the time of induction. This gradient, in turn, depends on the patient's prior thermal environment and thermoregulatory status, both of which are difficult to determine clinically.

Following initial redistribution hypothermia, core temperature usually decreases in a slow, linear fashion for 2 to 4 hours. This reduction results simply from heat loss exceeding metabolic heat production,[62] and the rate at which core temperature decreases depends on the difference and size of the patient. After 3 to 4 hours of anesthesia, core temperature usually reaches a plateau and remains virtually constant for the duration of surgery.[35] The core temperature plateau may simply represent a thermal steady state (heat production equaling heat loss) in patients who remain relatively warm.[63] In others, however, the plateau phase is associated with peripheral thermoregulatory vasoconstriction triggered by core temperatures of 33° C to 35° C.[64]

Thermoregulatory vasoconstriction during anesthesia decreases cutaneous heat loss,[50] but this decrease alone is usually insufficient to produce a thermal steady state. Furthermore, neither adults[46] nor infants[48] appear able to increase intraoperative heat production in response to hypothermia. An additional mechanism must therefore contribute to the core temperature plateau. Evidence suggests that a primary factor is constraint of metabolic heat to the core thermal compartment. In this situation, distribution of metabolic heat (which largely is produced centrally) is restricted to the core compartment, thus maintaining its temperature. Peripheral tissue temperature, in contrast, continues to decrease because it is no longer being supplied with sufficient heat from the core.[51] A core temperature plateau resulting from thermoregulatory vasoconstriction is not a thermal steady state, and body heat content continues to decrease even though core temperature remains nearly constant.

NEURAXIAL ANESTHESIA

Autonomic thermoregulation is impaired during regional anesthesia, and the result typically is intraoperative core hypothermia. This hypothermia often is not consciously perceived by patients, but nonetheless triggers shivering.

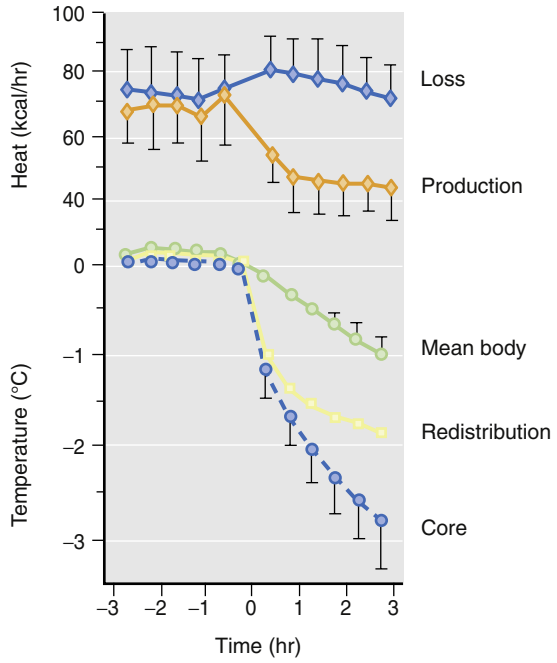

Figure 54-10. Changes in body heat content and distribution of heat within the body during induction of general anesthesia (at elapsed time zero). The change in mean body temperature was subtracted from the change in core (tympanic membrane) temperature, thereby leaving the core hypothermia specifically resulting from redistribution. Redistribution hypothermia was thus not a measured value; instead, it is defined by the decrease in core temperature not explained by the relatively small decrease in systemic heat content. After 1 hour of anesthesia, core temperature had decreased 1.6 ± 0.3° C, with redistribution contributing 81% to the decrease. Even after 3 hours of anesthesia, redistribution contributed 65% to the entire 2.8 ± 0.5° C decrease in core temperature. Results are presented as means ± SD. *(Modified from Matsukawa T, Sessler DI, Sessler AM, et al: Heat flow and distribution during induction of general anesthesia,* Anesthesiology *82:662-673, 1995.)*

The result, frequently, is a potentially dangerous clinical paradox: a hypothermic patient who denies feeling cold.

THERMOREGULATION

Epidural[65,66] and spinal[66,67] anesthesia each decrease the thresholds triggering vasoconstriction and shivering (above the level of the block) approximately 0.6° C (Fig. 54-11). Presumably, this decrease does not result from recirculation of neuraxially administered local anesthetic because impairment is similar during epidural and spinal anesthesia,[65-67] although the amount and location of administered local anesthetic differ substantially. Furthermore, lidocaine administered intravenously in doses producing plasma concentrations similar to those occurring during epidural anesthesia has no thermoregulatory effect.[68] Finally, neuraxial administration of 2-chloroprocaine, a local anesthetic with a plasma half-life of only approximately 20 seconds, also impairs thermoregulatory control.[69]

The vasoconstriction and shivering thresholds are comparably decreased during regional anesthesia,[67] a finding suggesting an alteration in central, rather than peripheral, control. The mechanism by which peripheral administration of local anesthesia impairs centrally

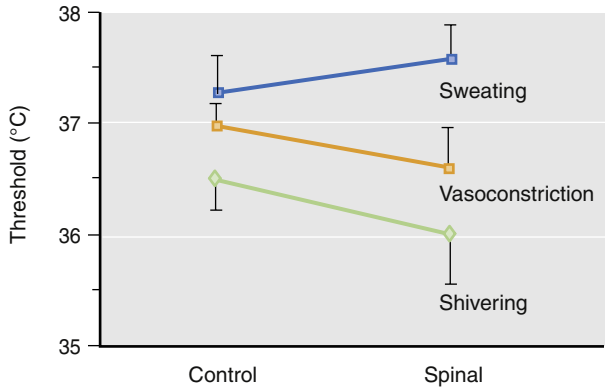

Figure 54-11. Spinal anesthesia increased the sweating threshold but reduced the thresholds for vasoconstriction and shivering. Consequently, the interthreshold range increased substantially. The vasoconstriction-to-shivering range, however, remained normal during spinal anesthesia. Results are presented as means ± SDs. *(From Kurz A, Sessler DI, Schroeder M, Kurz M: Thermoregulatory response thresholds during spinal anesthesia,* Anesth Analg *77:721-726, 1993.)*

mediated thermoregulation may involve alteration of afferent thermal input from the legs. The key factor here is that tonic cold signals dominate thermal input at leg skin temperatures in typical operating room environments.[2,70] Regional anesthesia blocks all thermal input from blocked regions, which in the typical case is primarily cold information. The brain may then interpret decreased cold information as relative leg warming. This appears to be an unconscious process because perceived temperature does not increase.[71] Given that skin temperature is an important input to the thermoregulatory control system, leg warming proportionately reduces the vasoconstriction and shivering thresholds. Consistent with this theory, a leg skin temperature near 38° C is required to produce the reduction in cold-response thresholds in an unanesthetized subject that is produced by regional anesthesia.[72] Furthermore, reduction in the thresholds is proportional to the number of spinal segments blocked (Fig. 54-12). [73] Major conduction anesthesia may thus reduce the vasoconstriction and shivering thresholds by producing an abnormal elevation of *apparent* (as opposed to actual) leg temperature. However, this explanation remains speculative.

Because neuraxial anesthesia prevents vasoconstriction and shivering in blocked regions, it is not surprising that epidural anesthesia decreases the maximum intensity of shivering. However, epidural anesthesia also reduces the gain of shivering, a finding that suggests that the regulatory system is unable to compensate for lower body paralysis (Fig. 54-13).[30] Thermoregulatory defenses, once triggered, are thus less effective than usual during regional anesthesia.

Neuraxial anesthesia is frequently supplemented with sedative and analgesic medications. Most of these drugs significantly impair thermoregulatory control.[25,31,74] Such inhibition may be severe when combined with the intrinsic impairment produced by regional anesthesia and other factors, including advanced age or preexisting illness.[11] Core hypothermia during regional anesthesia may not trigger a perception of cold.[65,75] The reason is

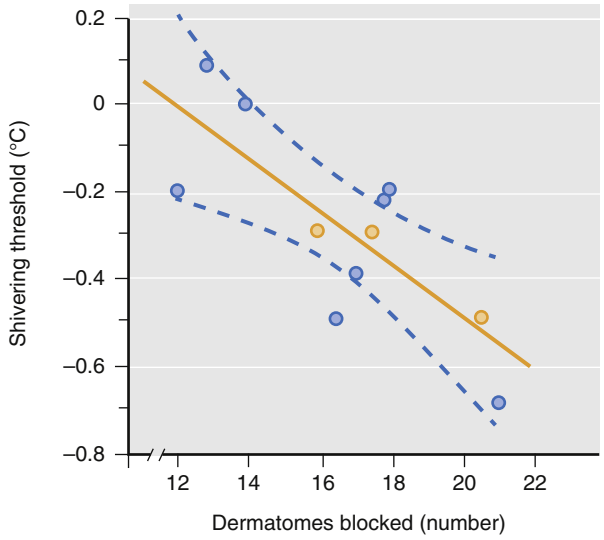

Figure 54-12. The number of dermatomes blocked (sacral segments = 5; lumbar segments = 5; thoracic segments = 12) versus reduction in the shivering threshold (difference between the control shivering threshold and spinal shivering threshold). The shivering threshold was reduced more by extensive spinal blocks than by less extensive ones (Δ threshold = 0.74 − 0.06 (dermatomes blocked); r^2 = 0.58, P <.006). The *dashed lines* indicate the 95% confidence intervals for the slope. *(From Leslie K, Sessler DI: Reduction in the shivering threshold is proportional to spinal block height,* Anesthesiology *84:1327-1331, 1996.)*

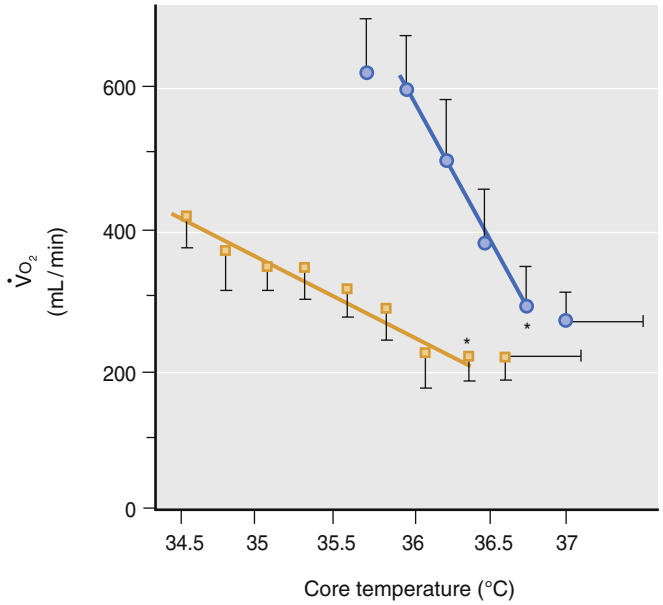

Figure 54-13. Systemic oxygen consumption ($\dot{V}_{O_2}$) without (*circles*) and with (*squares*) epidural anesthesia. The horizontal standard deviation bars indicate variability in the thresholds among the volunteers; although errors bars are shown only once in each series, the same temperature variability applies to each data point. The slopes of the $\dot{V}_{O_2}$ versus core temperature relationships (*solid lines*) were determined using linear regression. These slopes defined the gain of shivering with and without epidural anesthesia. Gain was reduced 3.7-fold, from −412 mL/min/°C (r^2 = 0.99) to −112 mL/min/°C (r^2 = 0.96). *(From Kim J-S, Ikeda T, Sessler D, et al: Epidural anesthesia reduces the gain and maximum intensity of shivering,* Anesthesiology *88:851-857, 1998.)*

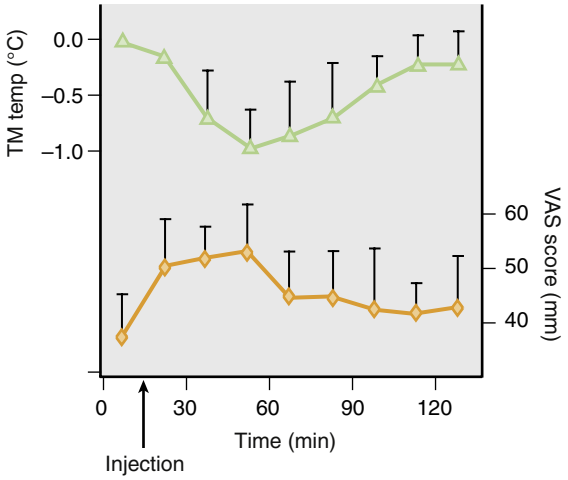

Figure 54-14. Induction of epidural anesthesia at elapsed time 15 minutes decreased core temperature and increased thermal comfort as determined by a 100–mm visual analog scale (VAS). However, maximal thermal comfort coincided with *minimum* core temperature. Results are presented as means ± SDs. *TM,* Tympanic membrane. *(Modified from Sessler DI, Ponte J: Shivering during epidural anesthesia,* Anesthesiology *72:816-821, 1990.)*

that thermal perception (behavioral regulation) is largely determined by skin temperature, rather than core temperature. During regional anesthesia, core hypothermia is accompanied by a real increase in skin temperature. The result typically is a perception of continued or increased warmth accompanied by autonomic thermoregulatory responses including shivering (Fig. 54-14).[65,75] Taken together, these data indicate that neuraxial anesthesia inhibits numerous aspects of thermoregulatory control. The vasoconstriction and shivering thresholds are reduced by regional anesthesia,[65-67,72,73] and they are further reduced by adjuvant drugs[25,40] and advanced age.[11] Even once triggered, the gain and maximum response intensity of shivering are approximately half normal.[76] Finally, behavioral thermoregulation is impaired.[75] The result is that cold defenses are triggered at a lower temperature than normal during regional anesthesia, defenses are less effective once triggered, and patients frequently do not recognize that they are hypothermic. Because core temperature monitoring remains rare during regional anesthesia, substantial hypothermia often goes undetected in these patients.[77]

HEAT BALANCE

Hypothermia is common during regional anesthesia and may be nearly as severe as during general anesthesia.[78] Core temperature typically decreases 0.5° C to 1.0° C shortly after induction of anesthesia. However, vasodilation induced by regional anesthesia only slightly increases cutaneous heat loss. Furthermore, metabolic heat production remains constant or increases because of shivering thermogenesis. This rapid decrease in core temperature, similar to the one that follows induction of general anesthesia, also results from an internal core-to-peripheral redistribution of body heat.[79] As during general anesthesia,[80,81] redistribution hypothermia

during regional anesthesia can be minimized by cutaneous warming before induction.[82]

Subsequent hypothermia results simply from heat loss exceeding metabolic heat production. Unlike patients given general anesthesia, however, core temperature does not necessarily plateau after several hours of surgery. Not only is the vasoconstriction threshold centrally impaired by regional anesthesia,[66,67] but more importantly, vasoconstriction in the legs is directly prevented by nerve block.[83,84] Because the legs constitute the bulk of the peripheral thermal compartment, an effective plateau cannot develop without vasoconstriction in the legs and the resulting decrease in cutaneous heat loss and constraint of metabolic heat to the core.

The importance of intraoperative leg vasoconstriction is illustrated during combined regional and general anesthesia. Consistent with the impairment of thermoregulatory responses with regional anesthesia alone,[66,67] vasoconstriction during combined regional and general anesthesia is triggered at a core temperature approximately 1° C less than during general anesthesia alone. Furthermore, vasoconstriction, once triggered, produces a core temperature plateau during general anesthesia alone but not during combined regional and general anesthesia. The result is that core temperature during combined regional and general anesthesia continues to decrease throughout surgery.[85] Consequently, core temperature monitoring and thermal management are especially important in patients given simultaneous regional and general anesthesia.

SHIVERING

Shivering-like tremor, so typical in neuraxial anesthesia, is preceded by core hypothermia and vasoconstriction (above the level of the block).[65] Furthermore, electromyographic analysis indicates that the tremor has the waxing-and-waning pattern of four to eight cycles/minute that characterizes normal shivering.[69] The tremor thus apparently is normal thermoregulatory shivering, triggered when redistribution hypothermia decreases core temperature.

Spinal thermal receptors have been detected in every mammal and bird tested. Experimental stimulation of these receptors reliably produces shivering in animals. Stimulation in humans of these putative receptors by epidural anesthetic injection theoretically could initiate thermoregulatory responses, including shivering. However, epidural administration of large amounts of ice-cold saline does not trigger shivering in volunteers.[86] Furthermore, the incidence of shivering is comparable in volunteers[65] and patients[87] given warm or cold epidural anesthetic injections. These data indicate that temperature of injected local anesthetic does not influence the incidence of shivering during major conduction anesthesia.

The risk of shivering during neuraxial anesthesia is markedly diminished by maintaining strict normothermia.[65] However, a distinct incidence of low-intensity, shivering-like tremor occurs in normothermic patients and is not thermoregulatory.[88] The cause of this muscular activity remains unknown. However, it is associated with pain,[89] and it may thus result from sympathetic nervous system activation (Fig. 54-15).

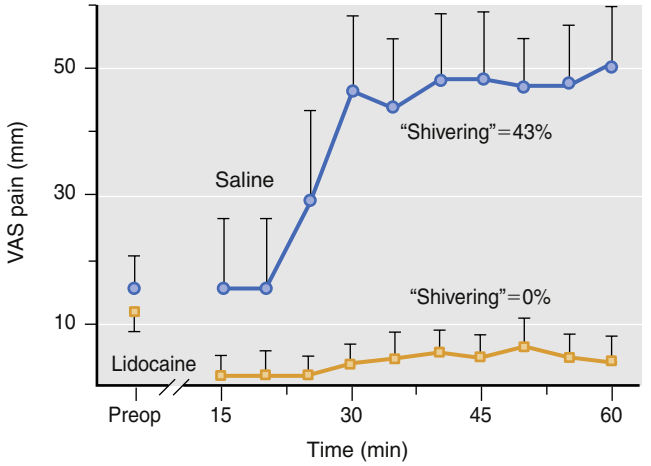

Figure 54-15. Visual analog pain scores (VAS) in normothermic patients given intraarticular lidocaine or saline after knee surgery. Pain was assessed postoperatively by an investigator blinded to the group assignment. Time zero indicates discontinuation of anesthesia. Data are presented as mean ± SD. Patients receiving a local anesthetic block (lidocaine) had significantly less postoperative pain than did those given saline; all values after 10 elapsed minutes differed significantly in the two groups. Shivering-like tremor was observed in 43% more of the patients given saline than those given lidocaine, a finding indicating that the tremor is related to pain. *(From Horn E-P, Schroeder F, Wilhelm S, et al: Postoperative pain facilitates non-thermoregulatory tremor,* Anesthesiology *91:979-984, 1999.)*

Shivering during neuraxial anesthesia can sometimes be treated by warming sentient skin. This approach augments cutaneous thermal input to the central regulatory system and thus increases the degree of tolerated core hypothermia.[90] Because the entire skin surface contributes 20% to thermoregulatory control,[5] and the lower body contributes approximately 10%,[72] sentient skin warming is likely to compensate for only small reductions in core temperature. The same drugs that are effective for postanesthetic tremor also are useful for shivering during regional anesthesia: these include meperidine (25 mg intravenously [IV] or epidurally),[91] clonidine (75 μg IV),[92] dexmedetomine,[93] ketanserin (10 mg IV),[92] and magnesium sulfate (30 mg/kg IV).[94]

CONSEQUENCES OF MILD INTRAOPERATIVE HYPOTHERMIA

Perianesthetic hypothermia produces potentially severe complications, as well as distinct benefits. Thermal management thus deserves the same thoughtful analysis of potential risks and benefits as other therapeutic decisions.

BENEFITS

Substantial protection against cerebral ischemia and hypoxia is provided by just 1° C to 3° C of hypothermia in animals.[95,96] Protection initially was thought to result from the approximate 8%/°C linear reduction in tissue metabolic rate. However, the efficacy of mild hypothermia far exceeds that of treatments such as high-dose isoflurane or barbiturate coma, which comparably reduce the metabolic rate.[97]

These data suggest that other actions (e.g., decreased release of excitatory amino acids) explain the protective action of hypothermia.[98] As such, no reason exists to expect protection to decrease linearly with temperature, and in animals, it appears that much of the total benefit from moderate hypothermia occurs within the first couple of degrees.

As could be expected from in vitro and animal studies, therapeutic hypothermia has twice been shown to improve outcomes from out-of-hospital cardiac arrest.[99,100] Rapid induction of hypothermia is thus becoming routine for patients after recovery from cardiac arrest. The other situation in which therapeutic hypothermia appears beneficial is in asphyxiated neonates.[101-103]

The potential protection afforded by mild hypothermia is so great that reduced core temperature (i.e., ≈34° C) is sometimes used during neurosurgery and other procedures in which tissue ischemia can be anticipated. The difficulty is that few outcome data are available to substantiate extrapolation from animal data to clinical practice. Furthermore, the appropriate target temperature for therapeutic hypothermia has yet to be established.

The Brain

Hypothermia for brain trauma was initially claimed to be therapeutic based on a post hoc subgroup analysis of a study that overall showed no benefit.[104] A subsequent large randomized trial was unable to demonstrate any benefit overall or in subgroups, although interpretation of the study was limited by violations in the fluid administration protocol in some patients.[105] More recently, hypothermia was shown to be beneficial in a nonrandomized study in which patients with brain trauma who had elevated intracranial pressure refractory to conventional treatment were assigned to therapeutic hypothermia. Despite being sicker than the comparison patients (who had low intracranial pressure), the hypothermic patients demonstrated improved outcome.[106] Small nonrandomized series suggested that mild hypothermia could improve the outcome from stroke.[107] A small feasibility trial for treatment of stroke with hypothermia has been published,[108] but no large trial is currently even in progress. Although initial feasibility trials were encouraging,[108,109] a subsequent large outcome trial failed to demonstrate any improvement caused by therapeutic hypothermia in patients having surgery for subarachnoid hemorrhage.[110] This result was especially disappointing because surgery is one of the few circumstances in humans when hypothermia can be instituted before the onset of ischemia.

The Heart and Other Organs

Hypothermic protection against ischemia may extend to other organs. For example, mild hypothermia markedly reduced infarct size in experimental acute myocardial infarction in human-sized pigs,[111] and a preliminary study in patients was encouraging.[112] However, a subsequent major outcome trial in humans failed to demonstrate convincing benefit (unpublished).

Acute malignant hyperthermia is more difficult to trigger in mildly hypothermic swine than in those kept normothermic. Furthermore, once triggered, the syndrome is less severe.[113,114] These data suggest that active warming should be avoided in patients known to be susceptible to malignant hyperthermia; instead, these patients should be allowed to become slightly hypothermic during surgery.

Limitations of most therapeutic hypothermia studies are that cooling began well after the ischemic insult, and patients typically took many hours to cool. It thus remains possible that benefit will yet be identified in future studies that initiate hypothermia earlier and use more recently developed systems to cool patients faster. Table 54-1 lists selected major studies that evaluated the potential benefits of mild perioperative hypothermia.

TABLE 54-1 POTENTIAL BENEFITS OF MILD PERIOPERATIVE HYPOTHERMIA IN HUMANS*

Consequence	First Author	Yr	*N*	ΔT_{core} (° C)	Normothermic	Hypothermic	*P*
Mortality after brain trauma	Clifton[105]	2001	392	4.2	27%	28%	NS

ADVERSE EFFECTS OF HYPOTHERMIA

Coagulation is impaired by mild hypothermia. The most important factor appears to be a cold-induced defect in platelet function.[115] The defect in platelet function is related to local temperature, not core temperature.[116] Wound temperature, however, is largely determined by core temperature and is distinctly higher in normothermic patients. Perhaps as importantly, hypothermia directly impairs enzymes of the coagulation cascade. This is not apparent during routine coagulation screening because the tests are performed at 37° C. When these tests are performed at hypothermic temperatures, however, the defect becomes apparent.[117]

Consistent with these in vitro defects, nearly all randomized trials indicate that mild hypothermia increases blood loss during hip arthroplasty and increases allogeneic transfusion requirements.[118-131] Similarly, nearly all randomized trials report an increased transfusion requirement in hypothermic patients.[118-120,122-125,130-132] Meta-analyses indicate that both blood loss (Fig. 54-16) and transfusion requirement (Fig. 54-17) are significantly

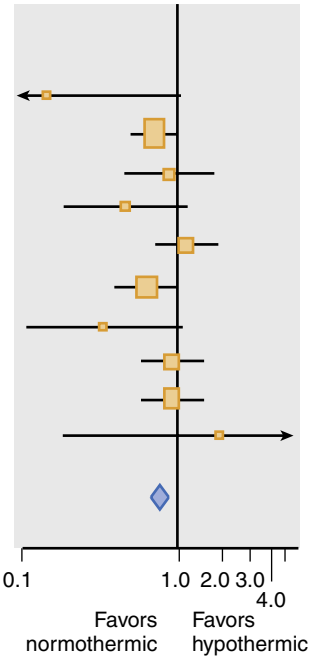

Figure 54-17. Transfusion meta-analysis and forest plot. Treatment effect expressed as the relative risk of transfusion in normothermic versus hypothermic patients. Normothermia is associated with 22% less risk of transfusion than hypothermia (95% confidence interval [CI], 3%, 37%; $P = .027$). *(From Rajagopalan S, Mascha E, Na J, Sessler DI: The effects of mild perioperative hypothermia on blood loss and transfusion requirement: a meta-analysis,* Anesthesiology *108:71-77, 2008.)*

increased by hypothermia.[133] The treatment effect is substantial with just 1° C of core hypothermia increasing each complication by approximately 20%.

Drug metabolism is markedly decreased by perioperative hypothermia. The duration of action of vecuronium is more than doubled by a 2° C reduction in core temperature (Fig. 54-18), and the prolongation is a pharmacokinetic effect, not a pharmacodynamic one.[134] Atracurium duration is less dependent on core temperature: a 3° C reduction in core temperature increases the duration of muscle relaxation only by 60%.[135] With each drug, the recovery index (time for 25% to 75% twitch recovery) remains normal during hypothermia. Core hypothermia per se decreases twitch strength 10% to 15%, even without muscle relaxants.[136] The efficacy of neostigmine as an antagonist of vecuronium-induced neuromuscular block is not altered by mild hypothermia, although onset time is approximately 20% longer.[137] The effects of temperature on muscle relaxants and antagonism of neuromuscular blocks was reviewed by Heier and Caldwell.[138]

During a constant infusion of propofol, plasma concentration is approximately 30% greater than normal when individuals are 3° C hypothermic.[135] The effects of mild hypothermia on the metabolism and pharmacodynamics of most other drugs has yet to be reported. However, the results for muscle relaxants and propofol suggest that the effects are substantial. Hypothermia also alters the pharmacodynamics of the volatile anesthetics, thus reducing minimum alveolar concentration (MAC) approximately 5%/°C.[139] Consequently, no anesthesia whatsoever is required to prevent movement in response to skin incision at core temperatures lower than 20° C.[140] As could be expected from the pharmacokinetic and pharmacodynamic effects of hypothermia, the duration of postanesthetic recovery is significantly prolonged—even when temperature is not a discharge criterion. When "fitness for discharge" and a core temperature exceeding 36° C are required (as in many postanesthesia care units), recovery duration is prolonged by several hours.[141]

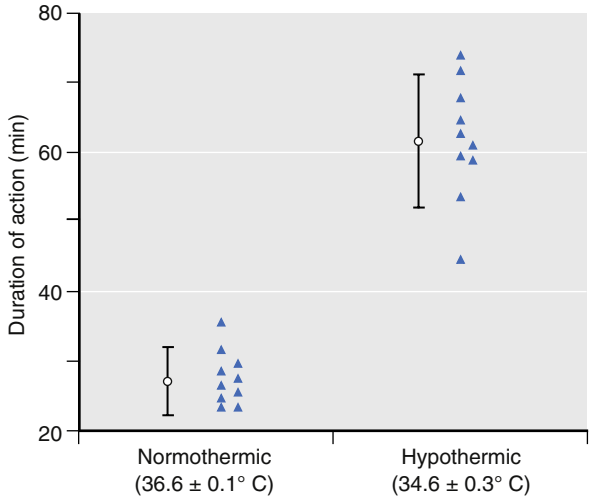

Figure 54-18. Just 2° C reduction in core temperature more than doubled the duration of action of vecuronium. *(From Heier T, Caldwell JE, Sessler DI, Miller RD: Mild intraoperative hypothermia increases duration of action and spontaneous recovery of vecuronium blockade during nitrous oxide-isoflurane anesthesia in humans,* Anesthesiology *74:815-819, 1991.)*

Wound infections are among the most common serious complications of anesthesia and surgery, and they probably cause more morbidity than all other anesthetic complications combined.[142] Hypothermia can contribute to wound infections both by directly impairing immune function[143] and by triggering thermoregulatory vasoconstriction that, in turn, decreases wound oxygen delivery.[144] It is well established that fever is protective and that infections are aggravated when naturally occurring fever is prevented.[145] Similarly, mild hypothermia, maintained only during anesthesia, impairs subsequent resistance to both *Escherichia coli* and *Staphylococcus aureus* dermal infections in guinea pigs.[146,147] As could be expected from these in vitro and animal data, a prospective, randomized clinical trial indicated that mild intraoperative hypothermia tripled the incidence of surgical wound infection in patients undergoing colon surgery. Furthermore, hypothermia delayed wound healing and prolonged the duration of hospitalization 20% even in patients without infection.[132] Consistent with poor wound healing, urinary nitrogen excretion remains elevated for several postoperative days in patients allowed to become hypothermic during surgery.[148]

Thermal comfort is markedly impaired by postoperative hypothermia; this feeling persists for several hours in patients who are several degrees centigrade hypothermic at the beginning of recovery (Fig. 54-19).[149] Patients, asked years after surgery, often identify feeling cold in the immediate postoperative period as the worst part of their hospitalization—sometimes rating it worse than surgical pain. Postoperative thermal discomfort is also physiologically stressful, by elevating blood pressure, heart rate, and plasma catecholamine concentrations.[150,151] These factors presumably contribute to what may be the

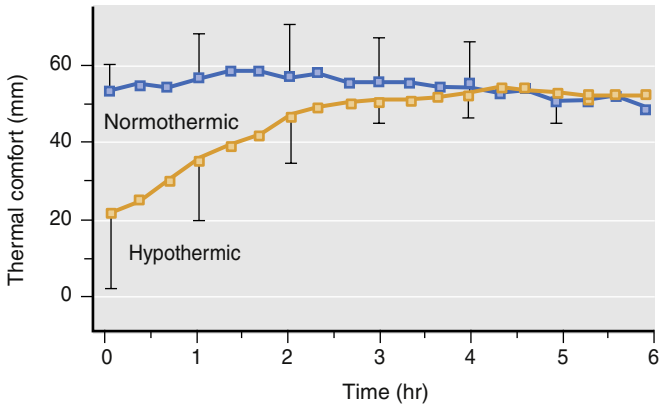

Figure 54-19. Patients who started recovery approximately 2° C hypothermic reported feeling unpleasantly cold, and the sensation persisted for more than 2 hours. Only a few of the warmed patients shivered at any time during the recovery period. In contrast, most of the hypothermic patients demonstrated grades 2 or 3 tremor during the first postoperative hour. By the end of the first elapsed hour, however, shivering was rare, even in the hypothermic patients. Error bars indicate standard deviations. Thermal comfort is shown on a 100-mm visual analog scale where 0 mm is the worst possible cold sensation, 50 mm is neutral, and 100 mm is extreme heat. *(From Kurz A, Sessler DI, Narzt E, et al: Postoperative hemodynamic and thermoregulatory consequences of intraoperative core hypothermia,* J Clin Anesth *7:359-366, 1995.)*

most important consequence of mild perioperative hypothermia: a threefold increase in morbid myocardial outcomes.[126] Given that myocardial ischemia is among the leading causes of unanticipated perioperative death, the results of this prospective randomized trial must be taken extremely seriously.

Table 54-2 lists the major studies that evaluated complications caused by mild perioperative hypothermia.

POSTANESTHETIC SHIVERING

The incidence of postoperative shivering-like tremor reportedly is approximately 40%, but it now appears to be less as more patients are kept normothermic and opioids are administered more frequently and in larger doses than in the past. This potentially serious complication increases oxygen consumption roughly 100%, in proportion to intraoperative heat loss.[152] However, myocardial ischemia is poorly correlated with shivering, a finding suggesting that increased metabolic rate is not the primary etiology of this complication.[126] In addition to increasing intraocular and intracranial pressures, postoperative shivering possibly aggravates wound pain by stretching incisions. The most important determinants of shivering risk are young age and core temperature.[153]

Over the years, postanesthetic tremor has been attributed to uninhibited spinal reflexes, pain, decreased sympathetic activity, pyrogen release, adrenal suppression, respiratory alkalosis, and, most commonly, simple thermoregulatory shivering in response to intraoperative hypothermia. Unfortunately, the etiologies of postanesthetic, shivering-like tremor remain unclear. Certainly, much postoperative tremor is simply normal shivering. As early as 1972, however, investigators recognized the existence of at least two distinct tremor patterns.[154] That perceptive observation subsequently was confirmed in a study that used electromyography to demonstrate that postoperative tremor has the following patterns: (1) a tonic pattern resembling normal shivering, typically having a waxing-and-waning component of four to eight cycles/minute; and (2) a phasic, 5- to 7-Hz bursting pattern resembling pathologic clonus.[155] The clonic pattern was consistent with the previous observation that pathologic spinal cord responses, including clonus, nystagmus, and exaggerated deep tendon reflexes, were common during recovery from general anesthesia.[156]

Not until 1991 did a triple crossover study in volunteers establish that the tonic and clonic patterns were both thermoregulatory (i.e., always preceded by core hypothermia and arteriovenous shunt vasoconstriction).[157] The tonic pattern consistently demonstrated the waxing-and-waning pattern of four to eight cycles/minute that characterizes normal shivering,[18] and apparently it is a simple thermoregulatory response to intraoperative hypothermia. In contrast, the clonic pattern is not a normal component of thermoregulatory shivering and appears specific to recovery from volatile anesthetics. Although the precise etiology of this tremor pattern remains unknown, the cause may be anesthetic-induced disinhibition of normal descending control over spinal reflexes. More recent data in surgical patients, however, belies the simple conclusion from the volunteer study[157] that all postanesthetic tremor is thermoregulatory. Instead, there appears to be a distinct incidence of nonthermoregulatory tremor in normothermic postoperative patients.[158] A similar nonthermoregulatory tremor has been observed in women during labor.[88] The etiology of this tremor and the reason that volunteers and patients should respond differently remain unknown; however, surgical pain appears to be a key factor.[89]

Postanesthetic shivering can be treated by skin surface warming because the regulatory system tolerates more core hypothermia when cutaneous warm input is augmented.[90] However, the skin surface contributes only 20% to control of shivering,[5,6] and available skin surface warmers increase mean skin temperature only a few degrees

TABLE 54-2 MAJOR COMPLICATIONS OF MILD PERIOPERATIVE HYPOTHERMIA IN HUMANS*

Consequence	First Author	Yr	*N*	ΔT_{core} (° C)	Normothermic	Hypothermic	*P*

*Only prospective, randomized human trials are included; subjective responses were evaluated by observers blinded to treatment group and core temperature. Different outcomes of some studies are shown in separate rows. The study by Just et al is but one of dozens of studies showing that hypothermia provokes shivering. Results are presented as means ± SDs or median (interquartile range) unless otherwise specified. For the effects of hypothermia on perioperative blood loss and transfusion requirement, see the meta-analysis by Rajagopalan and colleagues.[133]

ΔT_{core}, Difference in core temperature between the treatment groups; *N*, total number of subjects; *NS*, not significant; *VAS*, a 100-mm visual analog scale (0 mm, intense cold; 100 mm, intense heat).

centigrade.[159,160] Consequently, cutaneous warming compensates for only small amounts of core hypothermia and does not usually prove effective in most patients with core temperatures much lower than 35° C.[161]

Postanesthetic shivering also can be treated using a variety of drugs, including clonidine (75 μg IV),[92] ketanserin (10 mg IV),[92] tramadol,[162] physostigmine (0.04 mg/kg IV),[163] nefopam (0.15 mg/kg),[164] dexmedetomidine, and magnesium sulfate (30 mg/kg IV).[94] The specific mechanisms by which ketanserin, tramadol, physostigmine, and magnesium sulfate stop shivering remain unknown. Similarly, how clonidine arrests shivering also remains unknown. However, clonidine[36] and dexmedetomidine[26] comparably reduce the vasoconstriction and shivering thresholds, a finding suggesting that they act on the central thermoregulatory system, rather than preventing shivering peripherally. Postoperative shivering has been reviewed in detail,[165] and treatment options have been subjected to a systematic review.[166]

Alfentanil, a pure μ-receptor agonist, significantly impairs thermoregulatory control.[25] However, meperidine is considerably more effective in treating shivering than are equianalgesic doses of other μ agonists.[167] Clinically, this efficacy is manifested as a shivering threshold that is reduced twice as much as the vasoconstriction threshold,[31] without a decrease in the gain or maximum intensity of shivering.[52] The efficacy of meperidine is at least partially preserved during administration of moderate doses of naloxone (0.5 μg/kg/minute) but is virtually obliterated by larger doses (5.0 μg/kg/minute).[168] These data suggest that action of this drug is in part mediated by non–μ opioid receptors. Meperidine possesses considerable κ activity,[169] and it also has central anticholinergic activity, although neither mechanism appears to mediate the special antishivering activity of meperidine.[12] Instead, it may result from agonist activity at central α adrenoceptors.[170] Whatever the mechanism, however, meperidine appears to be a considerably more effective treatment for postoperative shivering than the other opioids.

PERIOPERATIVE THERMAL MANIPULATIONS

Intraoperative thermoregulatory vasoconstriction, once triggered, is remarkably effective in preventing further core hypothermia.[43,51] Nonetheless, most patients are poikilothermic during surgery because they do not become sufficiently hypothermic to trigger thermoregulatory responses.[24,25,27,28] Therefore, intraoperative hypothermia can be minimized by any technique that limits cutaneous heat loss to the environment resulting from cold operating rooms, evaporation from surgical incisions, or conductive cooling produced by administration of cold intravenous fluids. The efficacy of various approaches differs enormously, however.

Mean body temperature decreases when heat loss to the environment exceeds metabolic heat production. Heat production during anesthesia is approximately 0.8 kcal/kg/hour. Because the specific heat of the human body is approximately 0.83 kcal/kg,[171] body temperature decreases approximately 1° C/hour when heat lost to the environment is twice metabolic production. Normally, approximately 90% of metabolic heat is lost through the skin surface. During anesthesia, additional heat is also lost directly from surgical incisions and by administration of cold intravenous fluids.

EFFECTS OF VASOMOTOR TONE ON HEAT TRANSFER

Thermoregulatory vasodilation causes the initial core-to-peripheral redistribution of body heat[61]; similarly, reemergence of vasoconstriction in patients becoming sufficiently hypothermic produces a core temperature plateau.[51] It is thus evident that vasomotor tone alters intercompartmental heat transfer. In addition to thermoregulatory arteriovenous shunt status, arteriolar tone is directly modulated by anesthetics per se.[58] Both factors potentially influence the speed with which peripherally applied heat reaches the core thermal compartment.

Thermoregulatory vasoconstriction slightly impairs induction of therapeutic hypothermia during neurosurgery.[172] However, arteriovenous shunt tone has little effect on intraoperative cooling[173] or heating.[174] Intraoperative vasoconstriction thus only slightly impedes peripheral-to-core transfer of cutaneous heating and cooling. Little clinical effect presumably results because intraoperative thermoregulatory vasoconstriction is opposed by direct anesthetic-induced peripheral vasodilation.

During postanesthetic recovery, however, the situation differs markedly. Here, anesthetic-induced peripheral dilation[58,175] dissipates, leaving unopposed thermoregulatory vasoconstriction. As could be expected, this vasoconstriction then becomes an important factor and significantly impairs transfer of peripherally applied heat to the core thermal compartment. Patients having a residual spinal anesthetic block thus warm considerably faster than do those recovering from general anesthesia alone (Fig. 54-20).[176] Heat balance studies indicate that core warming is slowed because vasoconstriction constrains up to 30 kcal in peripheral tissues.[177]

Because postoperative thermoregulatory vasoconstriction decreases peripheral-to-core transfer of heat, applied warming is most effective during surgery when patients are vasodilated. From a practical perspective, this means that it is easier to maintain intraoperative normothermia (when most patients are vasodilated) than to rewarm them postoperatively (when virtually all hypothermic patients are vasoconstricted). In addition to being more effective, intraoperative warming is more appropriate than postoperative treatment of hypothermia because it prevents the complications resulting from hypothermia.[118,126,132] Patients who unavoidably become hypothermic during surgery nonetheless should be actively heated postoperatively to increase thermal comfort, decrease shivering, and hasten rewarming.

PREVENTING REDISTRIBUTION HYPOTHERMIA

The initial 0.5° C to 1.5° C reduction in core temperature is difficult to prevent because it results from redistribution of heat from the central thermal compartment to cooler

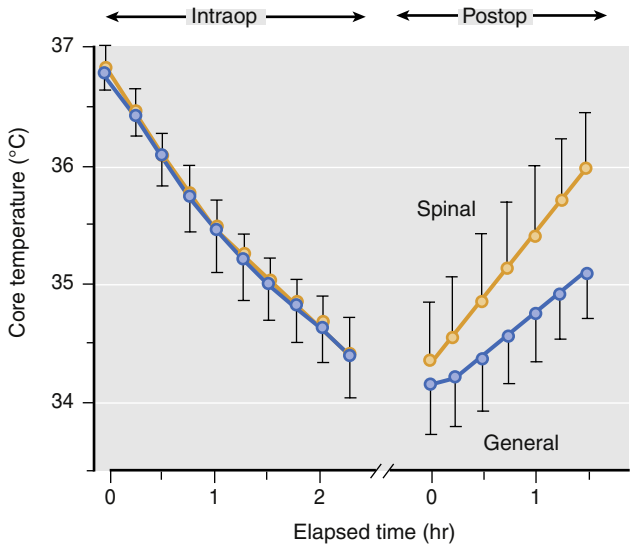

Figure 54-20. Intraoperative and postoperative core temperatures in patients assigned to general anesthesia ($n = 20$) and spinal anesthesia ($n = 20$). All patients were warmed with forced air during the postoperative period. Core temperature did not differ significantly during surgery, but it increased significantly faster postoperatively in patients given spinal anesthesia (1.2 ± 0.1° C/hour versus 0.7 ± 0.2° C/hour; means ± SDs). *(From Szmuk P, Ezri T, Sessler DI, et al: Spinal anesthesia only minimally increases the efficacy of postoperative forced-air rewarming,* Anesthesiology *87:1050-1054, 1997.)*

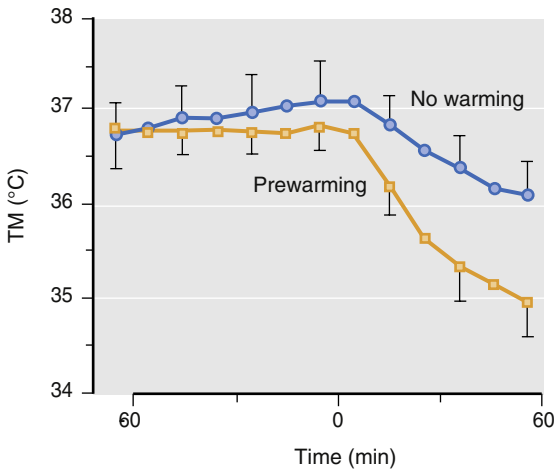

Figure 54-21. During the preinduction period (–120 to 0 minutes), volunteers were either actively warmed or passively cooled (no warming). At induction of anesthesia (time = 0 minutes), active warming was discontinued, and volunteers were exposed to the ambient environment. Initial tympanic membrane (TM) temperatures were similar before each preinduction treatment. During the 60 minutes following induction of anesthesia, core temperature decreased less when volunteers were prewarmed: (ΔT = –1.1 ± 0.3° C) compared with when the same volunteers were not warmed (ΔT = –1.9 ± 0.3° C). Data are presented as means ± SDs. *(From Hynson JM, Sessler DI, Moayeri A, et al: The effects of pre-induction warming on temperature and blood pressure during propofol/nitrous oxide anesthesia,* Anesthesiology *79:219-228, 1993.)*

peripheral tissues.[61] Consequently, surface warming usually fails to prevent hypothermia during the first hour of anesthesia.[62,132] Lack of efficacy during this period results both because the central-to-peripheral flow of heat is massive and because transfer of applied cutaneous heat to the core requires nearly an hour, even in vasodilated patients.

Although redistribution is difficult to treat,[62,132] it can be prevented. Redistribution results when anesthetic-induced vasodilation allows heat to flow peripherally down the normal temperature gradient. Skin surface warming before induction of anesthesia does not much increase core temperature (which remains well regulated), but it does increase body heat content. Most of the increase is in the legs, the most important component of the peripheral thermal compartment. When peripheral tissue temperature is sufficiently increased, subsequent inhibition of normal tonic thermoregulatory vasoconstriction produces little redistribution hypothermia because heat can flow only down a temperature gradient (Fig. 54-21).[80,81] Although substantial amounts of heat must be transferred across the skin surface, active prewarming for as little as 30 minutes likely prevents considerable redistribution.[178]

The "afterdrop" associated with discontinuation of cardiopulmonary bypass is a type of redistribution hypothermia that results from a substantial core-to-peripheral tissue temperature gradient. As could be expected, it is more impressive after bypass at 17° C[179] than at 27° C to 31° C.[180] Cutaneous warming during and after bypass reduces core temperature afterdrop by 60%. However, heat balance data indicate that this reduction results primarily because cutaneous warming prevents the typical decrease in body heat content after discontinuation of bypass, rather than by reducing redistribution.[181]

AIRWAY HEATING AND HUMIDIFICATION

Simple thermodynamic calculations indicate that less than 10% of metabolic heat production is lost via the respiratory tract. The loss results both from heating and humidifying inspiratory gases, but humidification requires two thirds of the heat.[56] Because little heat is lost via respiration, even active airway heating and humidification minimally influence core temperature.[62,182] The *apparent* clinical efficacy of these methods probably results from artifactual warming of proximally positioned esophageal stethoscopes.[183] Because respiratory heat loss remains virtually constant during anesthesia, the fraction of total heat lost via the respiratory tract decreases dramatically during large operations in which substantial heat is lost from evaporation within surgical incisions.[57] Consequently, airway heating and humidification are even less effective than usual in patients most in need of effective warming. Cutaneous warming maintains normothermia so much better than does respiratory gas conditioning that intraoperative active airway heating and humidification are rarely, if ever, indicated.

Airway heating and humidification are more effective in infants and children than in adults.[184] However, cutaneous warming also is more effective in these patients and transfers more than 10 times as much heat. Hygroscopic condenser humidifiers and heat-and-moisture exchanging filters ("artificial noses") retain substantial amounts of moisture and heat within the respiratory system. In terms of preventing heat loss, these passive devices are approximately half as good as active systems,[184] but they cost only a fraction as much. Heat retention is comparable in all clinically available heat-and-moisture exchangers.[56]

INTRAVENOUS FLUIDS

It is not possible to warm patients by administering heated fluids because the fluids cannot greatly exceed body temperature. Conversely, heat loss resulting from cold intravenous fluids becomes substantial when large amounts of crystalloid solution or blood are administered. One unit of refrigerated blood or 1 L of crystalloid solution administered at room temperature each decreases mean body temperature approximately 0.25° C. (The blood is twice as cold, but it has only half the volume.) Fluid warmers minimize these losses and should be used when large amounts of intravenous fluid or blood are administered. In smaller cases, however, they contribute little.

For routine cases, no clinically important differences are noted among the available fluid warmers. Although most warmers allow fluid to cool in the tubing between the heater and the patient, this cooling is of little consequence in adults. At high flows, little cooling occurs, and at low flows, the amount of fluid given is trivial.[185] Special high-volume systems with powerful heaters and little resistance to flow facilitate care of trauma victims and are useful in other cases in which large amounts of fluid must be administered quickly.

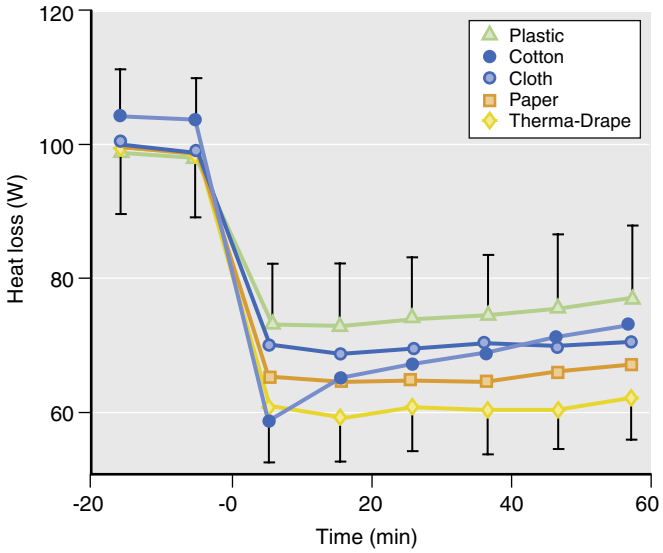

Figure 54-22. Insulators readily available in most operating rooms include cotton blankets, surgical drapes, plastic sheeting, and reflective composites ("space blankets"). A single layer of each reduces total cutaneous heat loss approximately 30%, and no clinically important differences exist among the insulation types. Data are presented as means ± SDs. *(From Sessler DI, McGuire J, Sessler AM: Perioperative thermal insulation,* Anesthesiology *74:875-879, 1991.)*

CUTANEOUS WARMING

Operating room temperature is the most critical factor influencing heat loss because it determines the rate at which metabolic heat is lost by radiation and convection from the skin and by evaporation from within surgical incisions. Consequently, increasing room temperature is one way to minimize heat loss. However, room temperatures exceeding 23° C are generally required to maintain normothermia in patients undergoing all but the smallest procedures.[186] Most operating room personnel find such temperatures uncomfortably warm. Infants may require ambient temperatures exceeding 26° C to maintain normothermia. Such temperatures are sufficiently high to impair performance of operating room personnel and decrease their vigilance.

The easiest method of decreasing cutaneous heat loss is to apply passive insulation to the skin surface. Insulators readily available in most operating rooms include cotton blankets, surgical drapes, plastic sheeting, and reflective composites ("space blankets"). A single layer of each reduces heat loss approximately 30%, and no clinically important differences exist among insulation types (Fig. 54-22).[187] Insulators therefore should be chosen strictly based on cost; paying a premium to purchase reflective composites, for example, is not justified.

The reduction in heat loss from all the commonly used passive insulators is similar because most of the insulation is provided by the layer of still air trapped beneath the covering. Consequently, adding additional layers of insulation further reduces heat loss only slightly. For example, one cotton blanket reduces heat loss by approximately 30%, but three cotton blankets reduce heat loss only by 50%. Furthermore, warming the cotton blankets provides little benefit, and the benefit is short-lived.[188] These data indicate that simply adding additional layers of passive insulation, or warming the insulation before application, usually will be insufficient in patients who become hypothermic while covered with a single layer of insulation.

Cutaneous heat loss is roughly proportional to surface area throughout the body.[189] (The popular perception that a large fraction of metabolic heat is lost from the head is false in adults. Loss from the head can be substantial in small infants,[190] but loss is high mostly because the head represents a large fraction of the total surface area.) Consequently, the amount of skin covered is more important than which surfaces are insulated. It does not make sense, for example, to cover the head and leave the arms exposed because the arms have more surface area than the head and account for more heat loss.

Passive insulation alone rarely is sufficient to maintain normothermia in patients undergoing large operations; active warming is required in those cases. Because approximately 90% of metabolic heat is lost via the skin surface, only cutaneous warming will transfer sufficient heat to prevent hypothermia. Consequently, for intraoperative use, circulating water and forced air are the two major systems requiring consideration.

Studies consistently report that circulating-water mattresses are nearly ineffective.[191] Presumably, they are unable to maintain normothermia because little heat is lost from the back into the 5 cm of foam insulation covering most operating room tables. Furthermore, the combination of heat and decreased local perfusion (resulting when the patient's weight reduces capillary blood flow) increases the propensity for pressure and heat necrosis ("burns"). Such tissue injury can occur even when water temperature does not exceed 40° C.[192] Circulating water is more effective—and safer—when it is placed *over* patients rather than *under* them and, in that position, can almost completely eliminate metabolic heat loss.[159]

Metabolic heat production increases mean body temperature approximately 1° C/hour when cutaneous heat loss is eliminated. Circulating-water garments transfer large amounts of heat by increasing the warmed surface area or by using materials that facilitate conduction.[193,194]

The most common perianesthetic warming system is forced air. The best forced-air systems completely eliminate heat loss from the skin surface.[159,160] Forced air usually maintains normothermia even during the largest operations,[62,132] and it is superior to circulating-water mattresses.[195] It is also remarkably safe, with few if any injuries reported with proper use. The hospital cost of forced-air warming in the United States is now only approximately $10, and it is justifiably by far the most common warming method.

INDUCTION OF MILD THERAPEUTIC HYPOTHERMIA

A paucity of evidence supports the application of therapeutic hypothermia for indications other than out-of-hospital cardiac arrest and asphyxiated neonates. Nonetheless, hypothermia is occasionally used during neurosurgery or acute myocardial infarction. Typically, target core temperatures are 32° C to 34° C, and it is thought to be important to reach the target temperature quickly.

Passive cooling is far too slow for induction of therapeutic hypothermia. Immersion in cold water is the quickest noninvasive method of actively cooling patients. However, immersion is difficult under clinical conditions and poses a substantial electrical safety risk. Administration of refrigerated intravenous fluids also is effective and reduces mean body temperature 0.5° C/L.[196] However, this method may be impractical in neurosurgical patients in whom fluids must be restricted.

Forced-air cooling is easy to implement, but it is relatively slow, taking approximately 2.5 hours to cool neurosurgical patients to 33° C.[172] Conventional circulating-water mattresses are unlikely to be efficient because relatively little skin surface contacts the mattress, and the patient's own body weight reduces bloodborne convection of heat to the back (i.e., circulating water probably does not cool well, for the same reason it heats poorly).[159] Newer circulating-water systems include garment-like covers or "energy exchange pads" that cover far more skin surface and transfer large amounts of heat and are fairly effective.[197,198]

The best way to induce therapeutic hypothermia rapidly is probably endovascular cooling. These systems consist of a heat-exchanging catheter, usually inserted into the inferior vena cava via the femoral artery, and a servocontroller. They can decrease core temperatures at rates approaching 4° C/hour (Fig. 54-23).[199]

Inducing therapeutic hypothermia during surgery is relatively easy because anesthetics profoundly impair thermoregulatory responses. In contrast, unanesthetized patients—even those who have suffered a stroke—vigorously defend core temperature by vasoconstricting and shivering.[200] It is thus necessary to induce tolerance to hypothermia pharmacologically. The best method so far identified is the combination of buspirone and meperidine, drugs that synergistically reduce the shivering threshold to approximately 34° C without provoking excessive sedation or respiratory toxicity.[201] The combination of dexmedetomidine and meperidine may also be helpful, although the interaction is simply additive in this case.[93] In contrast, ondansetron,[202] doxapram,[203] and magnesium sulfate[204] only slightly reduce the shivering threshold in humans. Although initially reported to be effective,[205] neither arm warming nor face warming reduces the shivering threshold by clinically important amounts.[206]

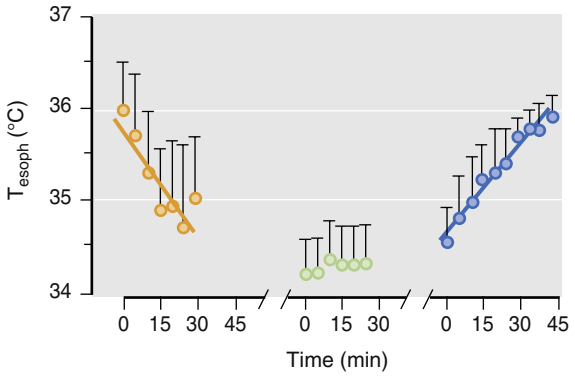

Figure 54-23. Average (± SDs) intraoperative esophageal temperatures (T_{esoph}) during the cooling (*yellow circles*), temperature maintenance (*green circles*), and rewarming (*blue circles*) periods in eight neurosurgical patients who were cooled with endovascular heat-exchanging catheters in the vena cava. Time zero identified the beginning of each thermal management period; the duration of these periods differed in individual patients depending on the duration of surgery and other factors. The regression lines are shown for the cooling *(yellow line)* and rewarming *(blue line)* periods. *(From Doufas AG, Akça O, Barry A, et al: Initial experience with a novel heat-exchanging catheter in neurosurgical patients,* Anesth Analg *95:1752-1756, 2002.)*

DELIBERATE SEVERE INTRAOPERATIVE HYPOTHERMIA

Severe hypothermia may be induced deliberately to confer protection against tissue ischemia, specifically during cardiac surgery and, occasionally, neurosurgery. Drugs such as barbiturates and volatile anesthetics provide considerably less protection than even mild hypothermia.[97] Because many organs compensate poorly for hypothermia, temperatures as low as those deliberately induced are usually lethal when unintentional. Deliberate hypothermia is safe only because anesthesiologists understand and treat the physiologic changes caused by core temperatures 10° C to 15° C lower than normal.

Although deep hypothermia (i.e., 28° C) has been used to facilitate cardiopulmonary bypass for decades, more recent evidence suggests that this degree of hypothermia is either unhelpful or simply harmful. For example, hypothermia may be associated with prolonged ventricular dysfunction,[207] and it does not limit cognitive impairment after bypass.[208] Furthermore, normothermia appears to improve major outcomes after bypass surgery.[209] Consequently, cardiac surgery is increasingly performed at either "tepid" temperatures (i.e., 33° C) or normothermia. Increasing evidence indicates that outcomes of bypass

surgery, whether on or off pump, are improved by maintaining normothermia or near normothermia.[210,211] Deep hypothermia (i.e., 18° C) remains routine for cases of intentional circulatory arrest.[179]

ORGAN FUNCTION

Ischemia damages tissues because oxygen deprivation forces cells to obtain energy anaerobically. Given that this mechanism is inefficient, it may not provide adequate energy. Anaerobic metabolism also produces more toxic metabolic waste products (e.g., lactate and superoxide radicals) than does the Krebs cycle; this is particularly serious when these waste products are not removed by circulating blood.

Hypothermia decreases whole-body metabolic rate by approximately 8%/°C,[46] to approximately half the normal rate at 28° C.[212] Whole-body oxygen demand diminishes, and oxygen consumption in tissues that have higher than normal metabolic rates, such as the brain, is especially reduced. Brain oxygenation is thus improved by hypothermia.[213] Low metabolic rates allow aerobic metabolism to continue during periods of compromised oxygen supply; toxic waste production declines in proportion to the metabolic rate. Although decreased metabolic rate certainly contributes to the observed protection against tissue ischemia, other effects of hypothermia, including "membrane stabilization" and decreased release of toxic metabolites and excitatory amino acids, appear to be most important.[98]

Cerebral blood flow also decreases in proportion to metabolic rate during hypothermia because of an autoregulatory increase in cerebrovascular resistance.[98] The arteriovenous oxygen tension (Pao_2–Pvo_2) difference thus remains constant, and venous lactate concentration does not increase. Cerebral function is well maintained until core temperatures reach approximately 33° C, but consciousness is lost at temperatures lower than 28° C. Primitive reflexes such as gag, pupillary constriction, and monosynaptic spinal reflexes remain intact until approximately 25° C. Nerve conduction decreases, but peripheral muscle tone increases, resulting in rigidity and myoclonus at temperatures near 26° C. Somatosensory- and auditory-evoked potentials are temperature dependent, but they are not significantly modified at core temperatures of 33° C or higher.

Hypothermic effects on the heart include a decrease in heart rate, increased contractility, and well-maintained stroke volume.[214] Cardiac output and blood pressure both decrease. At temperatures lower than 28° C, sinoatrial pacing becomes erratic, and ventricular irritability increases. Fibrillation usually occurs between 25° C and 30° C, and electrical defibrillation is usually ineffective at these temperatures. Because coronary artery blood flow decreases in proportion to cardiac work, hypothermia per se does not cause myocardial ischemia. However, even mild hypothermia decreases tissue damage in response to experimental cardiac ischemia.[111]

Hypothermia decreases blood flow to the kidneys by increasing renovascular resistance. Inhibition of tubular absorption maintains normal urinary volume. As temperature decreases, reabsorption of sodium and potassium is progressively inhibited, causing antidiuretic hormone–mediated "cold diuresis." Despite increased excretion of these ions, plasma electrolyte concentrations usually remain normal. Kidney functions return to normal when patients are rewarmed. Respiratory strength is diminished at core temperatures less than 33° C, but the ventilatory CO_2 response is minimally affected. Hepatic blood flow and function also decrease, thus significantly inhibiting metabolism of some drugs.

ACID-BASE CHANGES

The pH of neutral water ($[OH^-] = [H^+]$) increases 0.017 units for each 1° C reduction in temperature.[215] The pH of blood in a closed system (e.g., test tube or artery) changes similarly. Cold-blooded animals allow pH to vary with body temperature as it would in vitro (i.e., blood becomes more alkalotic as temperature decreases); in contrast, homeotherms, which decrease body temperature during hibernation, maintain a pH_a near 7.4 that is known as pH-stat management. Interpretation of arterial pH in hypothermic humans is difficult because it is unclear which strategy is optimal.[216]

To mimic the compensatory mechanisms used by hibernating homeotherms, blood pH (which is measured by electrodes at 37° C) traditionally has been "corrected" to the patient's actual body temperature. Without correction, tissue oxygen availability decreases because hemoglobin's affinity for oxygen increases approximately 1.7%/°C. This effect is small compared with the 5.7%/°C increase in oxyhemoglobin affinity caused by hypothermia itself. Fortunately, the combined increases in affinity are offset by the 8%/°C reduction in metabolic rate caused by hypothermia. Tissue hypoxia is thus unlikely, with or without correction, and it has not been demonstrated experimentally.

Ectothermic strategy also is known as alpha stat because the dissociation constant of the α-imidazole group in histidine changes parallel to those of water. Maintaining constant imidazole ionization results in optimal enzyme function as temperature changes. In contrast, homeothermic dynamics significantly decrease metabolic function, and animals are essentially anesthetized by cold. Constant relative alkalinity also maintains a stable intracellular-to-extracellular gradient that promotes removal of acidic products of intracellular metabolism, a process that may be salutary.[217]

Both alpha-stat and pH-stat management strategies appear to work well, and physiologic differences between them appear to be subtle. However, increasing evidence indicates that pH-stat management better preserves neurons in the context of ischemic stress.[218-220] Furthermore, clinical outcomes appear to be improved by pH-stat management[221]—or at least not worsened.[222] Nonetheless, alpha-stat management remains common, and no consensus indicates that either strategy markedly influences the outcome of cardiac surgery.

HYPERTHERMIA AND FEVER

Hypothermia is by far the most common perianesthetic thermal perturbation. However, hyperthermia is probably

more dangerous than a comparable degree of hypothermia, and hyperthermia is certainly more dangerous when perturbations exceed a few degrees centigrade. *Hyperthermia* is a generic term simply indicating a core body temperature exceeding normal values. In contrast, *fever* is a regulated increase in the core temperature targeted by the thermoregulatory system. Hyperthermia can result from a variety of causes and usually indicates a problem of sufficient severity that intervention by the physician is required.

PASSIVE HYPERTHERMIA AND MALIGNANT HYPERTHERMIA

Passive intraoperative hyperthermia results from excessive patient heating and is most common in infants and children. It is especially frequent when effective active warming is used without adequate core temperature monitoring. Passive hyperthermia, by definition, does not result from thermoregulatory intervention. Consequently, it can easily be treated by discontinuing active warming and removing excessive insulation.

The increase in body temperature during malignant hyperthermia results from an enormous increase in metabolic heat produced by both internal organs and skeletal muscles.[223] Central thermoregulation presumably remains intact during acute crises, but efferent heat loss mechanisms may be compromised by intense peripheral vasoconstriction resulting from circulating catecholamine concentrations 20 times normal.[224] For comprehensive information on malignant hyperthermia, see Chapter 43.

FEVER

Normal body temperature is neither set nor maintained by circulating factors. In contrast, fever results when endogenous pyrogens increase the thermoregulatory target temperature ("setpoint"). Identified endogenous pyrogens include interleukin-1, tumor necrosis factor, interferon-α, and macrophage inflammatory protein-1.[225] Although it was initially believed that these factors acted directly on hypothalamic thermoregulatory centers,[226] increasing evidence indicates a more complicated system involving vagal afferents.[227] Most endogenous pyrogens have peripheral actions (e.g., immune system activation) in addition to their central generating capabilities.

Fever is relatively rare during general anesthesia, considering how often febrile stimuli are likely to be present. It is rare because volatile anesthetics per se inhibit expression of fever (Fig. 54-24),[228] as do opioids.[229] Infection is by far the most common cause of fever. Such fevers may reflect preexisting infection or may result, for example, from urologic manipulations. However, perioperative fever also occurs in response to mismatched blood transfusions, blood in the fourth cerebral ventricle, and allergic reactions. Some degree of fever is also typical after surgery.[230] The causes of fever are sufficiently diverse—and potentially serious—that a search for a specific etiology usually is warranted.

Treatment of hyperthermia depends on the etiology, with the critical distinction being between fever and the other causes of hyperthermia. (In general, patients with fever and increasing core temperature have constricted fingertips whereas those with other types of hyperthermia are vasodilated.) It is always appropriate to treat underlying causes, but nonfebrile hyperthermia also improves with cooling.

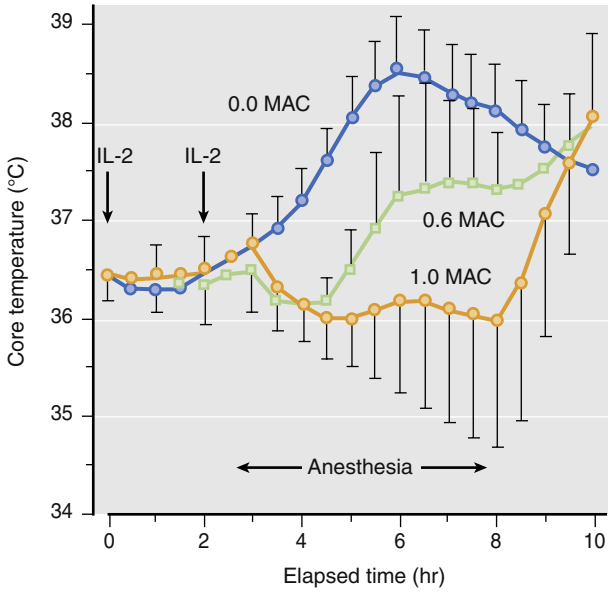

Figure 54-24. Change in core temperature after administration of 50,000 IU/kg of interleukin-2 (IL-2) followed by a second dose of 100,000 IU/kg 2 hours later. The first dose of IL-2 defined elapsed time zero; anesthesia was started after 3 elapsed hours and continued for 5 hours. Data are presented as means ± SDs. *MAC,* Minimum alveolar concentration. *(From Negishi C, Lenhardt R, Sessler DI, et al: Desflurane reduces the febrile response to interleukin-2 administration,* Anesthesiology *88:1162-1169, 1998.)*

The first- and second-line treatments for fever are amelioration of the underlying cause and administration of antipyretic medications. The first treatment strategy often fails because the etiology of fever remains unknown; alternatively, the source may be known but unresponsive. The second strategy also often fails or is only partially effective, perhaps because some fever is mediated by mechanisms that bypass conventional antipyretics.[225] In these patients, third-line treatment is most likely to be implemented: active cooling (Table 54-3). Active cooling of febrile patients is intuitive. However, it often fails to reduce core temperature while simultaneously worsening the situation by triggering thermoregulatory defenses, including intense discomfort, shivering, and autonomic nervous system activation.[231] Active cooling of febrile patients should thus be instituted with considerable care, to be sure that the putative benefits outweigh the stress induced by activation of thermoregulatory defenses.

HYPERTHERMIA DURING EPIDURAL ANALGESIA

Hyperthermia frequently complicates epidural analgesia for labor and delivery,[232] as well as in nonpregnant postoperative patients.[233] This is especially the case when labor is long, more than 8 hours. A clinical consequence of this hyperthermia is that women given epidural analgesia

TABLE 54-3 ACTIVE CUTANEOUS COOLING AS A TREATMENT FOR FEVER*

	Control	Cooling	Warming
Integrated core temperature (°C/hr)	6.0 ± 1.6	5.7 ± 2.2	6.4 ± 1.2
Oxygen consumption (mL/min)	330 ± 50	430 ± 40†	310 ± 30
Duration of shivering (min)	33 ±11	229 ± 35	20 ± 0
Mean arterial pressure (mm Hg)	90 ± 4	98 ± 6†	86 ± 6‡
Mean norepinephrine (nM)	1.0 ± 0.4	1.4 ± 0.7†	1.1 ± 0.5‡
Baseline epinephrine (nM)	0.3 ± 0.1	0.3 ± 0.1	0.3 ± 0.1
Mean epinephrine during treatment (nM)	0.3 ± 0.1	0.5 ± 0.1†	0.4 ± 0.1
Severe cold sensation (% of time)	27	89†	11

*Volunteers were given 30,000 IU/kg of interleukin-2 (IL-2), followed 2 hours later by an additional dose of 70,000 IU/kg. The first dose of IL-2 defined elapsed time zero; thermal management started after 3 elapsed hours and continued for 5 hours. Each volunteer participated on 3 separate days: no warming or cooling, active cooling, and active warming. Mean and integrated values are presented over the treatment period, from 3 to 8 elapsed hours. Times are presented in terms of hours elapsed since the first injection of IL-2. Data are presented as means ± SDs.
†Statistically significant differences from control.
‡Statistically significant differences from the cooling day.
Modified from Lenhardt R, Negishi C, Sessler DI, et al: The effects of physical treatment on induced fever in humans, *Am J Med* 106:550-555, 1999.

are more often given antibiotics than are women treated conventionally, and their infants are more commonly treated for sepsis.[234]

Because passive hyperthermia and excessive heat production are unlikely etiologies, elevated body temperature in laboring and postoperative patients is presumably true fever (i.e., a regulated increase in core temperature) resulting from infection or inflammation.[235] For example, Dashe and co-workers concluded: "Epidural analgesia is associated with intrapartum fever, but only in the presence of placental inflammation. This suggests that the fever reported with epidural analgesia is due to infection rather than the analgesia itself."

The conventional assumption is that hyperthermia is *caused* by the technique, although no convincing mechanism has been proposed. It is worth remembering, however, that pain in "control" patients is usually treated with opioids—which themselves attenuate fever.[229] Fever associated with infection or tissue injury could then be suppressed by low doses of opioids, which are usually given to "control" patients, while being expressed normally in patients given epidural analgesia (Fig. 54-25).[236] The extent to which this mechanism contributes remains to be determined and has been disputed,[237] but no convincing alternative explanation has been advanced.

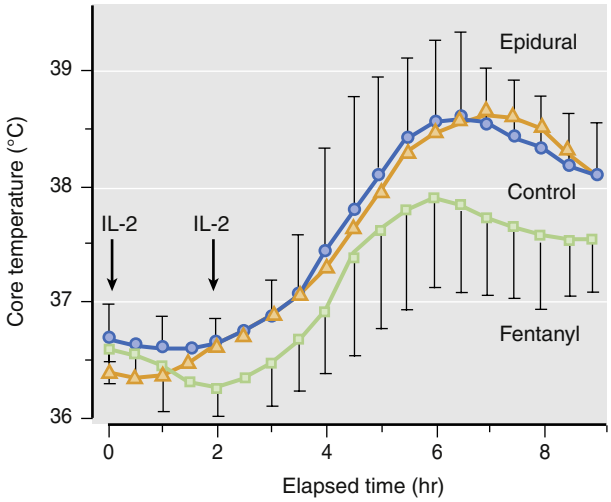

Figure 54-25. Core temperatures after administration of 50 IU/g of interleukin-2 (IL-2) followed by a second dose of 100 IU/g 2 hours later. The first dose of IL-2 defined elapsed time zero. Data are presented as means ± SDs. Error bars for the epidural days are omitted for clarity, but they were similar to those shown for control and intravenous fentanyl. *(From Negishi C, Lenhardt R, Ozaki M, et al: Opioids inhibit febrile responses in humans, whereas epidural analgesia does not: an explanation for hyperthermia during epidural analgesia,* Anesthesiology *94:218-222, 2001.)*

TEMPERATURE MONITORING

Core temperature measurements (e.g., tympanic membrane as measured with a thermocouple, pulmonary artery, distal esophagus, and nasopharynx) are used to monitor intraoperative hypothermia, prevent overheating, and facilitate detection of malignant hyperthermia. Muscle or skin surface temperatures may be used to evaluate vasomotion,[238] as well as to ensure the validity of peripheral neuromuscular monitoring.[239]

Both core and skin surface temperature measurements are required to determine the thermoregulatory effects of different anesthetic drugs. The combination of core and mean skin temperature can be used to estimate mean body temperature, and therefore body heat content, with remarkable accuracy.[240] Temperatures are not uniform within the body; consequently, temperatures measured at each site have different physiologic and practical significance.

THERMOMETERS

Mercury-in-glass thermometers are slow and cumbersome and thus have universally been replaced with electronic systems. The most common electronic thermometers are thermistors and thermocouples. Both devices are sufficiently accurate for clinical use and inexpensive enough to be disposable. Also sufficiently accurate for clinical use are "deep tissue" thermometers that are based on actively reducing cutaneous heat flux to zero[241]. Infrared monitors that extrapolate tympanic membrane temperature from outer ear temperature are

unreliable,[242] as are infrared systems that scan forehead skin.[243]

TEMPERATURE MONITORING SITES

The core thermal compartment is composed of highly perfused tissues whose temperature is uniform and high compared with the rest of the body. Temperature in this compartment can be evaluated in the pulmonary artery, distal esophagus, tympanic membrane, or nasopharynx.[244,245] Temperature probes incorporated into esophageal stethoscopes must be positioned at the point of maximal heart sounds, or even more distally, to provide accurate readings. Even during rapid thermal perturbations, such as cardiopulmonary bypass, these temperature-monitoring sites remain reliable. Core temperature can be estimated with reasonable accuracy using oral, axillary, rectal, and bladder temperatures, except during extreme thermal perturbations.[244,245]

Skin surface temperatures are considerably lower than core temperature. Skin surface temperatures—when adjusted with an appropriate offset—nonetheless reflect core temperature reasonably well.[246] However, skin temperatures fail to confirm the clinical signs of malignant hyperthermia (tachycardia and hypercarbia) reliably in swine,[247] and they have not been evaluated for this purpose in humans (Fig. 54-26). Rectal temperature also normally correlates well with core temperature,[244,245] but it fails to increase appropriately during malignant hyperthermia crises[247] and under other documented situations.[248] Consequently, rectal and skin surface temperatures must be used with considerable caution.

Even during cardiopulmonary bypass, the core temperature monitoring sites (e.g., tympanic membrane, nasopharynx, pulmonary artery, and esophagus) remain useful. In contrast, rectal temperatures lag behind those measured in core sites. Consequently, rectal temperature is considered an "intermediate" temperature in deliberately cooled patients. During cardiac surgery, bladder temperature is equal to rectal temperature (and therefore intermediate) when urine flow is low, but it is equal to pulmonary artery temperature (and thus core) when flow is high.[249] Because bladder temperature is strongly influenced by urine flow, it may be difficult to interpret in these patients. The adequacy of rewarming is best evaluated by considering both "core" and "intermediate" temperatures.

WHEN TEMPERATURE MONITORING IS REQUIRED

Core temperature monitoring is appropriate during most general anesthetic cases both to facilitate detection of malignant hyperthermia and to quantify hyperthermia and hypothermia. Malignant hyperthermia is best detected by tachycardia and an increase in end-tidal CO_2 tension (P_{CO_2}) out of proportion to minute ventilation.[250] Although increasing core temperature is not the first sign of acute malignant hyperthermia, it certainly helps confirm the diagnosis. More common than malignant hyperthermia is intraoperative hyperthermia, which has other causes, including excessive warming, infectious fever, blood in the fourth cerebral ventricle, and mismatched blood transfusions. By far the most common perioperative thermal disturbance is inadvertent hypothermia. Core temperature usually decreases 0.5° C to 1.5° C in the first 30 minutes following induction of anesthesia. Hypothermia results from internal redistribution of heat and a variety of other factors whose importance in individual patients is difficult to predict.[61,79] Core temperature perturbations during the first 30 minutes of anesthesia thus are difficult to interpret, and measurement is not usually required. Body temperature should, however, be monitored in patients undergoing general anesthesia exceeding 30 minutes in duration and in all patients whose surgery lasts longer than 1 hour.

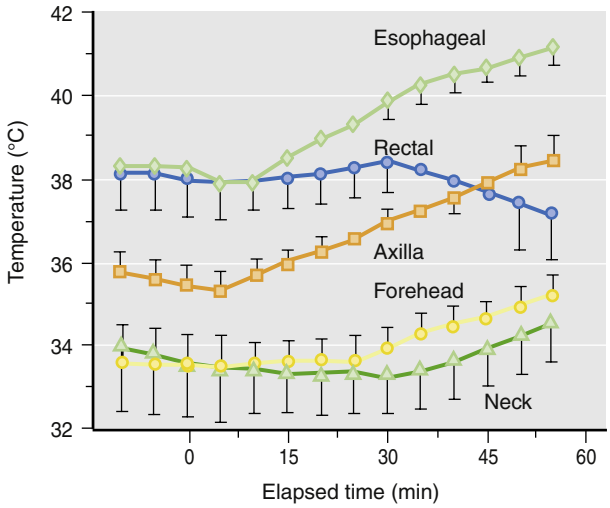

Figure 54-26. Axillary and esophageal temperatures correlated well during acute malignant hyperthermia in swine, but forehead and neck skin temperatures did not. Rectal temperature also failed to identify the onset of malignant hyperthermia promptly. Elapsed time zero indicates an end-tidal P_{CO_2} of 70 mm Hg. These data indicate that forehead and neck skin surface temperatures do not adequately confirm other clinical signs of malignant hyperthermia. Valid core temperature monitoring sites include the distal esophagus, pulmonary artery, nasopharynx, and tympanic membrane. Except during cardiopulmonary bypass, body temperature also can be measured in the mouth, axilla, and bladder. Data are presented as means ± SDs. *(Modified from Iaizzo PA, Kehler CH, Zink RS, et al: Thermal response in acute porcine malignant hyperthermia,* Anesth Analg *82:803-809, 1996.)*

Local anesthetics (including amides), which are used to produce regional blocks, and sedatives, which are used during monitored anesthesia care, do not trigger malignant hyperthermia.[251] Nonetheless, core hypothermia is as common during epidural and spinal anesthesia as during general anesthesia, and it can be nearly as severe.[77] Therefore, core temperature should be measured during regional anesthesia in patients likely to become hypothermic, which at the very least includes those undergoing body cavity surgery.

TEMPERATURE MONITORING AND THERMAL MANAGEMENT GUIDELINES

The objectives of temperature monitoring and perioperative thermal management are to detect thermal disturbances

and to maintain appropriate body temperature during anesthesia. Available data suggest the following guidelines:

1. Core body temperature should be measured in most patients given general anesthesia for longer than 30 minutes.
2. Temperature should also be measured during regional anesthesia when changes in body temperature are intended, anticipated, or suspected.
3. Unless hypothermia is specifically indicated (e.g., for protection against ischemia), efforts should be made to maintain intraoperative core temperature higher than 36° C.

Various organizations have also proposed temperature monitoring and thermal management strategies. The American Society of Anesthesiologists (ASA) standards require only that "every patient receiving anesthesia shall have temperature monitored when clinically significant changes in body temperature are intended, anticipated or suspected." For office-based sedation, regional anesthesia, or general anesthesia, the ASA also requires that "the body temperature of pediatric patient shall be measured continuously."

The State of New Jersey has stronger requirements, specifically that the body temperature of each patient under general or regional anesthesia shall be continuously monitored. Italy probably has one of the strongest local standards, which require, among other things, that (1) core temperature is measured in adults undergoing general anesthesia for more than 30 minutes (and all children), (2) ambient operating room temperature exceeds 21° C, (3) patients are kept normothermic, and (4) patients who become hypothermic remain in the postanesthesia care unit until normothermia is restored.

In 2007, the American College of Cardiology and American Heart Association published guidelines for the care of patients undergoing noncardiac surgery. They include a class 1 recommendation that "maintenance of body temperature in a normothermic range is recommended for most procedures other than during periods in which mild hypothermia is intended to provide organ protection (e.g., during high aortic cross-clamping)."[252] Based on overwhelming evidence of hypothermia-induced complications, maintaining perioperative normothermia became one of the first anesthetic "pay-for-performance" measures.

SUMMARY

Body temperature normally is controlled by a negative-feedback system in the hypothalamus, which integrates thermal information from most tissues. Approximately 80% of this thermal input is derived from core body temperature, which can be measured using distal esophageal, nasopharyngeal, or tympanic membrane thermometer probes. The hypothalamus coordinates increases in heat production (nonshivering thermogenesis and shivering), increases in environmental heat loss (sweating), and/or decreases in heat loss (vasoconstriction) as needed to maintain normothermia.

Thermal steady state requires that heat loss to the environment equals metabolic heat production; hypothermia occurs when heat loss exceeds production. Mild core hypothermia is common during surgery and anesthesia. It results initially from redistribution of body heat from the core to peripheral tissues and subsequently from heat loss exceeding metabolic heat production. Clinical doses of general anesthetics decrease the threshold for response to hypothermia from approximately 37° C (normal) to 33° C to 35° C. Anesthetized patients whose core temperatures exceed these values usually are poikilothermic and do not actively respond to thermal perturbations. Patients who become sufficiently hypothermic do trigger thermoregulatory vasoconstriction, and the vasoconstriction is remarkably effective in minimizing further core hypothermia.

Mild intraoperative hypothermia provides significant protection against tissue ischemia and hypoxia in animals. However, the only situations in which improved outcome has been demonstrated with therapeutic hypothermia in humans are out-of-hospital cardiac arrest and neonatal asphyxia. Hypothermia also decreases triggering of malignant hyperthermia, and it reduces the severity of the syndrome, once triggered. However, most consequences of inadvertent hypothermia are harmful. Major adverse effects include morbid myocardial outcomes, reduced resistance to surgical wound infections, increased blood loss and transfusion requirement, prolonged duration of drug action, shivering, and decreased postoperative thermal comfort.

Little metabolic heat is lost via the respiratory tract. Consequently, even active airway heating and humidification are of little benefit. Administration of sufficient volumes of cold intravenous fluid can produce substantial hypothermia. Fluids therefore should be warmed in patients requiring intravenous administration of more than several liters per hour; however, fluid warming should always be secondary to active cutaneous warming. Among the clinically available active systems, forced air offers the best combination of efficacy, safety, and price. Forced air can usually maintain normothermia even during the largest operations.

Regional anesthesia produces both peripheral and central inhibition of thermoregulatory control. Peripheral inhibition results when local anesthetics block nerves that are required for thermoregulatory defenses. Hypothermia during neuraxial anesthesia results initially from core-to-peripheral redistribution of body heat and subsequently from heat loss exceeding heat production. Hypothermia during major conduction anesthesia may be as severe as that during general anesthesia.

Increased core temperature can result from augmented thermogenesis (malignant hyperthermia), excessive heating (passive hyperthermia), or a specific increase in the thermoregulatory target temperature (fever). Because the causes of hyperthermia are varied and often serious, the etiology of observed increases in core temperature should be sought and appropriate treatments instituted.

A reasonable strategy for detecting and preventing thermal disturbances is to monitor core temperature in patients having general anesthesia lasting longer than 30 minutes and in those undergoing major surgery with regional anesthesia. Unless hypothermia is specifically indicated (i.e., for protection against cerebral ischemia), core temperature should be maintained higher than 36° C.

Chapter 55

Airway Management in the Adult

CARIN A. HAGBERG • CARLOS A. ARTIME

Acknowledgment: The editors and the publisher would like to thank Dr. John Henderson, who was a contributing author to this topic in the prior edition of this work. It has served as the foundation for the current chapter.

Key Points

- One of the fundamental responsibilities of the anesthesiologist is to mitigate the adverse effects of anesthesia on the respiratory system by maintaining airway patency and ensuring adequate ventilation and oxygenation. The term *airway management* refers to this practice and is a cornerstone of anesthesia.
- Successful airway management requires a range of knowledge and skill sets—specifically, the ability to predict difficulty with airway management and to formulate an airway management plan, as well as have the skills necessary to execute that plan using the wide array of airway devices available.
- The American Society of Anesthesiologists' *Practice Guidelines for Management of the Difficult Airway* and the accompanying "Difficult Airway Algorithm" provide guidelines for the evaluation of the airway and preparation for difficult airway management and can guide clinical decision making when an anesthesiologist is faced with a known or potentially difficult airway.
- A detailed understanding of airway anatomy is essential for the anesthesia provider.
- A complete evaluation of the airway and knowledge of difficult airway predictors can alert the anesthesiologist to the potential for difficulty with airway management and allow for appropriate planning.
- To facilitate airway management, some form of anesthesia is usually required to provide comfort for the patient, to blunt airway reflexes, and to blunt the hemodynamic response to airway instrumentation, which may be accomplished with the induction of general anesthesia or by the application of local anesthesia to the airway.
- Over the past 25 years, the laryngeal mask airway (LMA) has emerged as one of the most important developments in airway devices.
- Endotracheal intubation establishes a definitive airway, provides maximal protection against the aspiration of gastric contents, and allows for positive-pressure ventilation with higher airway pressures than via a facemask or supraglottic airway.
- Flexible scope intubation of the trachea in an awake, spontaneously ventilating patient is the *gold standard* for the management of the difficult airway.
- Percutaneous (invasive) airways are indicated as a rescue technique when attempts at establishing a noninvasive airway fail. The anesthesia practitioner should become proficient with techniques for transtracheal jet ventilation and cricothyrotomy.
- Extubation is a critical component of airway management with the potential for significant complications. The plan for an extubation of the trachea must be preemptively formulated and includes a strategy for reintubation of the trachea should the patient be unable to maintain an adequate airway after extubation.

INTRODUCTION

General anesthesia is associated with various effects on the respiratory system, including the loss of airway patency, loss of protective airway reflexes, and hypoventilation or apnea. Therefore one of the fundamental responsibilities of the anesthesiologist is to establish airway patency and to ensure adequate ventilation and oxygenation. The term *airway management* refers to the practice of establishing and securing a patent airway and is a cornerstone of anesthetic practice. Traditionally, ventilation via a mask and endotracheal intubation has been the foundation of airway management; in the past 25 years, however, the laryngeal mask airway (LMA) has emerged as one of the most important developments in airway devices.

Because failure to secure a patent airway can result in hypoxic brain injury or death in only a few minutes, difficulty with airway management has potentially grave implications. Analysis of the American Society of Anesthesiologists (ASA) "Closed Claims Project" database has shown that the development of an airway emergency increases the odds of death or brain damage by 15-fold.[1] Although the proportion of claims attributable to airway-related complications has decreased over the past 3 decades, airway complications are still the second-most common cause of claims.[2] In 1993, the ASA published the first *Practice Guidelines for Management of the Difficult Airway*, which was written with the intent to "facilitate the management of the difficult airway and to reduce the likelihood of adverse outcomes."[3] The most recent update to this report, published in 2013, defines the difficult airway as "the clinical situation in which a conventionally trained anesthesiologist experiences difficulty with ventilation of the upper airway via a mask, difficulty with tracheal intubation, or both" and provides guidelines for the evaluation of the airway and preparation for difficult airway management, including a "Difficult Airway Algorithm" intended to guide clinical decision making when an anesthesiologist is faced with a known or potential difficult airway (Figure 55-1).[4]

Successful airway management requires a range of knowledge and skill sets—specifically, the ability to predict difficulty with airway management, to formulate an airway management plan, and to have the skills necessary to execute that plan using the wide array of available airway devices.[5] Development of these skills should be an ongoing endeavor for all anesthesiologists. As with any manual skill, continued practice improves performance and may reduce the likelihood of complications. New airway devices are continually being introduced into the clinical arena, each with unique properties that may be advantageous in certain situations. Becoming familiar with new devices under controlled conditions is important for the anesthesia practitioner—the difficult airway is not an appropriate setting during which to experiment with a new technique.

FUNCTIONAL AIRWAY ANATOMY

A detailed understanding of airway anatomy is essential for the anesthesiologist. Various aspects of airway management depend on a working knowledge of the anatomy involved, including airway assessment, preparation of the airway for awake intubation, and the proper use of airway devices. Knowledge of normal anatomy and anatomic variations that may render airway management more difficult helps with the formulation of an airway management plan. Because some critical anatomic structures may be obscured during airway management, the anesthesiologist must be familiar with the interrelationship between different airway structures.

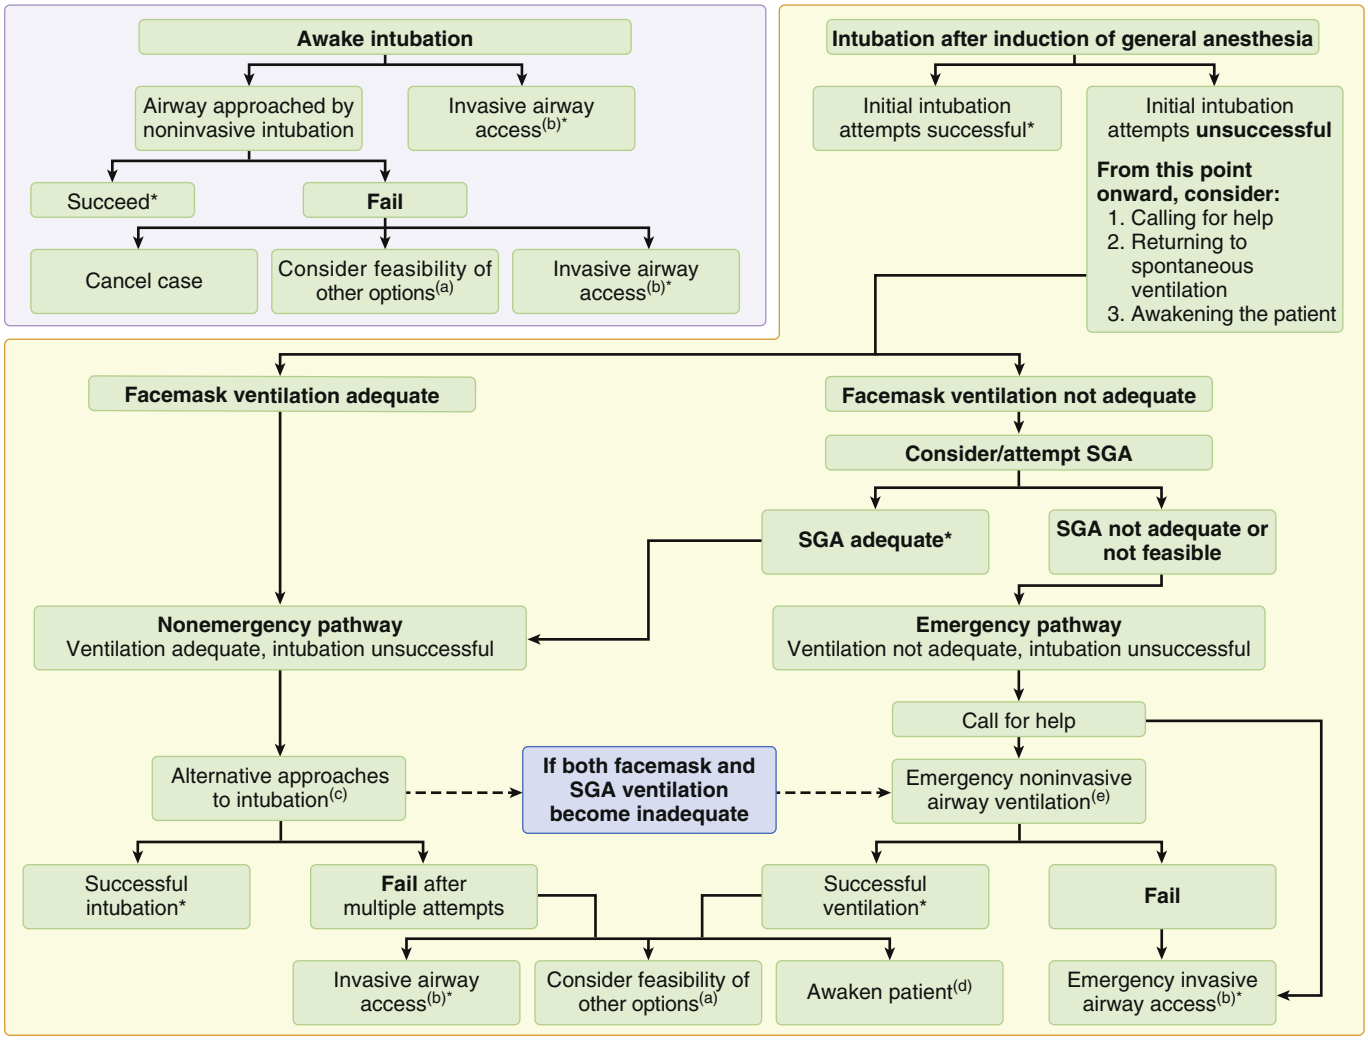
The airway can be divided into the upper airway, which includes the nasal cavity, the oral cavity, the pharynx, and the larynx; and the lower airway, which consists of the tracheobronchial tree.

NASAL CAVITY

The airway begins functionally at the naris (*pl.* nares), the external opening of the nasal passages. The nasal cavity is divided into the right and left nasal passages (or fossae) by the nasal septum, which forms the medial wall of each passage. The septum is formed by the septal cartilage anteriorly and by two bones posteriorly—the ethmoid (superiorly) and the vomer (inferiorly). Nasal septal deviation is common in the adult population[6]; therefore the more patent side should be determined before passing instrumentation through the nasal passages. The lateral wall of the nasal passages is characterized by the presence of three turbinates (or conchae) that divide the nasal passage into three scroll-shaped meatuses (Figure 55-2). The inferior meatus, between the inferior turbinate and the floor of the nasal cavity, is the preferred pathway for passage of nasal airway devices[7]; improper placement of objects in the nose can result in avulsion of a turbinate.[8,9] The roof of the nasal cavity is formed by the cribriform plate, part of the ethmoid bone. This fragile structure, if fractured, can result in communication between the nasal and intracranial cavities and a resultant leakage of cerebrospinal fluid. Because the mucosal lining of the nasal cavity is highly vascular, vasoconstrictor should be applied, usually topically, before instrumentation of the nose to avoid epistaxis. The posterior openings of the nasal passages are the choanae, which lead into the nasopharynx.

ORAL CAVITY

Because of the relatively small size of the nasal passages and the significant risk of trauma, the mouth is often used as a conduit for airway devices. Many airway procedures require adequate mouth opening, which is accomplished by rotation within the temporomandibular joint (TMJ) and subsequent opening by sliding (also known as *protrusion* or *subluxation*) of the condyles of the mandible within the TMJ.[10]



The oral cavity leads to the oropharynx and is inferiorly bounded by the tongue and superiorly by the hard and soft palates. The hard palate, formed by parts of the maxilla and the palatine bone, makes up the anterior two thirds of the roof of the mouth; the soft palate (velum palatinum), a fibromuscular fold of tissue attached to the hard palate, forms the posterior one third of the roof of

1. Assess the likelihood and clinical impact of basic management problems:
   - Difficulty with patient cooperation or consent
   - Difficult mask ventilation
   - Difficult supraglottic airway placement
   - Difficult laryngoscopy
   - Difficult intubation
   - Difficult surgical airway access

2. Actively pursue opportunities to deliver supplemental oxygen throughout the process of difficult airway management.

3. Consider the relative merits and feasibility of basic management choices:
   - Awake intubation *vs.* intubation after induction of general anesthesia
   - Noninvasive technique *vs.* invasive techniques for the initial approach to intubation
   - Video-assisted laryngoscopy as an initial approach to intubation
   - Preservation *vs.* ablation of spontaneous ventilation

4. Develop primary and alternative strategies:

***Confirm ventilation, tracheal intubation, or SGA placement with exhaled CO_2.**

a. Other options include (but are not limited to): surgery using facemask or supraglottic airway (SGA) anesthesia (e.g., LMA, ILMA, laryngeal tube), local anesthesia infiltration, or regional nerve blockade. Pursuit of these options usually implies that mask ventilation will not be problematic. Therefore these options may be of limited value if this step in the algorithm has been reached via the Emergency Pathway.
b. Invasive airway access includes surgical or percutaneous airway, jet ventilation, and retrograde intubation.
c. Alternative difficult intubation approaches include (but are not limited to): video-assisted laryngoscopy, alternative laryngoscope blades, SGA (e.g., LMA or ILMA) as an intubation conduit (with or without fiberoptic guidance), fiberoptic intubation, intubating stylet or tube changer, light wand, and blind oral or nasal intubation.
d. Consider re-preparation of the patient for awake intubation or cancelling surgery.
e. Emergency noninvasive airway ventilation consists of a SGA.

the mouth. The tongue is anchored to various structures by its extrinsic musculature; of these, the most clinically relevant to the anesthesiologist is the genioglossus, which connects the tongue to the mandible. The jaw-thrust maneuver uses the sliding component of the TMJ to move the mandible and the attached tongue anteriorly, thereby relieving airway obstruction caused by the posterior displacement of the tongue into the oropharynx.[10] Beneath the tongue, the mylohyoid muscles separate the floor of the mouth into the sublingual space superiorly and the submental space inferiorly. Cellulitis (Ludwig angina) or hematoma formation in these spaces can cause elevation and posterior displacement of the tongue and resultant airway obstruction.[11]

PHARYNX

The pharynx is a muscular tube that extends from the base of the skull down to the level of the cricoid cartilage and connects the nasal and oral cavities with the larynx and esophagus. The posterior wall of the pharynx is made up of the buccopharyngeal fascia, which separates the pharynx from the retropharyngeal space. Improper placement of a gastric or tracheal tube can result in laceration of this fascia and the formation of a retropharyngeal dissection.[12,13] The pharyngeal musculature in the awake patient helps maintain airway patency; loss of pharyngeal muscle tone is one of the primary causes of upper airway obstruction during anesthesia.[14,15] A chin lift with mouth closure increases longitudinal tension in the pharyngeal muscles, counteracting the tendency of the pharyngeal airway to collapse.[16]

The pharynx can be divided into the nasopharynx, the oropharynx, and the hypopharynx (Figure 55-3). Along the superior and posterior walls of the nasopharynx are the adenoid tonsils, which can cause chronic nasal obstruction and, when enlarged, can cause difficulty passaging airway devices. The nasopharynx ends at the soft palate; this region is termed the *velopharynx* and is a common site of airway obstruction in both awake and anesthetized patients.[14] The oropharynx begins at the soft palate and inferiorly extends to the level of the epiglottis. The lateral walls contain the palatoglossal folds and the palatopharyngeal folds, also termed the *anterior* and *posterior faucial* (tonsillar) *pillars*, respectively; these

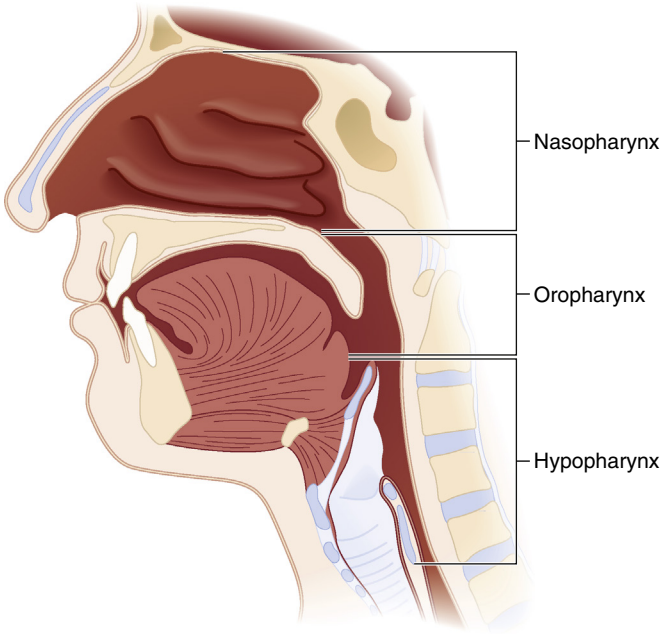

Figure 55-3. Sagittal section through the head and neck showing the subdivisions of the pharynx. *(From Redden RJ: Anatomic considerations in anesthesia. In Hagberg CA, editor:* Handbook of difficult airway management*, Philadelphia, 2000, Churchill Livingstone, p. 7, Figure 1-6.)*

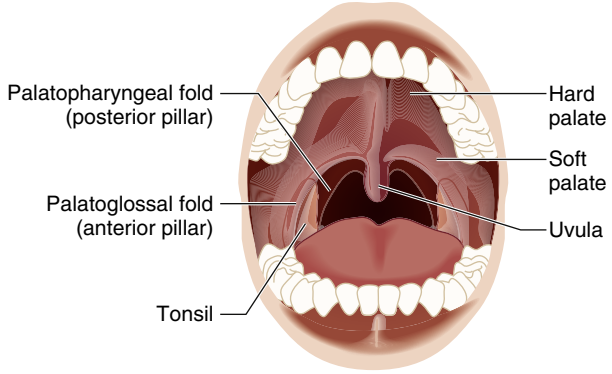

Figure 55-4. Oral cavity and oropharynx. *(From Redden RJ: Anatomic considerations in anesthesia. In Hagberg CA, editor:* Handbook of difficult airway management*, Philadelphia, 2000, Churchill Livingstone, p. 8, Figure 1-7.)*

folds contain the palatine tonsils, which can hypertrophy and cause airway obstruction (Figure 55-4). The base of the tongue lies in the anterior aspect of the oropharynx, connected to the epiglottis by the glossoepiglottic folds, which bound paired spaces known as the *valleculae* (although these are frequently referred to as a single space called the *vallecula*). The hypopharynx begins at the level of the epiglottis and terminates at the level of the cricoid cartilage, where it is continuous with the esophagus. The larynx protrudes into the hypopharynx, creating two piriform recesses on either side (Figure 55-5).

LARYNX

The larynx is a complex structure of cartilage, muscles, and ligaments that serves as the inlet to the trachea and

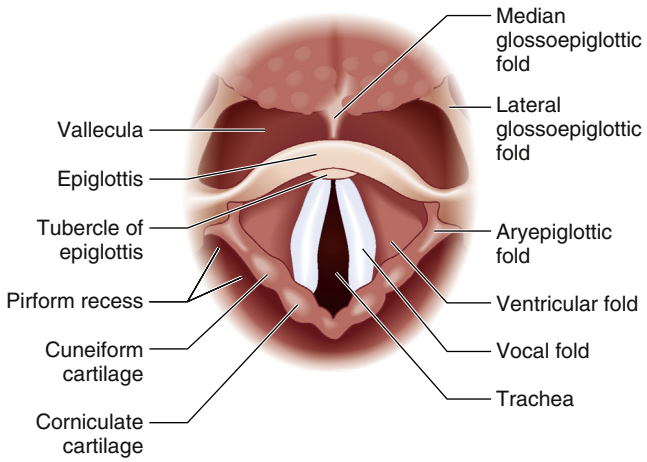

Figure 55-5. Larynx as visualized from the hypopharynx. *(From Redden RJ: Anatomic considerations in anesthesia. In Hagberg CA, editor:* Handbook of difficult airway management*, Philadelphia, 2000, Churchill Livingstone, p. 8, Figure 1-8.)*

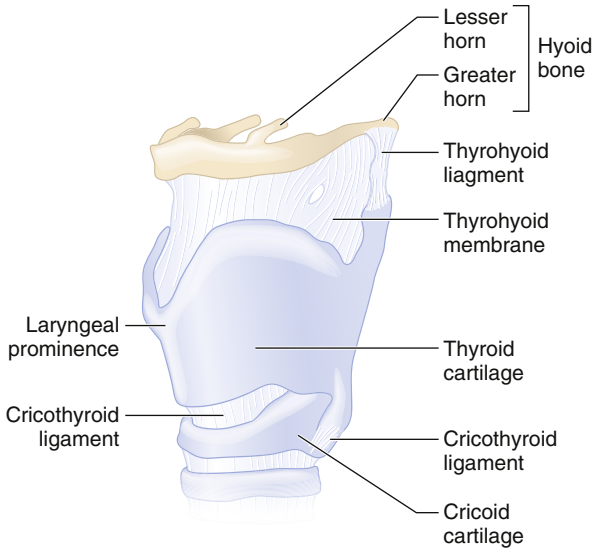

Figure 55-6. Cartilaginous and membranous components of the larynx. *(From Redden RJ: Anatomic considerations in anesthesia. In Hagberg CA, editor:* Handbook of difficult airway management*, Philadelphia, 2000, Churchill Livingstone, p. 10, Figure 1-9.)*

performs various functions, including phonation and airway protection. The cartilaginous framework of the larynx is made up of nine separate cartilages: the thyroid and cricoid cartilages; the paired arytenoid, corniculate, and cuneiform cartilages; and the epiglottis. They are joined by ligaments, membranes, and synovial joints, and are suspended by the hyoid bone via the thyrohyoid ligaments and membrane (Figure 55-6).

The thyroid cartilage is the largest of these cartilages and supports most of the soft tissues of the larynx. The superior thyroid notch and the associated laryngeal prominence *(Adam's apple)* are appreciable from the anterior neck and serve as important landmarks for percutaneous airway techniques and laryngeal nerve blocks. The cricoid cartilage, at the level of the sixth cervical vertebra, is the inferior limit of the larynx and is anteriorly connected to the thyroid cartilage by the cricothyroid membrane (CTM). It is the only complete cartilaginous ring in the airway. The arytenoid cartilages articulate with the posterior cricoid and are the posterior attachments for the vocal cords.

When viewed from the pharynx, as during direct laryngoscopy (DL), the larynx begins at the epiglottis, which is a cartilaginous flap that serves as the anterior border of the laryngeal inlet. It functions to divert food away from the larynx during the act of swallowing, although its role in this regard is not essential to prevent tracheal aspiration.[17] The anterior surface of the epiglottis is attached to the upper border of the hyoid bone by the hyoepiglottic ligament. The laryngeal inlet is bound laterally by the aryepiglottic folds, and posteriorly by the corniculate cartilages and the interarytenoid notch (see Figure 55-5).

The space inferior to the laryngeal inlet down to the inferior border of the cricoid cartilage is the laryngeal cavity. The ventricular folds (also referred to as the *vestibular folds* or *false vocal cords*) are the most superior structure within the laryngeal cavity. Beneath these are the true vocal cords, which attach to the arytenoids posteriorly and the thyroid cartilage anteriorly, where they join together to form the anterior commissure. The space between the vocal cords is termed the *glottis*; the portion of the laryngeal cavity above the glottis is known as the *vestibule*, and the portion inferior to the vocal cords is known as the *subglottis*.

TRACHEA AND BRONCHI

The trachea begins at the level of the cricoid cartilage and extends to the carina at the level of the fifth thoracic vertebra; this length is 10 to 15 cm in the adult. It consists of 16 to 20 C-shaped cartilaginous rings that open posteriorly and are joined by fibroelastic tissue; the trachealis muscle forms the posterior wall of the trachea. At the carina, the trachea bifurcates into the right and left mainstem bronchi. In the adult, the right mainstem bronchus branches off at a more vertical angle than the left mainstem bronchus, resulting in a greater likelihood of foreign bodies and endotracheal tubes (ETTs) entering the right bronchial lumen.[18]

AIRWAY ASSESSMENT

Although the anesthesia provider should always be prepared for potential difficulty with airway management, the ability to predict the difficult airway in advance is obviously desirable. Certain physical findings or details from the patient's history can be prognostic of difficulty with mask ventilation, supraglottic airway placement, laryngoscopy, endotracheal intubation, or the performance of a surgical airway. No single test has been devised to predict a difficult airway accurately 100% of the time; however, a complete evaluation of the airway and knowledge of the difficult airway predictors can alert the anesthesiologist to the potential for difficulty and allow for appropriate planning.

Airway assessment should begin with a directed patient history whenever possible.[4] One of the most

BOX 55-1 ***Components of the Physical Examination of the Airway***

- Visual inspection of the face and neck
- Assessment of mouth opening
- Evaluation of oropharyngeal anatomy and dentition
- Assessment of neck range of motion (ability of the patient to assume the sniffing position)
- Assessment of the submandibular space
- Assessment of the patient's ability to slide the mandible anteriorly (test of mandibular prognathism)

predictive factors for difficult intubation is a history of previous difficulty with intubation.[19] On the other hand, a history of a previously easy airway does not rule out the possibility of difficulty with ventilation or intubation. In either case, the patient interview should specifically address changes in weight, symptomatology, and pathologic conditions since the last induction of an anesthetic (if there was one), and attempts should be made at obtaining prior anesthetic records; they may yield useful information concerning airway management. The presence of pathologic states that increase the risk of a difficult airway should be elicited by performing a medical history. A focused review of systems can alert the anesthesiologist to other potential factors that may predict difficult airway management; for example, a history of snoring has been shown to be predictive of difficult mask ventilation.[20,21]

A physical examination of the airway should be preoperatively performed, when possible, to detect any physical characteristics that may suggest a difficult airway.[4] The specific characteristics that should be evaluated in this examination are listed in Box 55-1.

The visual inspection of the face and neck should focus on any physical characteristics that may indicate the potential for difficulty with airway management. These include obvious facial deformities, neoplasms involving the face or neck, facial burns, a large goiter, a short or thick neck, or a receding mandible. The presence of a beard has been shown to be associated with difficult ventilation attributable to the difficulty in obtaining a mask seal.[20,21] Cervical collars or cervical traction devices can interfere with both mask ventilation and DL. A neck circumference greater than 43 cm (17 inches) is associated with difficulty with tracheal intubation[22] (also see Chapter 71); Brodsky showed that a large neck circumference is, in fact, more predictive of difficulty with endotracheal intubation than a high body mass index (BMI).[23]

Assessment of the mouth opening and inspection of the oropharyngeal anatomy is achieved by instructing the patient to open his or her mouth as wide as possible. An interincisor distance of less than 3 cm (or two fingerbreadths), as measured from the upper to the lower incisors with maximal mouth opening, can suggest the possibility of difficult intubation[24]; some studies have used 4 or 4.5 cm as the cutoff.[25] A thorough inspection of the oropharynx can help identify pathologic characteristics that may result in difficulty with intubation, such as neoplasm, a high arched palate, or macroglossia. In

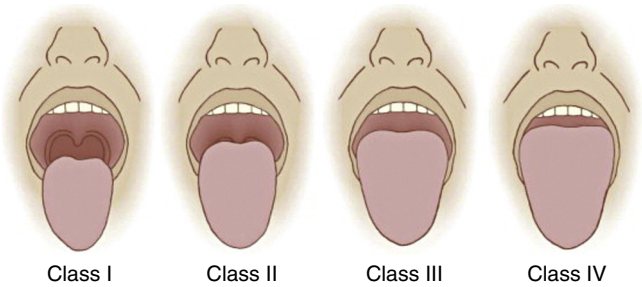

Figure 55-7. Modified Mallampati classification as described by Samsoon and Young. Classes are differentiated on the basis of the structures visualized: class I—soft palate, fauces, uvula, tonsillar pillars; class II—soft palate, fauces, uvula; class III—soft palate, base of the uvula; class IV—soft palate not visible. *(From Mallampati SR: Recognition of the difficult airway. In Benumof JL, editor:* Airway management principles and practice*, St Louis, 1996, Mosby, p. 132.)*

1983, Mallampati and associates described a clinical sign to predict difficult tracheal intubation based on the size of the base of the tongue.[26] A Mallampati classification of I to III is assigned, based on the visibility of the faucial pillars, uvula, and soft palate when the patient is seated upright with the head neutral, the mouth open, the tongue protruded, and no phonation.[27] Higher scores on the Mallampati classification indicate poor visibility of the oropharyngeal structures attributable to a large tongue relative to the size of the oropharyngeal space, and, subsequently, a more difficult laryngoscopy. The modified Mallampati classification described by Samsoon and Young,[28] which adds a fourth classification, is the most commonly used airway assessment test in current anesthesia practice and is defined as follows (Figure 55-7):

- Class I: Faucial pillars, uvula, and soft palate are visualized.
- Class II: Base of the uvula and soft palate are visualized.
- Class III: Soft palate only is visualized.
- Class IV: Hard palate only is visualized.

As a stand-alone test, the modified Mallampati classification is insufficient for accurate prediction of difficult intubation; however, it may have clinical utility in combination with other difficult airway predictors.[29] Some studies support obtaining a Mallampati score with the head in full extension to improve the predictive value of the test.[27,30] A Mallampati *zero* classification has been proposed when the epiglottis can be visualized during examination of the oropharynx; this finding is usually associated with easy laryngoscopy,[31,32] although difficulty with airway management attributable to a large, floppy epiglottis in patients with a Mallampati zero classification can occur.[33,34]

An examination of dentition should be performed when the oropharyngeal anatomy is being evaluated.[24] Relatively long upper incisors can impair DL. Poor dentition and loose teeth increase the risk of dental trauma and present a risk of tooth dislodgment with subsequent aspiration; very loose teeth should be removed before laryngoscopy. Cosmetic dental work, such as veneers, caps, crowns, and bridges, are particularly susceptible to

damage during airway management. Edentulousness is predictive of easy tracheal intubation but potentially difficult mask ventilation.[35]

The ideal positioning for DL is achieved by cervical flexion and atlantooccipital extension and is most commonly referred to as the *sniffing position*[36] (see Preparation and Positioning). Assessment of a patient's ability to assume this position should be included in the airway examination; an inability to extend the neck at the atlantooccipital joint is associated with difficult laryngoscopy.[37] Head and neck mobility can also be quantitatively assessed by measuring the sternomental distance between the sternal notch and the point of the chin with the head in full extension and the mouth closed. Distances less than 12.5 cm are associated with difficult intubation.[38] An assessment of overall neck range of motion can be performed by measuring the angle created by the forehead when the neck is fully flexed and then fully extended; a measurement of less than 80 degrees is predictive of difficult intubation.[39]

During DL, the tongue is displaced into the submandibular space; glottic visualization may be inadequate if this space is diminished because of a small mandible. This scenario is frequently referred to as an *anterior larynx*. A thyromental distance of less than 6.5 cm (three fingerbreadths), as measured from the thyroid notch to the lower border of the mentum, is indicative of reduced mandibular space and may predict difficulty with intubation.[25,38] Compliance of this space should also be assessed; a lack of compliance or the presence of a mass is a nonreassuring finding.[24]

Tests of the ability for mandibular protrusion (prognathism) have predictive value and should be included in the airway assessment. The inability to extend the lower incisors beyond the upper incisors may be indicative of difficult laryngoscopy.[40] A similar evaluation, the upper lip bite test (ULBT) described by Khan and colleagues, has been shown to predict difficult laryngoscopy with higher specificity and less interobserver variability than the Mallampati classification; an inability of the lower incisors to bite the upper lip is associated with more difficult laryngoscopy.[41,42]

Although individual airway tests are limited by low sensitivity and positive predictive value, multivariable assessments have been shown to have higher predictive power. The Mallampati score has been shown to have improved predictive value when combined with thyromental, sternomental, and/or interincisor distances.[38,43] Models that use several risk factors, such as the Wilson risk sum score (weight, head and neck movement, jaw movement, receding mandible, and buck teeth) and the El-Ganzouri risk index (mouth opening, thyromental distance, Mallampati class, neck movement, prognathism, weight, and history of difficult intubation) have been developed in an attempt to improve the predictive value of airway assessment.[39,44] Langeron and associates developed a computer-assisted model that uses complex interactions among several risk factors (BMI, mouth opening, thyromental distance, Mallampati class, and receding mandible) to predict difficult intubation more accurately than other models based on simpler statistical analyses.[45]

PHYSIOLOGIC CONCEPTS FOR AIRWAY MANAGEMENT

PREOXYGENATION

With the induction of anesthesia, hypoxemia can quickly develop as a result of hypoventilation or apnea in combination with decreases in functional residual capacity (FRC) attributable to the supine position, muscle paralysis, and the direct effects of the anesthetic agents themselves. Preoxygenation, the process of replacing nitrogen in the lungs with oxygen, provides an increased length of time before hemoglobin desaturation occurs in a patient with apnea. This lengthened *apnea time* provides an improved margin of safety while the anesthesiologist secures the airway and resumes ventilation. Adequate preoxygenation is essential when mask ventilation after the induction of anesthesia is contraindicated or anticipated to be difficult, when intubation is anticipated to be difficult, and in patients with a smaller FRC (i.e., patients who are obese or pregnant)[46] (also see Chapters 71 and 77). Because difficulty with airway management can unexpectedly occur, routine preoxygenation before induction of general anesthesia is recommended.[47]

Preoxygenation is typically performed via a facemask attached to either the anesthesia machine or a Mapleson circuit. To ensure adequate preoxygenation, 100% oxygen must be provided at a flow rate high enough to prevent rebreathing (10 to 12 L/min), and no leaks around the facemask must be present. An end-tidal concentration of oxygen greater than 90% is considered to maximize apnea time. Two primary methods are used to accomplish preoxygenation. The first method uses tidal volume ventilation through the facemask for 3 minutes, which allows the exchange of 95% of the gas in the lungs.[46] The second method uses vital capacity breaths to achieve adequate preoxygenation more rapidly. Four breaths over 30 seconds is not as effective as the tidal volume method but may be acceptable in certain clinical situations; eight breaths over 60 seconds has been shown to be more effective.[46] Head-up positioning has been shown to improve the quality of preoxygenation in both obese[48] and nonobese patients.[49] The use of noninvasive positive-pressure ventilation (PPV) for preoxygenation also prolongs apnea time.[50,51]

PULMONARY ASPIRATION OF GASTRIC CONTENTS

In 1946, Mendelson was the first to describe aspiration pneumonitis attributable to the pulmonary aspiration of acidic gastric secretions in pregnant women undergoing anesthesia.[52] This potentially fatal complication, occasionally referred to as Mendelson syndrome, has since been the intense focus of preventive efforts among the anesthesia community. Prevention of aspiration of gastric contents is primarily accomplished by adherence to established preoperative fasting guidelines, premedication with drugs that may decrease the risk of aspiration pneumonitis, and specialized induction techniques, which are discussed later in this chapter (also see Chapter 77).

Traditionally, patients who were scheduled for elective procedures requiring sedation, regional anesthesia, or general anesthesia were instructed to remain NPO (Latin for *nulla per os* or *nothing by mouth*) after midnight to ensure an empty stomach to decrease the risk of regurgitation. Based on evidence that allowing ingestion of clear liquids 2 to 4 hours before surgery resulted in lower gastric volumes and higher gastric pH, the ASA published *Practice Guidelines for Preoperative Fasting and the Use of Pharmacologic Agents to Reduce the Risk of Pulmonary Aspiration* in 1999 that liberalized the traditional NPO policy and allowed clear liquids up to 2 hours before beginning elective procedures requiring anesthesia. The guidelines, updated in 2011, recommend 4 hours of fasting from breast milk and 6 hours of fasting from solid foods, infant formula, and nonhuman milk. Fried or fatty foods may require longer fasting times (e.g., 8 hours or more).[53] Although the ASA guidelines do not specifically address chewing gum, hard candies, or smoking, guidelines published by the European Society of Anaesthesiology on the topic do not recommend delaying the start of anesthesia if a patient has consumed any of these immediately before the induction of anesthesia.[54]

The routine use of drugs as prophylaxis against aspiration pneumonitis is not recommended by the ASA guidelines[53] but may be beneficial in patients with specific risk factors for aspiration, such as a full stomach, symptomatic gastroesophageal reflux disease (GERD), hiatal hernia, presence of a nasogastric tube, morbid obesity, diabetic gastroparesis, or pregnancy. The goal of aspiration prophylaxis is twofold: to decrease gastric volume and to increase gastric fluid pH. Commonly used agents include nonparticulate antacids (e.g., Bicitra), promotility drugs (e.g., metoclopramide), and H_2-receptor antagonists. These drugs may be used alone or in combination.[55]

AIRWAY REFLEXES AND THE PHYSIOLOGIC RESPONSE TO INTUBATION OF THE TRACHEA

One of the most important teleologic functions of the larynx is that of airway protection, which is primarily provided by the glottic closure reflex. This reflex is triggered by sensory receptors in the glottic and subglottic mucosa and results in strong adduction of the vocal cords.[56] An exaggerated, maladaptive manifestation of this reflex, referred to as *laryngospasm*, is a potential complication of airway management. Laryngospasm is usually provoked by glossopharyngeal or vagal stimulation attributable to airway instrumentation or vocal cord irritation (e.g., from blood or vomitus) in the setting of a light plane of anesthesia (stage II of the Guedel classification), but it can also be precipitated by other noxious stimuli and can persist well after the removal of the stimulus. Treatment of laryngospasm includes removal of airway irritants, deepening of the anesthetic, and the administration of a rapid-onset neuromuscular blocking drug (NMBD), such as succinylcholine.[57] Continuous positive airway pressure with 100% oxygen is commonly cited as a therapeutic maneuver, although the pressure may push the aryepiglottic folds closer together and may actually promote laryngospasm by acting as a mechanical stimulus.[58,59] Bilateral pressure at the *laryngospasm notch* between the condyle of the mandible and the mastoid process can be effective at treating laryngospasm by causing an intense, painful stimulus, which may function to terminate laryngospasm by arousing a semiconscious patient or by activating autonomic pathways.[57]

The tracheobronchial tree also possesses reflexes to protect the lungs from noxious substances. Irritation of the lower airway by a foreign substance activates a vagal reflex–mediated constriction of bronchial smooth muscle, resulting in bronchospasm. Untreated bronchospasm can result in an inability to ventilate because of an extremely elevated airway resistance. Treatment includes a deepening of anesthetic with propofol or a volatile agent and the administration of inhaled β_2-agonist or anticholinergic medications. Administration of intravenous (IV) lidocaine has been studied, but the evidence does not support its use for treatment of bronchospasm.[60]

Endotracheal intubation, as well as laryngoscopy and other airway instrumentation, provides an intense noxious stimulus via vagal and glossopharyngeal afferents that results in a reflex autonomic activation, which is usually manifested as hypertension and tachycardia in adults and adolescents; in infants and small children, autonomic activation may result in bradycardia. Hypertension and tachycardia are usually of short duration; however, they may have consequences in patients with significant cardiac disease. Central nervous system activation as a result of airway management results in increases in electroencephalographic (EEG) activity, cerebral metabolic rate, and cerebral blood flow, which may result in an increase in intracranial pressure in patients with decreased intracranial compliance.[60]

ANESTHESIA FOR AIRWAY MANAGEMENT

To facilitate airway management, some form of anesthesia is usually required to provide comfort for the patient, to blunt airway reflexes, and to blunt the hemodynamic response to airway instrumentation. Most commonly, airway management is performed after induction of general anesthesia. Alternatively, an *awake* technique, which means establishing an airway (including endotracheal intubation) by using local anesthesia of the airway and/or sedation, can be used to meet these goals when clinically indicated. In emergency scenarios where the patient is obtunded or comatose, such as in the event of acute respiratory or cardiac arrest, anesthetic drugs may not be required.

AIRWAY MANAGEMENT AFTER THE INDUCTION OF GENERAL ANESTHESIA

Airway management is usually performed after the induction of general anesthesia if the anesthesiologist determines that it is safe to do so. Several pharmacologic techniques are used for the induction of anesthesia, each with its own implications for airway management. The decision of which induction technique to use should be made with careful consideration of the specific clinical circumstances at hand.

Standard Intravenous Induction With Neuromuscular Blockade

The most common technique for induction of general anesthesia is the standard IV induction, which entails the administration of a rapid-acting IV anesthetic, followed by a NMBD. Muscle relaxation achieved by the administration of NMBDs improves intubating conditions by facilitating laryngoscopy, preventing both reflex laryngeal closure and coughing after intubation.[10,61]

Propofol is the most frequently used IV anesthetic drug; other options include etomidate, ketamine, thiopental, and midazolam (also see Chapter 30). The choice of drug depends on a variety of factors including the patient's hemodynamic status, comorbidities, and allergies, as well as drug pharmacokinetics, side effects, physician preference, and availability.[62] Whether the choice of an anesthetic drug has any effect on the quality of intubating conditions when NMBDs are also administered is not well-established. Studies comparing propofol, etomidate, and thiopental in combination with NMBDs showed no difference in intubating conditions between the different anesthetics.[63,64] On the other hand, one study, during which patients received cisatracurium, showed that larger doses of propofol were associated with improved intubating conditions, as compared with smaller doses.[65]

For many years, succinylcholine was the most frequently used NMBD for routine IV induction[62]; recently, however, nondepolarizing NMBDs have gained greater popularity attributable to the risk of adverse effects from succinylcholine administration, including bradycardia, myalgia, hyperkalemia, increased intracranial pressure, and increased intragastric pressure[66] (also see Chapter 34). Succinylcholine, the only depolarizing NMBD in clinical use, has the benefit of a rapid onset, combined with a short duration of action, and it is currently used most often when those properties are desired. Most notably, succinylcholine is still commonly used in the setting of a suspected difficult airway; its short duration of action theoretically allows for the resumption of spontaneous ventilation before severe hypoxia develops in a preoxygenated patient, although evidence suggests that this may not predictably occur *in vivo*.[67]

Nondepolarizing NMBDs are the more frequently used relaxants for routine IV induction of anesthesia.[66] The most commonly used nondepolarizing NMBDs in current practice—rocuronium, vecuronium, and cisatracurium—are notable for having a favorable safety profile with relatively few side effects. The primary limitation of these drugs is a significantly longer duration of action; once administered, a functional airway must be established within minutes to avoid life-threatening hypoxia. Sugammadex is a selective relaxant-binding agent for rocuronium that has the ability to reverse profound neuromuscular blockade rapidly in a time comparable with spontaneous recovery from succinylcholine.[68] The introduction of sugammadex, which is currently unavailable in the United States, may result in a further reduction in the use of succinylcholine for routine induction of general anesthesia (also see Chapter 35).

Traditional teaching has advocated withholding NMBDs until the ability to mask ventilate has been established. If ventilation via a mask cannot be achieved, a patient who has been breathing oxygen can then resume spontaneous ventilation or be awakened before the onset of hypoxia.[69] This practice has been increasingly questioned in the literature due, in part, to a number of studies demonstrating that ventilation via a mask is *not* rendered more difficult by muscle relaxation[70,71]; rather, mask ventilation is, in fact, facilitated by muscle relaxation.[72] One issue with the traditional paradigm is that the theoretic advantage of the practice—the ability to awaken the patient if ventilation via a mask fails—is rarely used.[73] The desire to preserve that ability may, in fact, result in giving an inadequate dose of anesthetic during induction, resulting in a difficult mask ventilation situation when one would not have otherwise occurred.[73] Delaying the administration of NMBDs can result in the onset of hypoxia before spontaneous recovery (with succinylcholine) or reversal (with rocuronium and sugammadex) is possible.

Proponents of traditional teaching point to the fact that the effect of muscle relaxation on the ability to ventilate via a mask has only been studied in patients with normal airways. In patients with predicted or known difficult airways, checking the ability to mask ventilate allows for the formulation of the best airway management plan. In the authors' opinions, in patients with normal airways in whom difficulty with mask ventilation is often a result of glottic closure attributable to opioid-mediated rigidity or airway irritation, withholding an NMBD is not likely to be of benefit. In patients with a potentially difficult airway, the ability to ventilate via a mask should be confirmed before administering long-acting NMBDs when the ability to reverse quickly with sugammadex is not an option.

Rapid-Sequence Induction of Anesthesia and Intubation of the Trachea

Rapid-sequence induction of anesthesia and intubation (RSII) of the trachea (frequently referred to as simply *rapid sequence induction* [RSI] in the anesthesia literature) is a specialized method of IV induction commonly used when a frequent risk for gastric regurgitation and pulmonary aspiration of gastric contents is present. After adequate preoxygenation and while cricoid pressure is applied, an induction dose of IV anesthetic is rapidly followed by 1 to 1.5 mg/kg of IV succinylcholine, and the trachea is intubated without attempts at PPV, all while cricoid pressure is applied. The goal is to achieve optimal intubating conditions rapidly to minimize the length of time between the loss of consciousness (LOC) and securing of the airway with a cuffed ETT. Cricoid pressure, eponymously referred to as the Sellick maneuver after the physician who first described it, involves the application of pressure at the cricoid ring to occlude the upper esophagus, thereby preventing the regurgitation of gastric contents into the pharynx.[74] The recommended force to be applied is 10 Newtons (N) while the patient is awake, increased to 30 N after LOC. These values are based on esophageal manometry on patients undergoing induction of anesthesia and cadaver studies of safe amounts of pressure.[75] RSII is widely practiced and approaches a standard of care in patients with a full stomach (i.e., when NPO guidelines have not been observed) and in the setting of bowel obstruction.[76,77] RSII has historically been

recommended for patients who are pregnant, starting in the second trimester,[78] but this dogma has recently been called into question[79,80] (also see Chapter 77). Other clinical situations for which RSII may be considered due to a higher than normal risk for aspiration of gastric contents, include poorly controlled GERD, presence of a nasogastric tube, morbid obesity, and diabetic gastroparesis. RSII is also a useful induction technique when ventilation via a mask is predicted to be difficult, but intubation is not, such as with an edentulous, bearded patient with an otherwise reassuring airway examination.

Some common variations to RSII have developed from the technique first described in 1970.[81] When succinylcholine is contraindicated or its side effects are undesired, RSII can be accomplished using nondepolarizing NMBDs (rocuronium 1.0 to 1.2 mg/kg or vecuronium 0.3 mg/kg); these doses provide adequate intubating conditions in less than 90 seconds.[82,83] The primary disadvantage with these drugs is the prolonged duration of neuromuscular blockade; however, the introduction of sugammadex may result in their increased use (also see Chapters 34 and 35). Although traditional RSII calls for induction with a fixed dose of thiopental, the use of other anesthetics such as propofol, etomidate, or ketamine is common. Some advocate for the titration of the chosen anesthetic agent to LOC rather than the delivery of a fixed, predetermined dose.[77]

The application of cricoid pressure is the most controversial aspect of RSII.[77] Opponents point to studies showing that cricoid pressure results in a decrease in lower esophageal sphincter tone, potentially increasing the risk for regurgitation,[84] and to magnetic resonance imaging (MRI) studies showing that cricoid pressure does not, in fact, result in compression of the esophagus, but rather a lateral displacement.[85] Cricoid pressure also worsens laryngeal visualization during DL, potentially lengthening the time to intubation and increasing the risk of pulmonary aspiration, and can result in occlusion of the subglottic airway, resulting in difficulty with intubation of the trachea or ventilation via a mask.[86] On the other hand, advocates argue that properly applied cricoid pressure is effective in reducing the risk of aspiration and that reports of problems are due to incorrect application. The authors of a recent MRI study of cricoid pressure argue that the position of the esophagus is irrelevant because the effectiveness of cricoid pressure is due to occlusion of the hypopharynx.[87] In general, because of the relatively infrequent risk of application of cricoid pressure, its use is encouraged for RSII unless glottic visualization proves difficult, in which case it can be easily released.

The term *modified RSII* is frequently used, but no standardized definition exists. A survey of anesthesia residents and attending anesthesiologists in the United States showed that the term was most commonly used to refer to the use of mask ventilation in conjunction with cricoid pressure.[88] Indications for this technique include patients at risk for rapid development of hypoxemia (e.g., patients who are obese, pregnant, or critically ill; pediatric patients) in emergent situations during which preoxygenation cannot be satisfactorily completed or when a longer time to acceptable intubating conditions is required because of the use of standard doses of nondepolarizing NMBDs. Although the effect of PPV with cricoid pressure applied in terms of gastric insufflation of air is not definitively known, gentle PPV (inspiratory pressure <20 cm water [H_2O]) in conjunction with cricoid pressure may be acceptable in these clinical scenarios.[89]

Inhalational Induction of Anesthesia

Another option for the induction of general anesthesia is an inhaled induction with volatile anesthetic. This technique is commonly used in pediatric anesthesia to provide a painless, needle-free experience for the child (also see Chapter 93). In adults, an inhaled induction of anesthesia is used when IV access is not available or when the specific advantages of the technique are desirable. Advantages of an inhaled induction of anesthesia are the maintenance of spontaneous ventilation and the potential for gradual changes in the depth of anesthesia and associated respiratory and cardiovascular effects.[10] Inhaled induction of anesthesia has also been used for RSII, with a rapid-onset NMBD administered at LOC[90] (also see Chapter 34).

Sevoflurane is currently the most commonly used volatile anesthetic for inhalational induction because of its lack of pungency and low blood:gas solubility (see Chapter 21), allowing for a smooth induction of anesthesia that can provide suitable conditions for airway management with or without adjuvant drugs such as NMBDs or opioids.[91] The two principal techniques for sevoflurane induction of anesthesia are a *tidal volume induction*, in which patients are instructed to breathe normally through the facemask, and a *vital capacity induction*, in which patients are instructed to exhale to residual volume and then take a vital capacity breath from the facemask. High delivered concentrations of sevoflurane (8%) are used for vital capacity induction, whereas tidal volume inductions may start with lower sevoflurane concentrations before the concentration is increased. Nitrous oxide (N_2O) can be used with either method to speed induction via the second-gas effect (also see Chapter 21).[92] Both methods are effective and can be used for either LMA placement or endotracheal intubation.[91] Deep levels of anesthesia are required to achieve satisfactory intubating conditions when using sevoflurane as a sole induction agent, increasing the risk of adverse effects, such as hypotension. The administration of propofol,[93] fast-acting opioids,[94,95] NMBDs,[96] and ketamine[97] have all been shown to improve intubating conditions and allow for lower end-tidal concentrations of sevoflurane.

Halothane, which is still commonly used in developing countries, can also be used for an inhaled induction of anesthesia.[98] One main disadvantage of halothane is its high blood:gas coefficient, which leads to relatively long induction times. It also can produce cardiac dysrhythmias, myocardial depression, and halothane-induced hepatitis. Because of the inability to achieve deep levels of anesthesia with halothane as a result of its side effects, the use of NMBDs, opioids, or both, is often required.[91] The use of desflurane for inhaled induction of anesthesia is limited by its tendency to cause airway irritation, although reports of its use for induction in combination with opioids has been reported.[99,100]

Intravenous Induction Without Neuromuscular Blocking Drugs

IV induction of general anesthesia without the use of NMBDs is commonly used for LMA placement but can be used to achieve satisfactory intubating conditions as well. This technique is useful when the use of succinylcholine is contraindicated and the prolonged recovery time from nondepolarizing NMBDs is undesirable. Of the commonly available IV anesthetics, propofol is the best suited for induction without muscle relaxation because of its unique ability to suppress airway reflexes and to produce apnea.[101,102] Larger doses are required, however, when propofol is used as a sole anesthetic, increasing the risk of significant hypotension. Improvement of intubating conditions and smaller doses of propofol are possible when rapid-onset opioids (e.g., alfentanil, remifentanil) or IV magnesium are administered.[103,104] Remifentanil is more effective than comparable doses of alfentanil[103]; in combination with propofol 2 mg/kg, remifentanil 4 to 5 μg/kg can reliably provide good-to-excellent intubating conditions.[105] When combined with cricoid pressure and an avoidance of mask ventilation, this induction technique can be used for RSII.[106]

Disadvantages of this technique include a potentially more frequent incidence of difficult intubation[107] and an increased risk for laryngeal morbidity.[61,108] This technique also introduces the risk of opioid-induced muscle rigidity resulting in difficulty with mask ventilation. Although this risk is commonly attributed to chest wall rigidity, studies in intubated patients and patients with tracheostomies have shown that decreases in pulmonary compliance due to chest wall rigidity are not sufficient to explain an inability to mask ventilate after a large dose of an opioid.[109,110] Examination of the vocal cords during induction with opioids has shown that vocal cord closure is the primary cause of difficult ventilation after opioid-induced anesthesia.[111,112] Treatment with small doses of NMBD or topical lidocaine (laryngotracheal anesthesia) can be effective in relaxing the vocal cords to allow for mask ventilation and/or intubation.[111,113]

AIRWAY MANAGEMENT IN AN AWAKE (NONANESTHETIZED) PATIENT

In the ASA "Difficult Airway Algorithm," a consideration of whether the airway should be secured before or after induction of general anesthesia is one of the basic management choices that should be considered when an airway management plan is being devised.[24] The benefits of awake airway management include the preservation of pharyngeal muscle tone and patency of the upper airway, the maintenance of spontaneous ventilation, an ability to obtain a quick neurologic examination, and a safeguard against aspiration attributable to the preservation of protective airway reflexes.[114] In general, when difficult mask ventilation and difficult intubation are expected, the safest approach to airway management is to secure the airway while the patient remains awake.[24] Other indications for awake airway management include the risk of severe aspiration of gastric contents, facial or airway trauma, severe hemodynamic instability, and cervical spine pathologic instability.[115]

Because of the nature of these indications, endotracheal intubation is most often chosen as the goal of awake airway management; however, awake placement of an LMA for diagnostic bronchoscopy has been described. The most useful technique for awake intubation is the flexible scope intubation (FSI),[114] although other techniques have been successfully used, including video laryngoscopes (VLs),[116] optical stylets,[117] lighted nonoptical stylets,[118] intubating LMAs,[119] and retrograde intubation (RI).[120]

Topicalization of the airway with local anesthetics should, in most cases, be the primary anesthetic for awake airway management.[114] Lidocaine is the most commonly used local anesthetic for awake airway management because of its rapid onset, high therapeutic index, and availability in a wide variety of preparations and concentrations.[121,122] Benzocaine and Cetacaine (a topical application spray containing benzocaine, tetracaine, and butamben; Cetylite Industries, Pennsauken, NJ) provide excellent topical anesthesia of the airway, but their use is limited by the risk of methemoglobinemia, which can occur with as little as 1 to 2 seconds of spraying.[123] Topical cocaine is primarily used for anesthesia and vasoconstriction of the nasal mucosa during awake nasotracheal intubation.[124] A mixture of lidocaine 3% and phenylephrine 0.25%, which can be made by combining lidocaine 4% and phenylephrine 1% in a 3:1 ratio, has similar anesthetic and vasoconstrictive properties as topical cocaine and can be used as a substitute.[125]

Topicalization should primarily be focused on the base of the tongue (pressure receptors here act as the afferent component of the gag reflex), the oropharynx, the hypopharynx, and the laryngeal structures; anesthesia of the oral cavity is unnecessary. If a nasotracheal intubation is planned, then the nasal cavity should also be topicalized. Before airway topicalization, an anticholinergic should be administered to aid in the drying of secretions, which helps improve both the effectiveness of the topical local anesthetics and visualization during laryngoscopy. Glycopyrrolate is usually preferred because it has less vagolytic effects than atropine at doses that inhibit secretions and does not cross the blood-brain barrier. It should be administered as early as possible to maximize its effectiveness.

Direct application of topical cocaine, lidocaine 4% with epinephrine, or lidocaine 3%/phenylephrine 0.25% solution via cotton swabs or cotton pledgets is effective for anesthesia of the nasal mucosa. Oropharyngeal anesthesia can be achieved by the direct application of local anesthetic or by the use of an atomizer or nebulizer. Topicalization of the larynx can be achieved by aspiration of a local anesthetic or by the *spray-as-you-go* (SAYGO) method, which involves intermittently injecting local anesthetics through the suction port or working channel of a flexible intubation scope (FIS) or optical stylet, as it is advanced toward the trachea.

Topicalization of the airway mucosa using one or more of these methods is often sufficient. If supplemental anesthesia is required, then a variety of nerve blocks may be used. Three of the most useful are the glossopharyngeal nerve block, superior laryngeal nerve block, and translaryngeal block.

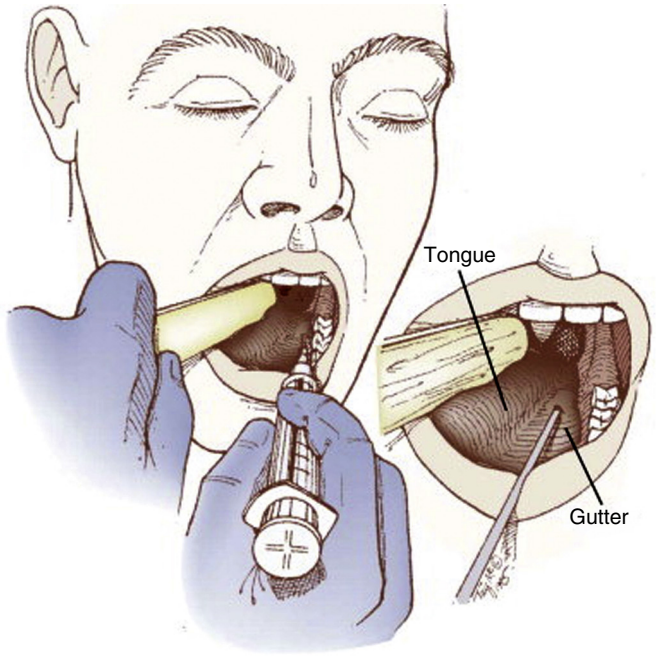

Figure 55-8. Left glossopharyngeal nerve block. *(Reprinted from Artime CA, Sanchez A: Preparation of the patient for awake intubation. The glossopharyngeal nerve supplies sensory innervation to the posterior third of the tongue, vallecula, the anterior surface of the epiglottis, and the posterior and lateral walls of the pharynx and is the afferent pathway of the gag reflex. To block this nerve, the tongue is displaced medially, forming a gutter (glossogingival groove). A 25-gauge spinal needle is inserted at the base of the anterior tonsillar pillar, just lateral to the base of the tongue, to a depth of 0.5 cm (Figure 55-8). After negative aspiration for blood or air, 2 mL of 2% lidocaine is injected. The process is then repeated on the contralateral side.[114]

The superior laryngeal nerve, a branch of the vagus nerve, provides sensory input from the lower pharynx and the upper part of the larynx, including the glottic surface of the epiglottis and the aryepiglottic folds. A block of this nerve may be achieved using one of three landmarks (Figure 55-9). Using either the superior cornu of the hyoid or the superior cornu of the thyroid cartilage, a 25-gauge spinal needle is walked off the cornu anteriorly toward the thyrohyoid ligament. Resistance is felt as the needle is advanced through the ligament, usually at a depth of 1 to 2 cm. After negative aspiration for blood and air, 1.5 to 2 mL of 2% lidocaine is injected and then repeated on the opposite side.[121] The third landmark for the superior laryngeal nerve block is particularly useful in patients who are obese, in whom palpation of the hyoid or the superior cornu of the thyroid cartilage may be difficult or uncomfortable for the patient. In this approach, the needle is inserted 2 cm lateral to the superior notch of the thyroid cartilage and directed in a posterior and cephalad direction to 1 to 1.5 cm depth, where 2 mL of 2% lidocaine is infiltrated and, again, repeated on the contralateral side.[126]

Translaryngeal (or transtracheal) block provides anesthesia of the trachea and vocal cords. This block may be particularly useful in situations where a neurologic examination is needed after intubation; it makes the presence of the ETT in the trachea more comfortable. The CTM is identified, and a 20- to 22-gauge needle attached to 5-mL syringe is directly advanced posteriorly and slightly caudally until air is aspirated, at which point 4 mL of either 2% or 4% lidocaine is quickly injected. This causes the patient to cough, anesthetizing the vocal cords and the trachea. To minimize the risk of trauma, a catheter may first be placed over the needle and the local anesthetic then injected through the catheter (Figure 55-10).[121]

These techniques may be used in various different combinations as long as the maximum dose of local anesthetic is not exceeded. The maximum dose of lidocaine for application to the airway is not well-established; different sources suggest total doses in the range of 4 to 9 mg/kg.[121,127,128] Monitoring for signs and symptoms of lidocaine toxicity, including tinnitus, perioral tingling, metallic taste, lightheadedness, dizziness, and sedation is important. Severe lidocaine overdose can cause hypertension, tachycardia, seizures, and cardiovascular collapse.[129]

Depending on the clinical circumstance, IV sedation may facilitate airway management in an awake patient

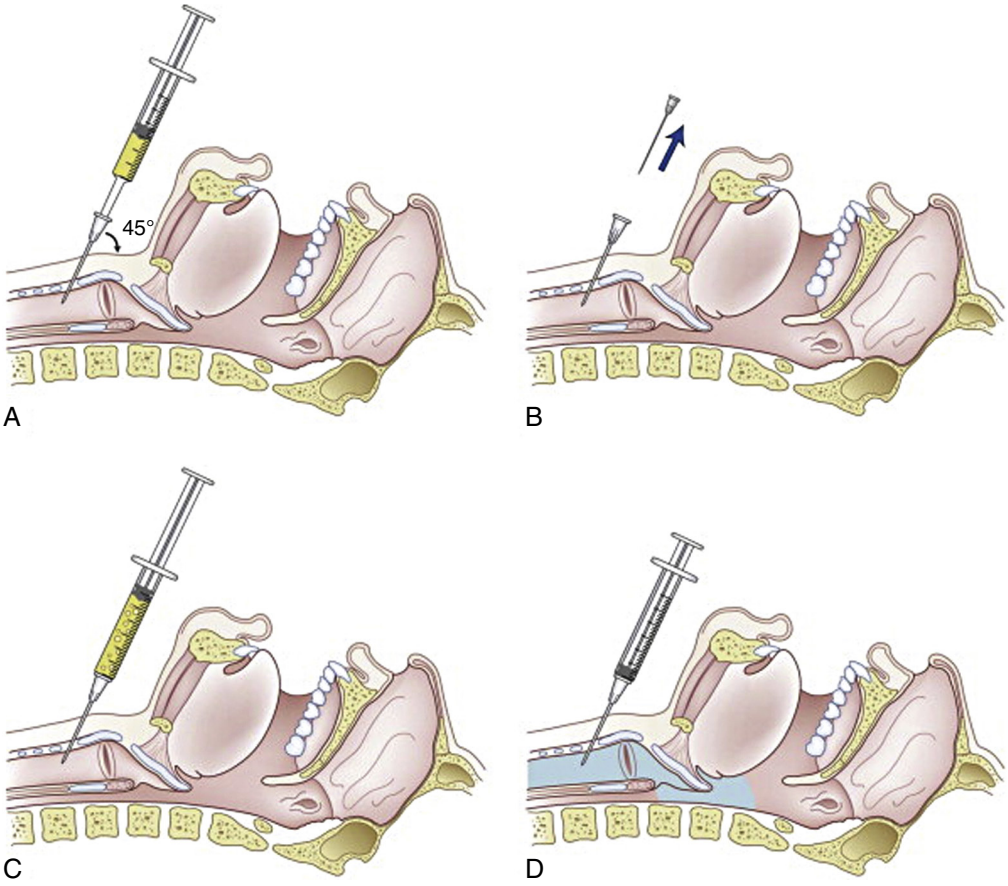

Figure 55-10. Translaryngeal anesthesia, angiocatheter technique (midsagittal view of the head and neck). **A,** The angiocatheter is inserted at the cricothyroid membrane, aimed caudally. An aspiration test is performed to verify the position of the tip of the needle in the tracheal lumen. **B,** The needle is removed from the angiocatheter. **C,** The syringe containing local anesthetic is attached, and the aspiration test is repeated. **D,** Local anesthetic is injected, resulting in coughing and nebulization of the local anesthetic *(shaded blue area). (Reprinted from Artime CA, Sanchez A: Preparation of the patient for awake intubation. In Hagberg CA, editor:* Benumof and Hagberg's airway management*, ed 3, Philadelphia, 2013, Saunders, p. 259. From* Difficult airway teaching aids*, Irvine, University of California, Department of Anesthesia.)*

by providing anxiolysis, amnesia, and analgesia. Benzodiazepines, opioids, IV hypnotics, α_2 agonists, and neuroleptics can be used alone or in combination. A summary of common medications used for sedation can be found in Table 55-1. These drugs should be carefully titrated to effect; oversedation can render a patient uncooperative and make awake intubation more difficult. Spontaneous ventilation should always be maintained. Care should be taken in situations with critical airway obstruction, because awake muscle tone is sometimes necessary in these patients to maintain airway patency. Avoiding oversedation is also important in the patient at high risk for aspiration of gastric contents, because an awake patient can protect his or her own airway if regurgitation should occur.[130]

VENTILATION VIA A MASK

Mask ventilation is a straightforward, noninvasive technique for airway management that can be used as a primary mode of ventilation for an anesthetic of short duration or as a bridge to establishing of a more definitive airway. Administration of oxygen via a facemask is common for "preoxygenation", and inhaled induction of anesthesia and as a means to provide oxygen and anesthetic gases to both a spontaneous ventilating patient and an anesthetized patient with apnea via PPV. Mask ventilation is not only used to ventilate and oxygenate before conditions for tracheal intubation have been achieved, but it is also a valuable rescue technique when tracheal intubation proves difficult. For this reason, mask ventilation is an important part of the ASA "Difficult Airway Algorithm" and an essential skill for the anesthesia practitioner.[24]

Mask ventilation is relatively contraindicated when the risk for regurgitation is increased; no protection from pulmonary aspiration of gastric contents exists. Mask ventilation should also be performed with caution in patients with severe facial trauma and in patients in whom head and neck manipulation must be avoided (e.g., those with an unstable cervical spine fracture).

Anesthesia facemasks are designed to form a seal around the patient's nose and mouth, allowing for PPV and the administration of anesthetic gases; they should not be confused with oxygen facemasks, which are designed only to administer supplemental oxygen. Early anesthesia facemasks were reusable and made of black rubber. These have been almost entirely replaced in clinical use

TABLE 55-1 **SEDATIVE DRUGS FOR AWAKE AIRWAY MANAGEMENT**

Drug	Class	Sedative Dose	Notes
Midazolam	Benzodiazepine	1-2 mg IV, repeated prn (0.025-0.1 mg/kg)	Frequently used in combination with fentanyl.
Fentanyl	Opioid	25-200 μg IV (0.5-2 μg/kg)	Usually used in combination with other agents (e.g., midazolam, propofol).
Alfentanil	Opioid	500-1500 μg IV (10-30 μg/kg)	Has faster onset, shorter duration than fentanyl.
Remifentanil	Opioid	Bolus 0.5 μg/kg IV, followed by an infusion of 0.1 μg/kg/min	Infusion can be subsequently titrated by 0.025-0.05 μg/kg/min in 5-minute intervals to achieve adequate sedation.
Propofol	Hypnotic	0.25 mg/kg IV in intermittent boluses or Continuous IV infusion of 25-75 μg/kg/min, titrated to effect	Can also be used in combination with remifentanil (decrease dose of both drugs).
Ketamine	Hypnotic	0.2-0.8 mg/kg IV	Pretreat with antisialagogue. Consider administration of midazolam to attenuate undesirable psychologic effects.
Dexmedetomidine	α_2 Agonist	Bolus 1 μg/kg IV over 10 minutes, followed by an infusion of 0.2-0.7 μg/kg/hr	Reduce dose in older adults and in patients with depressed cardiac function.

IV, Intravenous; *prn,* as needed, *pro re nata* (Latin).

by disposable, clear plastic masks, which are less frightening for patients and have the added benefit of allowing for better visualization of cyanosis and the need for oral suctioning. Facemasks are available in various styles and sizes but share a basic design: main body, seal, and connector. The seal is the portion of the mask that comes in contact with the face, and in clear plastic masks is comprised of a plastic, air-filled, high-volume, low-pressure cushion that conforms to the facial anatomy while minimizing the chance for pressure ischemia; some models have a valve on the cushion to allow changing the volume of the air within. The connector is a standard 22-mm female adapter that allows a connection to a standard anesthesia circuit or a bag-valve device; pediatric masks usually have a 15-mm male adapter that allows the same connections.

The technique for mask ventilation is dependent on two key elements: (1) maintenance of a seal between the facemask and the patient's face and (2) an unobstructed upper airway.[10] The mask is usually held with the left hand, with the thumb and index finger forming a C around the collar of the connector, the third and fourth digits on the ramus of the mandible, and the fifth digit on the angle of the mandible (Figure 55-11). The thumb and index finger are used to produce downward pressure to ensure a tight mask seal, while the remaining digits provide upward displacement of the mandible (jaw thrust) to aid with airway patency. The right hand is free to provide manual ventilation. Ensuring that pressure is placed on the bony ridge of the mandible and not the soft tissue is important—compression of the submandibular space can cause obstruction of the airway and difficulty with mask ventilation. Many facemasks have hooks around the collar for use with mask straps that can facilitate formation of a seal.

The one-handed technique is occasionally ineffective, especially in patients who are obese or edentulous, attributable to the failure to maintain a seal and/or a patent upper airway. In these situations, a two-handed technique

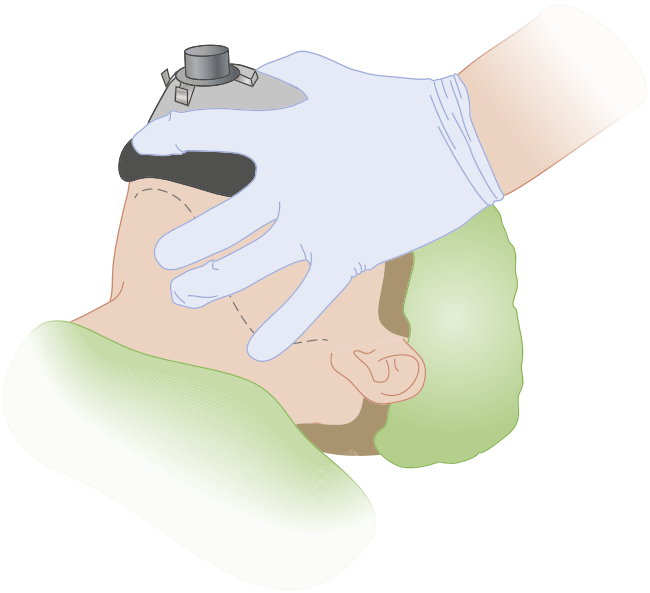

Figure 55-11. Standard one-handed facemask ventilation technique. The position of the fifth digit is at the angle of the jaw. *(From Matioc AA: The adult ergonomic face mask: historical and theoretical perspectives,* J Clin Anesth *21:300-304, 2009.)*

can be more successful. Two-handed techniques depend on either an assistant or the use of pressure-control ventilation (PCV) with the anesthesia machine to provide PPV. The use of PCV for mask ventilation results in lower peak airway pressures and reduced inspiratory flow rates when compared with manual ventilation, providing an additional measure of safety against gastric insufflation.[131] In one approach to the two-handed technique, the left hand is positioned as in the one-handed technique and the right hand is placed on the other side of the mask in an identical conformation. A more effective approach involves using the second and third digits to perform a jaw

thrust while the mask is held in place with the thumbs. A study in anesthetized patients showed that this technique improved upper airway patency, compared with the traditional one-handed technique, as measured by greater tidal volumes during PCV.[132] Additional techniques to improve the mask seal in difficult scenarios include leaving dentures in place in edentulous patients and placing an adhesive plastic dressing over facial hair.

Once a seal is established between the facemask and the patient's face, ventilation is achieved by either spontaneous ventilation or PPV. The effectiveness of mask ventilation should be ascertained by observing for chest rise, exhaled tidal volumes, pulse oximetry, and capnography. During controlled ventilation in patients with normal lungs and a patent airway, adequate tidal volumes should be achieved with peak inspiratory pressures less than 20 cm H_2O; higher pressures should be avoided to prevent gastric insufflation.[133] If PPV is inadequate at acceptable inspiratory pressures, then airway patency and pulmonary compliance should be assessed.

Because of a reduction in muscle tone as a result of general anesthesia, tissues fall backward under the influence of gravity in a supine patient and can obstruct the upper airway. Upper airway obstruction most commonly takes place at the level of the soft palate (velopharynx), epiglottis, and tongue.[10,14] To maximize airway patency, mask ventilation should be performed with maximal atlantooccipital extension in combination with the forward displacement of the mandible (jaw thrust) involved in the mask-holding techniques.[134] The addition of cervical flexion to head extension (i.e., placing the patient in the sniffing position) improves pharyngeal patency.[135] If the sniffing position and jaw thrust fail to relieve airway obstruction, then oropharyngeal or nasopharyngeal airways may be used to facilitate airway patency.

Oropharyngeal airways are the most commonly used. They follow the curvature of the tongue, pulling it away from the posterior pharynx (Figure 55-12). Because they place pressure on the base of the tongue and may come in contact with the epiglottis, oropharyngeal airways can precipitate coughing, retching, or laryngospasm if laryngeal and pharyngeal reflexes are not sufficiently blunted; therefore they are not appropriate for use in conscious patients. The oropharyngeal airway is sized by measuring from the corner of a patient's mouth to the angle of the jaw or the earlobe. Inappropriately sized oropharyngeal airways can actually worsen airway obstruction; therefore proper size selection is important. Proper placement is accomplished by inserting the oropharyngeal airway with the curvature facing posteriorly and then rotating 180 degrees; alternatively, a tongue depressor can be used to displace the tongue anteriorly as the oropharyngeal airway is inserted with the curvature facing anteriorly. Complications from oropharyngeal airways include lingual nerve palsy and damage to the teeth.[136,137] Once in place, nasopharyngeal airways are less stimulating than oropharyngeal airways and thus are more appropriate for conscious patients (Figure 55-13). Nasopharyngeal airways should be well lubricated before insertion and inserted with the bevel facing the nasal septum. To avoid epistaxis, force should never be used during insertion of a nasopharyngeal airway.

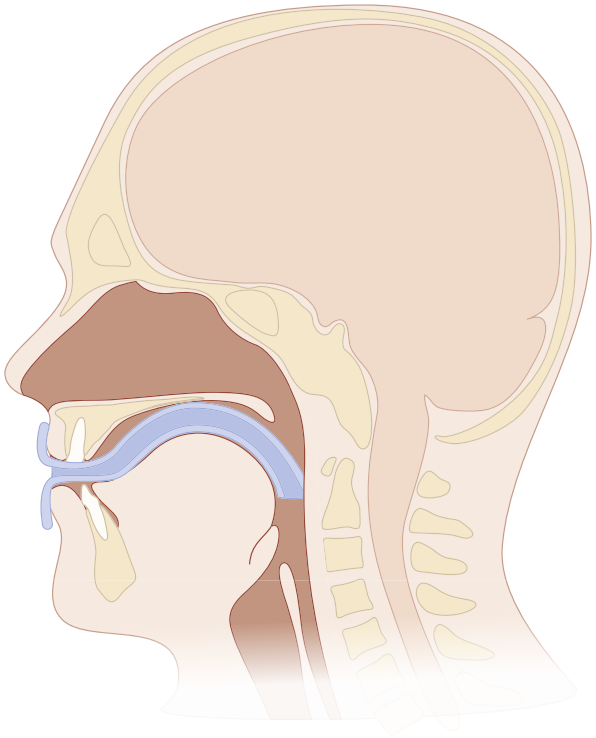

Figure 55-12. Oropharyngeal airway in place. The airway follows the curvature of the tongue. It pulls the tongue and the epiglottis away from the posterior pharyngeal wall and provides a channel for the passage of air. *(Adapted from Dorsch JA, Dorsch SE:* Understanding anesthesia equipment*, ed 4, Baltimore, 1999, Williams & Wilkins.)*

Difficult mask ventilation occurs when ventilating via the facemask is not possible because of an inadequate mask seal, excessive gas leak, and/or excessive resistance to the ingress or egress of gas.[24] Predictors for difficult mask ventilation that can be identified during the preoperative airway assessment are listed in Box 55-2.

SUPRAGLOTTIC AIRWAY

The term *supraglottic airway* (SGA) or *extraglottic airway* refers to a diverse family of medical devices that are blindly inserted into the pharynx to provide a patent conduit for ventilation, oxygenation, and delivery of anesthetic gases without the need for tracheal intubation. SGAs have the advantage of being less invasive than endotracheal intubation while providing a more definitive airway than a facemask, and can be used for either spontaneous ventilation or PPV. One of the first SGAs, the LMA, was described in 1983 by Dr. Archie Brain and introduced into clinical practice in 1988.[138] Since that time, the LMA has proved to be one of the single most important developments in both routine and difficult airway management and is a pivotal component of the ASA "Difficult Airway Algorithm." Various different designs of SGAs are now available and are widely used in current anesthesia practice as a primary airway management device, a rescue airway device, and a conduit for endotracheal intubation.

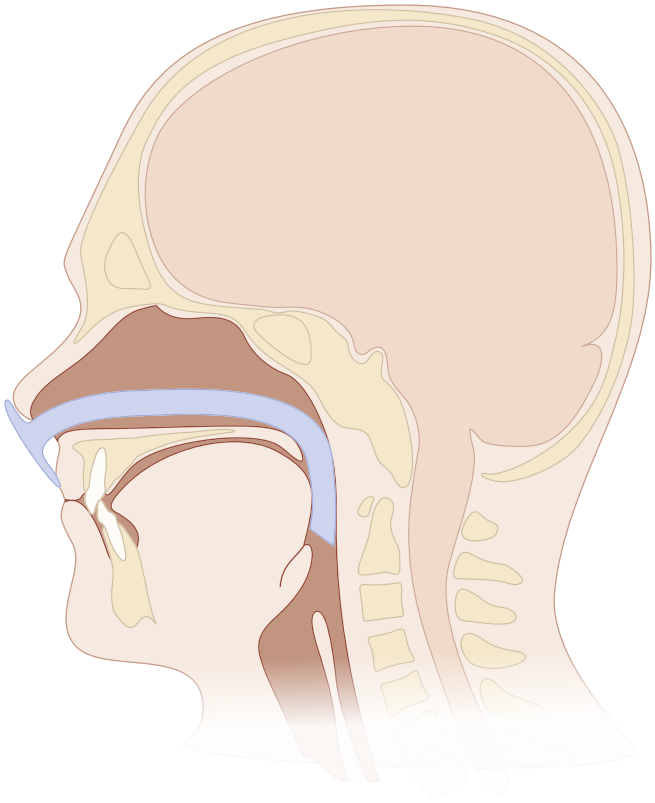

Figure 55-13. Nasopharyngeal airway in place. The airway passes through the nose and ends at a point just above the epiglottis. *(Adapted from Dorsch JA, Dorsch SE:* Understanding anesthesia equipment*, ed 4, Baltimore, 1999, Williams & Wilkins.)*

Figure 55-14. LMA Classic. *(Image provided courtesy of LMA North America, San Diego, CA.)*

BOX 55-2 ***Predictors of Difficult Mask Ventilation***

- Obstructive sleep apnea or history of snoring
- Age older than 55 years
- Male gender
- Body mass index of 30 kg/m^2 or greater
- Mallampati classification III or IV
- Presence of a beard
- Edentulousness

The specific advantages of SGAs include the ease and speed of placement, improved hemodynamic stability, reduced anesthetic requirements, lack of a need for muscle relaxation, and an avoidance of the risks of tracheal intubation (e.g., trauma to the teeth and airway structures, sore throat, coughing on emergence, bronchospasm).[139,140] The primary disadvantages are that SGAs have comparatively smaller seal pressures than ETTs, which can lead to ineffective ventilation when higher airway pressures are required, and they provide no protection from laryngospasm. First-generation SGAs also provide little protection from gastric regurgitation and aspiration, although newer devices have incorporated design elements to minimize this risk.

SGAs have many applications. They are considered the first choice for airway management for diagnostic and minor surgical procedures.[141] No standardized classification system exists for the different designs of SGAs, although several have been proposed. This chapter uses the terminology described by Donald Miller: perilaryngeal sealers; cuffless, anatomically preshaped sealers; and cuffed pharyngeal sealers.[142] Second-generation SGAs are differentiated from first-generation SGAs in that they incorporate features designed to reduce the incidence of aspiration.[143]

LARYNGEAL MASK AIRWAY

LMA Classic

The LMA (LMA North America, San Diego, CA) is the most widely used, well-studied SGA and is the archetype of the perilaryngeal sealer. The original version, the LMA Classic (cLMA), consists of an oval-shaped, silicone mask with an inflatable cuff that sits in the hypopharynx and forms a seal around the periglottic tissues (Figure 55-14). An airway tube attached to the mask exits the mouth and has a standard 15-mm connector for attachment to an anesthesia circuit or to a bag-valve device. The seal around the laryngeal inlet allows for the delivery of oxygen and inhaled anesthetics during spontaneous ventilation and permits PPV at pressures up to 20 cm H_2O. The cLMA is reusable up to 40 times and is available in a variety of sizes from size 1 (neonate) to size 6 (large adult, >100 kg).

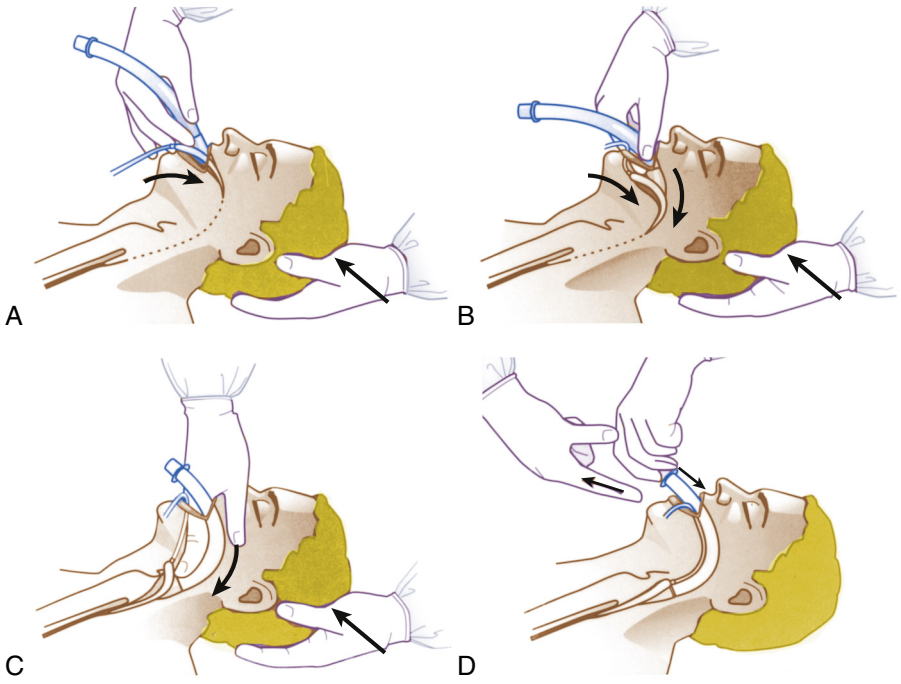

Figure 55-15. Insertion of a laryngeal mask airway (LMA). **A,** The tip of the cuff is pressed upward against the hard palate by the index finger while the middle finger opens the mouth. **B,** The LMA is pressed backward in a smooth movement. The nondominant hand is used to extend the head. **C,** The LMA is advanced until definite resistance is felt. **D,** Before the index finger is removed, the nondominant hand presses down on the LMA to prevent dislodgment during removal of the index finger. The cuff is subsequently inflated. *(Courtesy of LMA North America, San Diego, CA.)*

The LMA Classic Excel is an updated version that incorporates design features to facilitate endotracheal intubation through the device, including an epiglottic-elevating bar, a wider-bore airway tube, and a removable connector. A disposable, single-use version of the cLMA, the LMA Unique, is made from polyvinyl chloride (PVC) and has gained popularity because of its lower costs and maintenance, as well as concerns over the perceived risk of cross-contamination and the transmission of infection (e.g., human immunodeficiency virus [HIV], hepatitis C, prion-based diseases) with reusable medical devices. The LMA Flexible, available in reusable and single-use models, has a flexible, kink-resistant airway tube that can be positioned away from the surgical field for head and neck procedures.

To achieve a proper fit, the manufacturer of the LMA suggests placing the largest size LMA possible; an airtight seal is achieved more frequently with a size 5 LMA in the average adult man and a size 4 LMA in the average adult woman.[144] Using too small of an LMA can result in overinflation of the cuff to achieve a seal, which can predispose the patient to oropharyngolaryngeal morbidity and nerve damage.[145] Larger sizes, however, may be associated with a more frequent incidence of sore throat; therefore a smaller size may be appropriate when spontaneous ventilation through the LMA is planned.[146]

The manufacturer's instructions for the placement of the cLMA are summarized in Figure 55-15. Adequate depth of anesthesia for LMA insertion can be achieved with propofol or sevoflurane[147]; short-acting opioids such as fentanyl, alfentanil, and remifentanil may be coadministered to facilitate placement and to decrease the incidence of coughing, gagging, and laryngospasm.[148,149] Before insertion, the LMA cuff should be deflated and the posterior aspect of the mask should be lubricated with a water-based lubricant. Once positioned (see Figure 55-15), the cuff should be inflated with the minimum effective volume of air, with a target cuff pressure of 40 to 60 cm H_2O.[144] To allow the LMA to position itself correctly, the device should not be secured or attached to the anesthesia circuit until the cuff has been inflated. Confirmation of proper placement is performed by attempting gentle PPV while checking capnography and auscultation and by quantifying the inspiratory pressure at which a leak is audible, which should be 18 to 20 cm H_2O. Once proper positioning is confirmed, a roll of gauze is inserted as a bite block and the LMA is secured in place with tape. Several modifications to the recommended insertion technique have been described, including a *thumb insertion method* by the manufacturer, although these modifications are not detailed in this chapter.[150,151] Cuff pressure should be periodically monitored if N_2O is being used; cuff pressures may increase above the recommended threshold of 60 cm H_2O as a result of diffusion of N_2O into the cuff.

Initial difficulty with ventilation after the placement of an LMA may be due to a down-folded epiglottis. The *up-down maneuver* described by Dr. Brain may help correct this problem; the LMA is withdrawn 2 to 4 cm and reinserted without deflating the cuff. Head extension and LMA repositioning may also improve ineffective ventilation. If these actions do not correct the problem, then a different size may be needed. Insufficient depth of anesthesia, resulting in laryngospasm or bronchospasm, may make ventilation through an LMA impossible; the administration of topical, inhaled or IV anesthesia can help to correct this. Although not necessary, DL can also facilitate proper LMA placement.

Serious complications from LMA use are relatively rare. More commonly, minor oral, pharyngeal, or laryngeal injury occurs, expressed as complaints of a dry or sore throat.[152] The incidence of sore throat is approximately 10% to 20%,[140,153] and has been linked to higher cuff pressures and larger LMA sizes.[146,154] More serious cases of oropharyngolaryngeal injury have been described, such

as trauma to the uvula and pharyngeal necrosis.[155,156] Injury to the lingual, hypoglossal, and recurrent laryngeal nerves has also been reported; these usually spontaneously resolve over a period of weeks to months.[145] Predisposing factors include high cuff pressures (often attributable to the use of N_2O), using too small of an LMA, and nonsupine positions.[145]

LMA ProSeal

The LMA ProSeal (pLMA, LMA North America, San Diego, CA) is a reusable second-generation SGA that incorporates a posterior cuff, improving the perilaryngeal seal and allowing for PPV at pressures up to 30 cm H_2O. It also incorporates a gastric drainage tube that allows for gastric access with an orogastric tube and channels any regurgitated gastric contents away from the airway, effectively isolating the respiratory and gastrointestinal tracts.[157] Additional features include an incorporated bite block and a softer cuff.

The insertion technique is similar to the cLMA but requires deeper anesthetic levels.[157,158] An optional introducer can be used to facilitate insertion. As with the cLMA, cuff pressure should not exceed 60 cm H_2O. Once inserted, assessment of proper placement is accomplished by providing PPV; adequate tidal volumes should be accomplished with reasonable peak inspiratory pressures, leak pressure should be above 20 cm H_2O, and the capnography waveform should appear normal.[10] An additional test to confirm proper placement and separation of the airway and gastrointestinal tract is performed by placing a small layer (<5 mm) of water-based lubricant over the drainage tube orifice; PPV and suprasternal notch palpation should result in a small up-down movement of the gel meniscus. Easy passage of an orogastric tube through the gastric drainage tube confirms proper positioning.

LMA Supreme

The LMA Supreme (sLMA) is a single-use, second-generation SGA based on the pLMA design. Similar to the pLMA, the sLMA has an improved cuff design that produces higher airway leak pressures, a drainage tube that allows for gastric access, and an integrated bite block (Figure 55-16). A fixation tab allows for insertion without inserting the fingers in the mouth and provides a visual guide for determining proper sizing.

Although not clinically proven, evidence suggests that second-generation SGAs, such as the pLMA and the sLMA, reduce the risk of aspiration of gastric contents. This property, along with the improved airway seal and higher leak pressures, have enabled SGA devices to be used in various applications where the cLMA is potentially unsuitable, such as in nonsupine positions (e.g., lateral, prone),[159] in laparoscopic surgery (e.g., cholecystectomy, gynecologic surgery),[160,161] and in patients who are obese.[162] The successful, routine use of the sLMA in fasted, nonobese patients for cesarean section has also been reported.[163]

OTHER PERILARYNGEAL SEALERS

Over the past 10 years, a multitude of manufacturers have produced SGAs that incorporate the basic perilaryngeal sealing design of the cLMA. Because the term *LMA* is a protected trademark, these devices are referred to as *laryngeal masks* (LMs). Each has its own unique characteristics that may afford it specific advantages over other designs. Although an exhaustive description of every available LM is outside the scope of this chapter, some unique features merit mentioning.

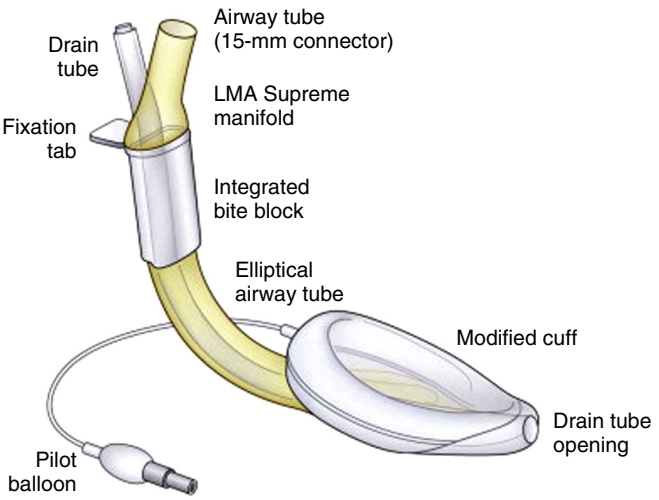

Figure 55-16. The LMA Supreme has a modified cuff design, a drainage tube that allows for gastric access, and an integrated bite block. *(From Verghese C, Mena G, Ferson DZ, Brain AIJ: Laryngeal mask airway. In Hagberg CA, editor:* Benumof and Hagberg's airway management, *ed 3, Philadelphia, 2013, Saunders, p. 459.)*

Some design features address the issue of high cuff pressures, which can lead to oropharyngolaryngeal morbidity, nerve palsies, and improper device positioning. The line of LMs manufactured by AES, Inc. (Black Diamond, WA) incorporates a cuff pilot valve (CPV) that allows constant cuff pressure monitoring. Color-coded indicator bands on the CPV alert the clinician to changes in cuff pressure attributable to temperature, N_2O, and movement within the airway, allowing the clinician to maintain the recommended cuff pressure of 60 cm H_2O. The air-Q SP (Cookgas LLC, St. Louis, MO; distributed by Mercury Medical, Clearwater, FL) has a self-pressurizing cuff that uses the positive pressure that ventilates the patient to also pressurize the cuff, obviating the need for an inflation line and eliminating the possibility of cuff overinflation. On exhalation, the mask cuff deflates to the level of positive end-expiratory pressure (PEEP), decreasing the total mucosal pressure over the course of an anesthetic, thereby potentially reducing the incidence of cuff pressure–related complications.

Other LMs incorporate design features that facilitate endotracheal intubation, such as removable connectors or wider bore airway lumina to allow intubation with standard-sized ETTs (see "Tracheal Intubation Through a Supraglottic Airway Device")

CUFFLESS ANATOMICALLY PRESHAPED SEALERS

Cuffless anatomically preshaped sealers do not have a cuff; rather, they provide an airway seal by their anatomically preshaped design. Advantages include simplicity of insertion and positioning and the lack of a need to inflate

a cuff. The first of these devices, the SLIPA (Curveair, London, UK), contains a hollow chamber that can trap regurgitated liquid and prevent aspiration. Newer cuffless devices such as the i-gel (Intersurgical Inc., Wokingham, Berkshire, UK) and the Baska Mask (Strathfield, NSW, Australia) can also be included in this classification.

CUFFED PHARYNGEAL SEALERS

Cuffed pharyngeal sealers have an airway with a pharyngeal cuff that seals at the level of the base of the tongue and can be subclassified as to whether they also possess an esophageal sealing cuff.[142] SGAs with only a pharyngeal cuff include the Cobra Perilaryngeal Airway (Cobra-PLA; Engineered Medical Systems, Indianapolis, IN) and the Tulip Airway (Marshall Medical, Bath, UK); they are not detailed in this chapter. The following devices all have an esophageal sealing cuff.

The esophageal-tracheal combitube (ETC) (Covidien, Mansfield, MA) is a uniquely designed SGA with both a pharyngeal and esophageal sealing cuff and two lumina. The ETC is primarily designed for emergency intubation and is mostly used in the prehospital setting, although it has occasionally been used during general anesthesia as both a primary airway and as a rescue airway device.[164,165] It is inserted blindly through the mouth in a curved, downward motion until the printed ring marks lie between the teeth. Both the proximal, oropharyngeal cuff and the distal esophageal-tracheal cuff are inflated. Greater than 90% of the time, esophageal placement of the device occurs, in which ventilation should be performed via the longer, blue, #1 (esophageal) lumen.[166] This lumen has a closed distal end with eight small perforations located between the two cuffs, which allow oxygenation and ventilation. When the device is placed into the trachea, ventilation should occur via the shorter, clear, #2 (tracheal) lumen, which is open at its distal end. When the ETC is placed in the esophagus, an orogastric tube may be passed through the tracheal lumen to empty the stomach. Use of the ETC as a primary airway is limited by a higher risk of complications, compared with the LMA or tracheal intubation, including hoarseness, dysphagia, and bleeding.[167] Because the oropharyngeal cuff of the ETC contains latex, this device should not be used in latex-sensitive individuals.

The Rüsch EasyTube (Teleflex Medical, Research Triangle Park, NC) is a double-lumen SGA that is similar to the ETC. The primary differences are its nonlatex construction and a proximal lumen that ends just below the oropharyngeal balloon, allowing for the passage of a tube exchanger or FIS. The insertion technique and risks are similar to the ETC; a comparative study showed shorter insertion times with the EasyTube.[168] The King LT series of SGAs (King Systems Corporation, Noblesville, IN) are similar in design to the ETC and EasyTube, with a ventilation port between the pharyngeal and esophageal cuffs. The King LT and the King LT-D (reusable and disposable, respectively) are single-lumen devices with a tapered distal tip that allows easy passage into the esophagus. The distal (esophageal) portion of the tube is occluded. The King LTS and the disposable King LTS-D, on the other hand, have an open distal tip with a secondary channel to allow suctioning of gastric contents. Although tracheal placement of a King LT device has not be reported, if it should occur, then the device should be removed and reinserted.

ENDOTRACHEAL INTUBATION

Endotracheal intubation is the gold standard for airway management. It establishes a definitive airway, provides maximal protection against the aspiration of gastric contents, and allows for PPV with higher airway pressures than with a facemask or an SGA. Endotracheal intubation is usually facilitated by DL; however, a wide variety of alternative intubation devices and techniques have been developed to circumvent the problems encountered when conventional DL is difficult.

In the fasted patient undergoing elective surgery with general anesthesia, an SGA is many times suitable. Certain conditions or clinical situations, however, favor endotracheal intubation, although the advent of second-generation SGAs has somewhat narrowed this list. Absolute indications for endotracheal intubation include patients with a full stomach or who are otherwise at high risk for aspiration of gastric secretions or blood, patients who are critically ill, patients with significant lung abnormalities (e.g., low lung compliance, high airway resistance, impaired oxygenation), patients requiring lung isolation, patients undergoing otorhinolaryngologic surgery during which an SGA would interfere with surgical access, patients who will likely need postoperative ventilatory support, and patients in whom SGA placement has failed. Other indications for intubation include a surgical requirement for NMBDs, patient positioning that would preclude rapid tracheal intubation (e.g., prone or turned away from the anesthesia provider), a predicted difficult airway, and prolonged procedures.[10]

ENDOTRACHEAL TUBES

The modern, standard ETT is a disposable, single-use, cuffed, plastic tube that is designed to be inserted through the nose or mouth and sit with its distal end in the midtrachea, providing a patent airway to allow for ventilation of the lungs. A variety of different types of ETTs are available for use in specialized situations. Several features are commonplace among the different styles, however, including a universal 15-mm adapter that allows the attachment of the proximal end to different ventilating circuits and devices; a high-volume, low-pressure cuff; a beveled tip to facilitate passage through the vocal cords; and an additional distal opening in the side wall of the ETT known as a *Murphy eye*, which serves to provide an additional portal for ventilation should the distal end of the lumen become obstructed by either soft tissue or secretions.

Cuffed ETTs are routinely used for endotracheal intubation in most patients; cuffless ETTs are used in neonates and infants. The high-volume, low-pressure cuff is inflated with air to provide a seal against the tracheal wall to protect the lungs from pulmonary aspiration and to ensure that the tidal volume delivered ventilates the lungs rather than escapes into the upper airway.[10] A pilot balloon with a one-way valve allows for the inflation of

the cuff and an assessment of the cuff pressure. The cuff should be inflated to the minimum volume at which no air leak is present with positive pressure inspiration; the cuff pressure should be less than 25 cm H_2O.[169] Excessive cuff pressure may result in tracheal mucosal injury, vocal cord dysfunction from recurrent laryngeal nerve palsy, and sore throat. Monitoring the cuff pressure with a pressure gauge is recommended. When N_2O is used as part of the anesthetic, cuff pressure should be periodically measured throughout the surgery; N_2O diffusion into the cuff can result in increases in cuff pressure to potentially dangerous levels.

ETT size is normally described in terms of its internal diameter (ID); the relationship of the ID to the external diameter varies between different designs and manufacturers. Selection of the ETT size depends on the reason for placement and patient-specific factors such as gender and airway pathologic conditions. Smaller ETTs result in increased airway resistance and work of breathing, and ETTs with a smaller than 8-mm ID preclude therapeutic fiberoptic bronchoscopy. Larger ETTs are more likely to be associated with laryngeal or tracheal mucosal trauma and have a higher incidence of sore throat after general anesthesia. Generally, in patients intubated only for the purposes of a general anesthetic, a smaller ETT may be used than on the patient who will remain intubated in the medium to long term as a result of respiratory failure; typically a 7-mm ETT is used for women and an 8-mm ETT is used for men.

A variety of specialized tracheal tubes are available for use in specific clinical situations. Preformed tubes, such as the nasal and oral Ring-Adair-Elwin (RAE) tubes, have a specific contour to maintain a low profile and to avoid surgical interference. Armored (reinforced) tubes have an embedded coil that minimizes kinking of the tube when it is subjected to angulation. Microlaryngeal tubes, which have small IDs with a longer length tube, are useful in laryngeal surgery or for specific applications, such as intubation through a cLMA. Other specialized tubes include laser-resistant tubes and both single- and double-lumen tubes that allow for one-lung ventilation.

OROTRACHEAL VERSUS NASOTRACHEAL INTUBATION

Endotracheal intubation can proceed via the orotracheal or nasotracheal route—this decision should be made before deciding which airway management technique will be used. Nasotracheal intubation is generally indicated when the orotracheal route is not possible (e.g., when the mouth opening is severely limited) or when the need for surgical access precludes an orotracheal route. In addition, certain intubation techniques, such as blind intubation, awake intubation, and FSI, are significantly easier when performed through the nose.

When the nasotracheal route is not specifically indicated, however, the orotracheal route is usually preferred for several advantages. The orotracheal route is potentially less traumatic and presents a lower risk of bleeding, it usually allows for the placement of a larger ETT, and it provides for more options in terms of airway management techniques. The major disadvantages include the potential for damage to the teeth and stimulation of the gag reflex during awake intubation, requiring denser airway anesthesia and potentially being less comfortable for the patient. Nasotracheal intubation, on the other hand, bypasses the gag reflex and is usually more easily tolerated by the awake patient. However, the risks of epistaxis, trauma to the nasal turbinates, and submucosal tunneling in the nasopharynx must be taken into account.[114] Nasotracheal intubation is relatively contraindicated in the setting of maxillary or skull base fractures.

DIRECT LARYNGOSCOPY

The most commonly used technique for endotracheal intubation is DL, which involves direct visualization of the glottis with the assistance of a laryngoscope. The ETT is inserted through the glottic opening into the trachea under continuous observation.

Preparation and Positioning

Preparation for DL includes proper patient positioning, adequate preoxygenation, and ensuring the availability and proper functioning of all necessary equipment—laryngoscopes, tracheal tubes, tube stylets, an empty syringe for inflating the tracheal tube cuff, a suction apparatus, and the essential equipment for mask ventilation, including an oxygen source. A skilled assistant should be present to help with external laryngeal manipulation and stylet removal, among other tasks. Adequate preparation is of the utmost importance; as with any airway procedure, the first attempt should be the best attempt.

For DL to be successful, a line of sight from the mouth to the larynx must be achieved. The classical model used to describe the anatomic relationships necessary to achieve this was proposed in 1944 by Bannister and Macbeth and involves the alignment of three anatomic axes—oral, pharyngeal, and laryngeal.[170] Positioning the patient in the sniffing position approximates this alignment. Cervical flexion aligns the pharyngeal and laryngeal axes, and maximal head extension at the atlantooccipital joint brings the oral axis closer into alignment (Figure 55-17). The accuracy of this model has been questioned,[171] and various alternative models to explain the anatomic advantage of the sniffing position have been proposed.[172,173] Regardless of the explanatory model, however, the evidence in the literature supports the assertion that the sniffing position is the optimal position for DL.[36,174]

Proper positioning in the sniffing position involves approximately 35 degrees of cervical flexion, which is accomplished by a 7- to 9-cm elevation of the head on a firm cushion; patients with shorter necks may require less head elevation.[36,175] Patients who are obese often require elevation of the shoulders and upper back to achieve adequate cervical flexion, which can be accomplished by placing the patient in the *ramped* position using either a specialized device, such as the Troop Elevation Pillow (Mercury Medical, Clearwater, FL) or folded blankets. Confirming horizontal alignment of the external auditory meatus with the sternal notch is useful for ensuring optimal head elevation in both obese and nonobese patients.[176] Adequate cervical flexion also facilitates maximal atlantooccipital extension, which provides optimal

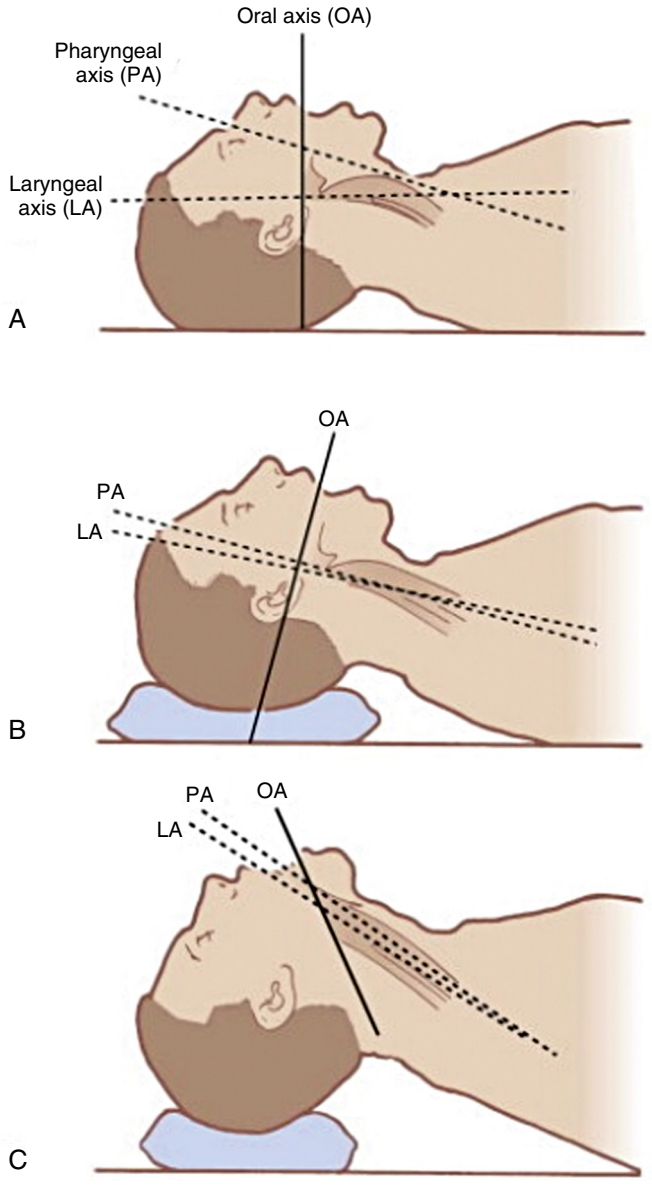

Figure 55-17. Visual axis diagram. **A,** The head is in the neutral position. None of the three visual axes align. **B,** Elevation of the head produces cervical flexion, which aligns the laryngeal axis (LA) and the pharyngeal axis (PA). **C,** Extension at the atlantooccipital joint brings the visual axis of the mouth into better alignment with those of the larynx and pharynx. *(From Stone DJ, Gal TJ: Airway management. In Miller RJ, editor:* Anesthesia*, ed 6, Philadelphia, 2005, Churchill Livingstone.)*

alignment of the oral and pharyngeal axes (the primary determinant for quality of laryngeal view) and enhanced mouth opening.[177]

Technique

The laryngoscope is a handheld instrument consisting of a blade attached to a handle containing a light source. Most are reusable and made of steel, although disposable, plastic versions are available. The curved blade and the straight blade are the two basic types of laryngoscope blades available for DL; multiple variations of both styles exist. The Macintosh is the most commonly used curved

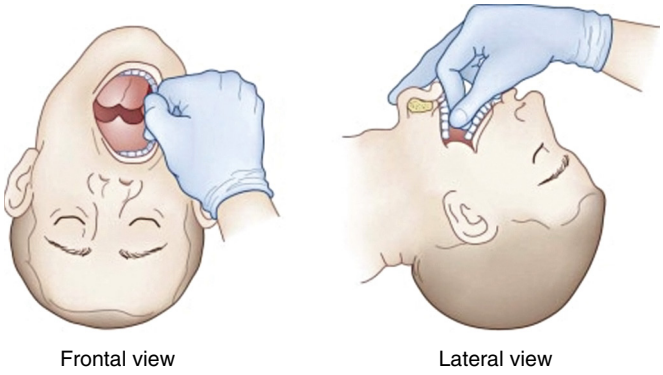

Figure 55-18. The *scissors* technique for mouth opening. The thumb of the right hand is pressed on the right, lower molars in a caudad direction while the index or third finger of the right hand presses on the right, upper molars in a cephalad direction. *(From Berry JM, Harvey S: Laryngoscopic orotracheal and nasotracheal intubation. In Hagberg CA, editor:* Benumof and Hagberg's airway management*, ed 3, Philadelphia, 2013, Saunders, p. 351.)*

blade, whereas the Miller is the most commonly used straight blade. Both are designed to be held in the left hand, and both have a flange on the left side that is used to retract the tongue laterally. Each type of blade has its benefits and drawbacks and is associated with its own technique for use.

The technique for laryngoscopy consists of the opening of the mouth, inserting the laryngoscope blade, positioning of the laryngoscope blade tip, applying a lifting force exposing the glottis, and inserting a tracheal tube through the vocal cords into the trachea. Mouth opening is best achieved using the *scissors* technique; the right thumb pushes caudally on the right lower molars while the index or third finger of the right hand pushes on the right upper molars in the opposite direction (Figure 55-18).

The decision of whether to use a Macintosh or a Miller blade is multifactorial; however, the personal preferences and experience of the laryngoscopist is a significant consideration. In general, the Macintosh is most commonly used for adults, whereas the straight blades are typically used in pediatric patients.[178] Curved blades provide greater room for passage of an ETT through the oropharynx, attributable to their larger flange, and are generally considered less likely to cause dental damage.[179] Straight blades are preferred in patients with a short thyromental distance and usually provide a better view of the glottis in patients with a long, floppy epiglottis. Often, when one style of laryngoscope does not provide an adequate view of the glottis, the other may be more effective. For most adults, a Macintosh size 3 or a Miller size 2 blade is usually the proper size; in larger patients or patients with a very long thyromental distance, a larger blade may be more appropriate.

The Macintosh blade is inserted in the right side of the mouth, and the flange is used to sweep the tongue to the left. Once the laryngoscope has been inserted in the mouth, the right hand can be used to ensure that the upper lip is not impinged between the laryngoscope and the upper incisors. The blade is advanced along the base of the tongue until the epiglottis is visualized; the tip of

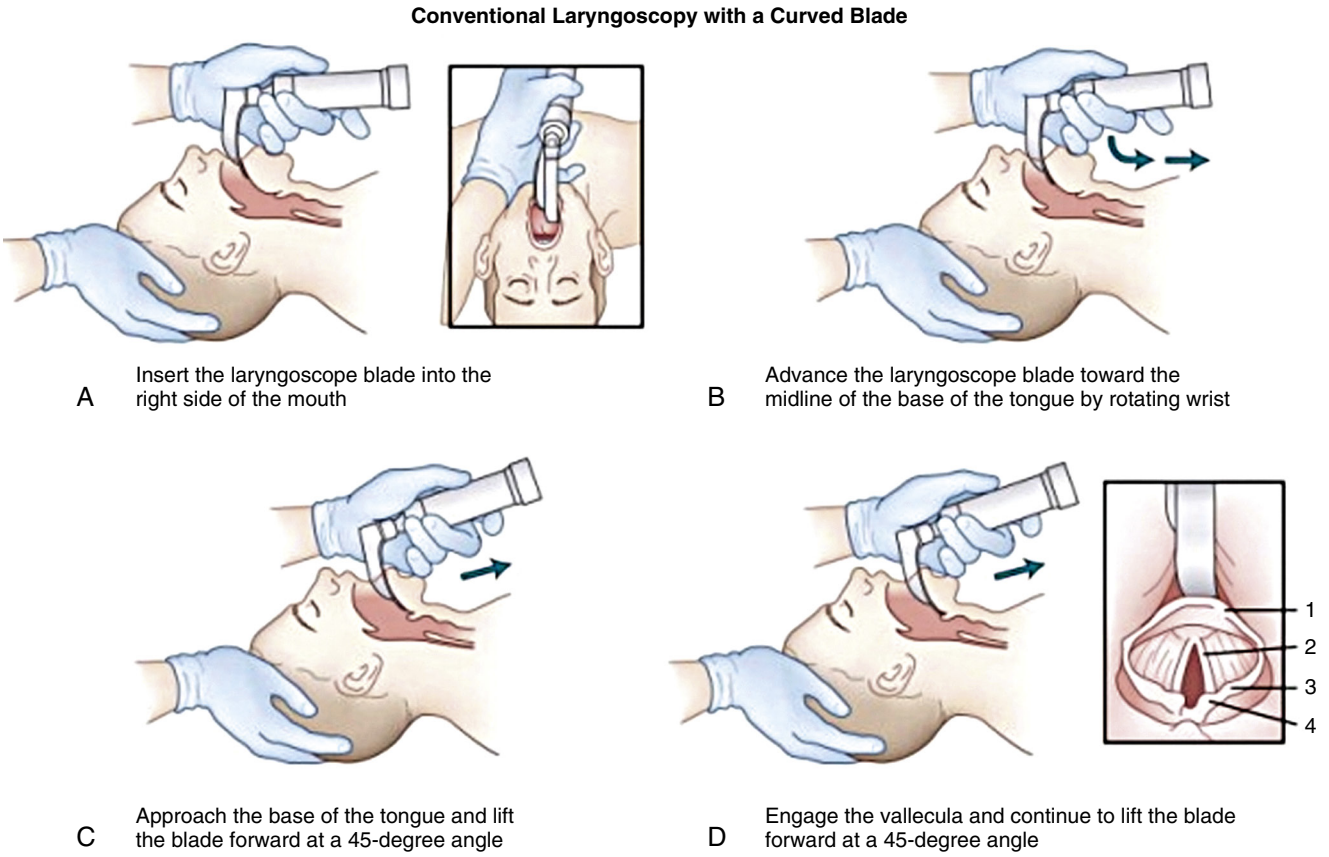

Figure 55-19. Conventional laryngoscopy with a Macintosh (curved) blade. **A,** The laryngoscope blade is inserted into the right side of the mouth, sweeping the tongue to the left of the flange. **B,** The blade is advanced toward the midline of the base of the tongue by rotating the wrist so that the laryngoscope handle becomes more vertical *(arrows)*. **C,** The laryngoscope is lifted at a 45-degree angle *(arrow)* as the tip of the blade is placed in the vallecula. **D,** Continued lifting of the laryngoscope handle at a 45-degree angle results in exposure of the laryngeal aperture. The epiglottis *(1)*, vocal cords *(2)*, cuneiform cartilage *(3)*, and corniculate cartilage *(4)* are identified. *(From Berry JM, Harvey S: Laryngoscopic orotracheal and nasotracheal intubation. In Hagberg CA, editor:* Benumof and Hagberg's airway management*, ed 3, Philadelphia, 2013, Saunders, p. 350.)*

the blade is then advanced further and positioned in the vallecula. A force oriented at a 45-degree angle up and away from the laryngoscopist indirectly lifts the epiglottis by placing tension on the hyoepiglottic ligament, exposing the glottic structures (Figure 55-19). The tip of the blade should not be lifted by using the laryngoscope as a lever, rocking back on the upper incisors, which can damage the teeth and provides an inferior view of the glottis. A properly oriented vector of force is achieved by using the anterior deltoid and triceps, not by radial flexion of the wrist. Once a complete view of the glottis is achieved, the ETT is grasped similar to a pencil with the right hand and guided through the vocal cords into the trachea. Passage of the ETT is facilitated by an anterior angulation of the tip, which can be accomplished by shaping the ETT with a malleable stylet into a *hockey stick* shape, with approximately a 60-degree angle formed 4 to 5 cm from the distal end, or by accentuating the natural anterior curvature of the ETT by inserting the tip into the 15-mm connector, forming a circle, for several minutes before performing DL.

The Miller laryngoscope blade is inserted using the paraglossal technique described by Henderson.[10] This method provides maximal tongue control and avoids contact of the laryngoscope with the maxillary incisors. The laryngoscope is inserted lateral to the tongue and carefully advanced along the paraglossal gutter between the tongue and tonsil. Application of continued moderate lifting force to the laryngoscope handle helps maintain lateral displacement of the tongue and reduces contact with the maxillary teeth. As the laryngoscope is advanced, the epiglottis comes into view and the tip of the laryngoscope is passed posterior to the epiglottis. The optimal position of the tip of the straight laryngoscope is in the midline of the posterior surface of the epiglottis, close to the anterior commissure of the vocal cords (Figure 55-20).[10] This position achieves good control of the epiglottis and facilitates the passage of the tracheal tube. The direction of force applied to the handle is the same as when using the Macintosh blade.

The use of external laryngeal manipulation can improve the laryngeal view. Backward, upward, rightward pressure (the BURP maneuver) on the thyroid cartilage is most commonly used. Optimal external laryngeal manipulation (OELM) is achieved when the laryngoscopist uses his or her right hand to guide the position and pressure is exerted by an assistant's hand on the larynx (Figure 55-21).

Difficulty with endotracheal intubation by DL is primarily a function of an inadequate view of the glottis.

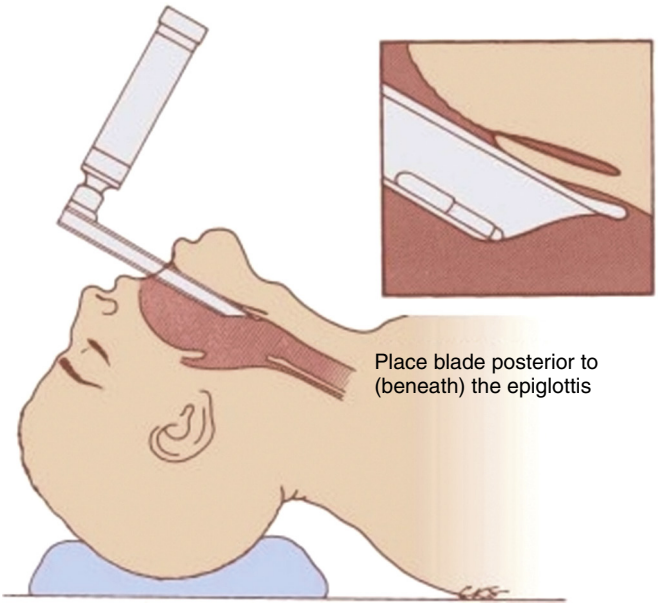

Figure 55-20. Conventional laryngoscopy with a Miller (straight) blade. The tip of the blade should be placed beneath the epiglottis and a 45-degree lifting force applied to expose the glottic aperture. *(From Berry JM, Harvey S: Laryngoscopic orotracheal and nasotracheal intubation. In Hagberg CA, editor:* Benumof and Hagberg's airway management*, ed 3, Philadelphia, 2013, Saunders, p. 352.)*

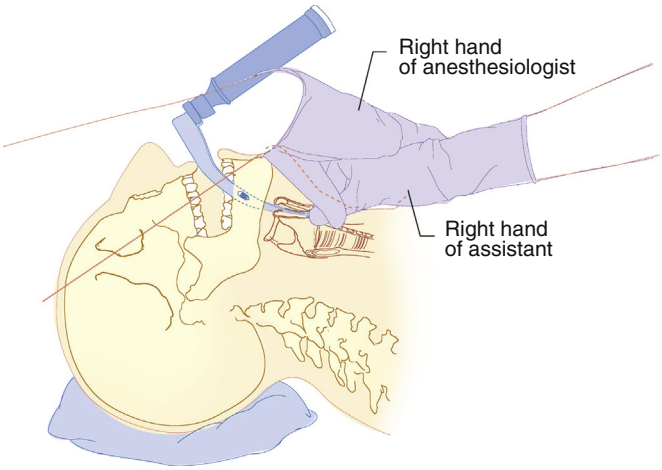

Figure 55-21. Optimal external laryngeal manipulation (OELM). The laryngoscopist guides the position, and pressure is exerted by the assistant's hand on the larynx to maximize the view of the vocal cords. The left hand of the laryngoscopist, which holds the laryngoscope handle, is omitted. *(From Henderson J: Airway management. In Miller RJ, editor:* Anesthesia*, ed 7, Philadelphia, 2009, Churchill Livingstone.)*

Predictors for difficult laryngoscopy that can be identified during the preoperative airway assessment are listed in Box 55-3. Cormack and Lehane developed a grading scale in 1984 to describe laryngoscopic views.[180] The grades range from I to IV, beginning with grade I (the best view), in which the epiglottis and vocal cords are in complete view, and culminating with grade IV (the most difficult view), in which the epiglottis or larynx is not visualized (Figure 55-22). A modified classification scheme with five different grades based on the Cormack-Lehane scoring

BOX 55-3 ***Predictors of Difficult Laryngoscopy***

- Long upper incisors
- Prominent overbite
- Inability to protrude mandible
- Small mouth opening
- Mallampati classification III or IV
- High, arched palate
- Short thyromental distance
- Short, thick neck
- Limited cervical mobility

Modified from Apfelbaum JL, Hagberg CA, Caplan RA, et al: Practice guidelines for management of the difficult airway: an updated report by the American Society of Anesthesiologists Task Force on Management of the Difficult Airway, Anesthesiology *118:251-270, 2013.*

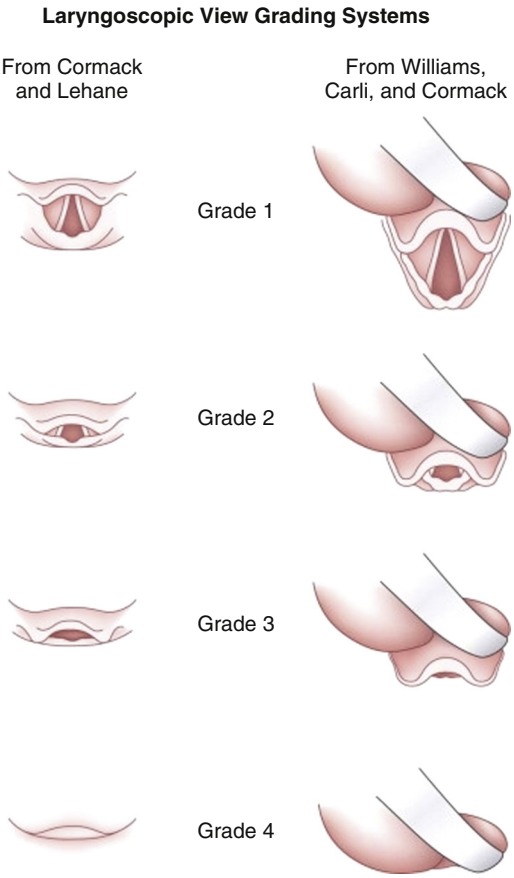

Figure 55-22. The Cormack-Lehane grading system for laryngoscopic view. Grade 1 is visualization of the entire laryngeal aperture; grade 2 is visualization of only the posterior portion of the laryngeal aperture; grade 3 is visualization of only the epiglottis; and grade 4 is no visualization of the epiglottis or larynx. *(Modified from Cormack RS, Lehane J: Difficult tracheal intubation in obstetrics,* Anaesthesia *39:1105, 1984; and Williams KN, Carli F, Cormack RS: Unexpected difficult laryngoscopy: a prospective survey in routine general surgery,* Br J Anaesth *66:38, 1991.)*

system is described by Yentis, who proposed that grade II be differentiated into IIA (partial view of the glottis) and IIB (arytenoids or posterior vocal cords only are visible).[181] Intubation is rarely difficult when a grade I or IIA view is achieved; grades IIB and III are associated

with a significantly higher incidence of failed intubation. A Grade IV laryngoscopic view requires an alternate method of intubation. An alternate method of rating laryngoscopic view is the percentage of glottic opening (POGO) scale, which is determined by the percentage of the vocal cords from the anterior commissure to the arytenoid notch that can be visualized during laryngoscopy. This scale has been shown to have a higher interobserver reliability than the Cormack-Lehane scoring system and is potentially more useful for research studies in direct and indirect laryngoscopy.[182]

When the laryngeal view is inadequate, the laryngoscopist should verify that the patient is in an optimal position, that OELM is being provided, and that the laryngoscope has not been inserted too deeply. Whether a larger laryngoscope or an alternate style of blade would be beneficial should be considered. When the ETT cannot be passed into the trachea under direct visualization, the options include the following: (1) attempts at blind passage of the ETT, which risks laryngeal trauma, bleeding, and airway obstruction; (2) the use of an intubating stylet (see Intubating Introducers and Stylets); and (3) alternative approaches to intubation as per the ASA "Difficult Airway Algorithm."

When the glottic view is adequate, the ETT should be inserted into the right corner of the mouth and advanced such that it intercepts the long axis of the laryngoscope blade at the glottis, rather than inserted midline and parallel to the long axis of the laryngoscope blade, which ensures that the view of the glottis is not obscured. The tip of the ETT is passed through the glottic inlet and advanced until the proximal portion of the cuff is approximately 2 cm past the vocal cords. If a stylet is being used, then the stylet should be removed when the tip of the ETT is right at the level of the vocal cords while the ETT is firmly held stationary; this technique helps limit trauma to the tracheal mucosa from the semirigid stylet.

Nasotracheal Intubation Technique

Before nasotracheal intubation, the more patent nostril should be selected. This selection can be accomplished by separately occluding each nostril and having the patient inhale—the patient will usually be able to inhale more effectively through one of the nares. To reduce the risk of epistaxis, a nasal mucosal vasoconstrictor (e.g., cocaine, phenylephrine, oxymetazoline) should be administered. The nasal ETT should be lubricated and inserted into the naris with the bevel facing away from the midline, which decreases the risk of avulsion of a turbinate. Cephalad traction should be applied as the ETT is advanced through the nasal passage to ensure a trajectory along the floor of the nose, beneath the inferior turbinate.

Once the ETT enters the oropharynx (typically at a depth of 14 to 16 cm), standard DL is performed. The ETT can be guided into the laryngeal inlet by repositioning the head as the ETT is advanced or with the aid of Magill forceps (Figure 55-23). Care should be taken to grasp the ETT proximal to the cuff to prevent cuff damage. Other techniques for nasotracheal intubation include blind nasal intubation, video laryngoscopy, and FSI.

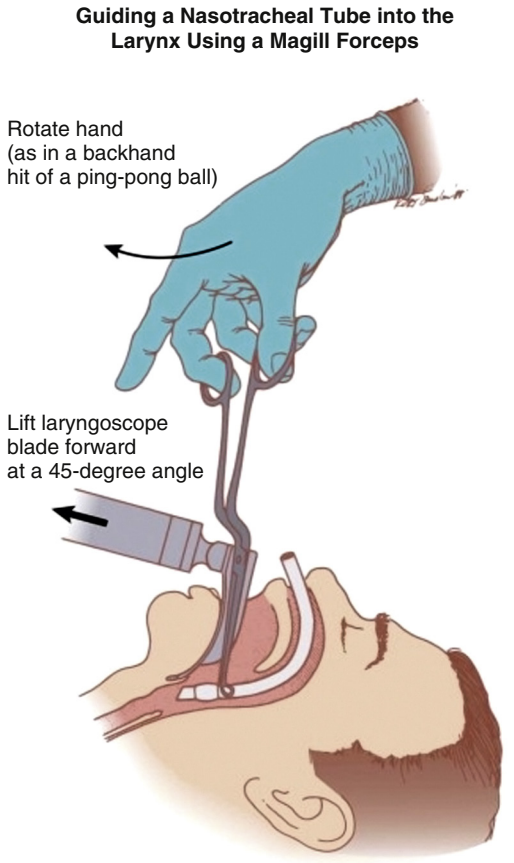

Figure 55-23. Guiding a nasal endotracheal tube (ETT) into the larynx with Magill forceps. *(From Berry JM, Harvey S: Laryngoscopic orotracheal and nasotracheal intubation. In Hagberg CA, editor:* Benumof and Hagberg's airway management*, ed 3, Philadelphia, 2013, Saunders, p. 357.)*

Confirmation of Endotracheal Tube Placement

Once the ETT is in place, the laryngoscope is removed from the mouth, the ETT cuff is appropriately inflated, and the patient is manually ventilated while the ETT is manually held in place. Immediate verification of endotracheal placement of the ETT is necessary; esophageal or endobronchial intubation is a significant source of avoidable anesthetic-related morbidity and mortality. Endotracheal placement can be determined by confirmation of chest rise, visible condensation in the ETT, equal breath sounds bilaterally over the chest wall, lack of breath sounds over the epigastrium, large exhaled tidal volumes, and appropriate compliance of the reservoir bag during manual ventilation.[179] The most important and objective indicator of endotracheal intubation, however, is the presence of a normal capnogram (carbon dioxide [CO_2] waveform) for the presence of at least three breaths. Severe bronchospasm, equipment malfunction, cardiac arrest, or hemodynamic collapse may prevent the appearance of a capnogram tracing, despite proper ETT placement. If doubt remains, then fiberoptic bronchoscopy, although not routinely used, is very reliable at confirming ETT placement.

Hypoxemia, increased airway pressures, asymmetric chest expansion, and the absence of breath sounds over one lung, generally the left, are indicative of endobronchial intubation; pneumothorax can also produce this picture. Fiberoptic bronchoscopy or chest radiography can be used if the clinical picture is unclear.

Securing the Endotracheal Tube

Once the proper depth of the ETT has been determined, the tube should be secured in place to prevent movement and inadvertent endobronchial intubation or extubation. The most common method is to tape the ETT to the skin of the face. Because it is less mobile, the skin of the maxilla is preferred. When tape cannot be used, such as in the case of a severe tape allergy, extensive facial burns, or epidermolysis bullosa, a surgical mask may be tied around the back of the head to secure the ETT. Other methods that may be used for intraoral or facial surgery include wire fixation to a tooth or suturing the ETT to the skin of the cheek.

INDIRECT LARYNGOSCOPY

Conventional DL requires wide mouth opening, cervical flexion, and atlantooccipital extension to create a direct line of vision from the mouth to the larynx. In certain conditions, this positioning is impossible or contraindicated. Other times, attributable to anatomic variations in the airway (e.g., redundant soft tissue, protruding incisors, anterior larynx), DL cannot be achieved, despite optimal positioning and technique. Indirect laryngoscopy entails the indirect visualization of the glottis by way of optical aids, such as fiberoptic bundles, video cameras, mirrors, prisms, or lenses. Various different devices that use indirect laryngoscopy are available, including FISs, VLs, and intubating optical stylets. They are indispensable tools for the management of the known or predicted difficult airway. Because no direct line of sight is needed, visualization of the larynx can occur without tissue distortion; consequently, these techniques can be readily used with topical anesthesia in an awake patient.[10]

Flexible Scope Intubation of the Trachea

The flexible fiberoptic bronchoscope (FOB) is the most widely-used, versatile, indirect laryngoscopy device. Since the first use of fiberoptics for airway management in 1967, FISs, including the FOB, have become invaluable tools for endotracheal intubation in both awake and anesthetized patients. There are various clinical scenarios within which FSI provides a superior technique for airway management, as compared with DL or alternative airway devices. FSI of the awake, spontaneously ventilating patient is well-accepted as the *gold standard* for the management of the difficult airway.[183]

The standard FOB (Figure 55-24) consists of thousands of flexible glass fibers approximately 8 to 10 μm in diameter that are capable of transmitting reflected light along their length. Light is transmitted from an external light source to the distal end of the FOB; the light reflecting off the object to be viewed is transmitted back along the length of the FOB to an eyepiece or video camera at the proximal end of the scope. In recent years, FOBs have been replaced by modern FISs that use video chip and light-emitting diode (LED) technology instead of fiberoptics. An example is the Storz Five Scope, which is a highly portable video bronchoscope for use with the C-MAC VL system.

Indications for FSI essentially include any indication for endotracheal intubation. However, FSI may be the airway management technique of choice in any one of the following clinical scenarios[183]:

- Known or anticipated difficult airway (i.e., cannot intubate or cannot ventilate [CICV])
- Undesirable extension of the neck (e.g., unstable cervical fracture, severe cervical stenosis, vertebral artery insufficiency, Chiari malformation)
- Increased Risk of dental damage (e.g., poor dentition, fragile dental work)
- Limited mouth opening (e.g., TMJ disease, mandibular-maxillary fixation, severe facial burns)

No specific contraindications exist for FSI; however, in certain clinical situations, successful FSI is unlikely. Severe airway bleeding can obscure anatomic landmarks and soil the tip of the FIS with blood, making visualization of the larynx extremely difficult. Obstruction or severe stenosis of the airway, resulting in the inability to pass a FIS can also make FSI impossible.

FSI provides several advantages over DL[183]:

- Allows for a more complete visual examination of the airway before intubation.
- Provides confirmation of tube placement, avoiding esophageal and endobronchial intubation.
- Eliminates the need for three-axis alignment; therefore FSI is among the techniques least likely to result in cervical spine movement.
- Is well-tolerated in awake patients; results in less tachycardia and hypertension.
- Has less of a potential for airway and dental trauma.
- Can be performed in multiple positions.

FSI can be performed in the awake or anesthetized patient. Indications for an awake FSI are generally those situations during which ventilation via a mask is anticipated to be difficult, when a postintubation neurologic examination is needed, or when induction of general anesthesia could cause adverse hemodynamic or respiratory consequences. The major technical disadvantage to performing FSI under general anesthesia is the loss of pharyngeal muscle tone, which can lead to upper airway collapse and difficult fiberoptic laryngoscopy.[183]

Before its use, the anesthesia practitioner or skilled assistant must ensure that the FIS, light source, and video monitor are in proper working condition and that all components have been fully prepared for use. This preparation includes focusing the image if using a FOB, ensuring proper view orientation if using a video camera, lubricating the distal third of the flexible insertion cord, applying antifogging solution to the tip of the scope, and connecting a suction line or oxygen source to the suction port. The ETT should be prepared by placing it in a warm water bath, which softens the plastic, easing passage into the trachea and minimizing airway trauma.

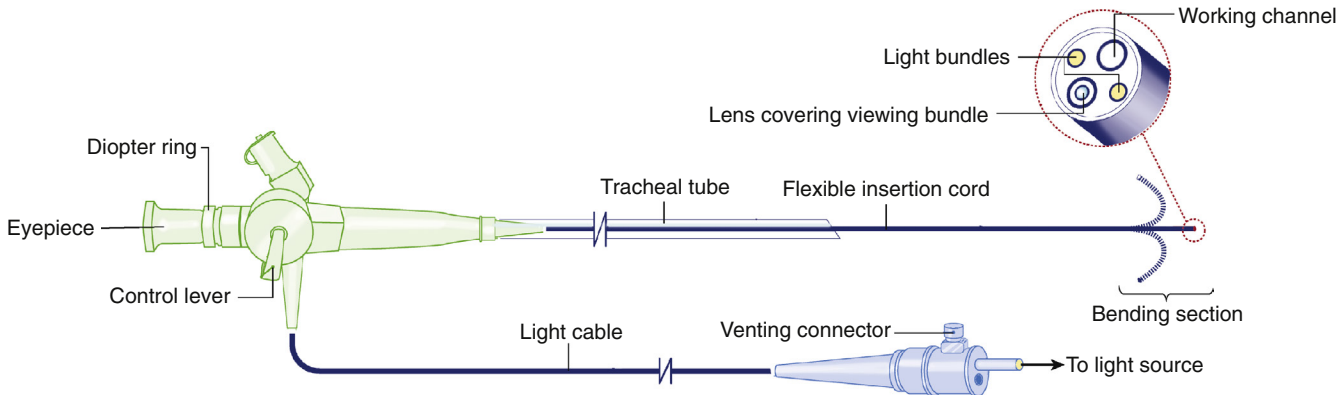

Figure 55-24. Flexible fiberoptic bronchoscope (FOB). *(From Henderson J: Airway management. In Miller RJ, editor:* Anesthesia*, ed 7, Philadelphia, 2009, Churchill Livingstone.)*

FSI is usually performed in the supine or sitting (i.e., beach-chair) position, although emergency FSI in the lateral decubitus or prone position has also been described.[184] When performing FSI in the supine position, the anesthesia provider stands at the head of the patient. Advantages to this position are that the laryngeal view through the FIS is in the same orientation as during DL, and the patient and physician are already in the optimal position to perform mask ventilation or other airway maneuvers, if necessary. When performing FSI with the patient in the sitting or beach-chair position, the practitioner should stand facing the patient at the patient's side. This position may be the position of choice in awake FSI as a result of improved ventilation and greater patient comfort. In addition, the sitting position optimizes airway anatomy and prevents airway collapse in patients who are obese, in patients with obstructive sleep apnea, and in patients with anterior extrinsic airway obstruction.[185]

Before FSI, unless contraindicated, an antisialagogue, such as glycopyrrolate 0.2 mg IV, should be administered to dry airway secretions. Both the orotracheal and nasotracheal routes can be used for FSI. While weighing the advantages and disadvantages, the clinician should determine which approach is best-suited for the clinical situation. Whichever route is chosen, however, essentially two steps to FSI must be taken[183]:

1. Indirect laryngoscopy and endoscopy are performed, obtaining a view of the glottis with the FIS and maneuvering the FIS through the vocal cords into the trachea.
2. The ETT is advanced over the FIS into its proper position in the trachea, and the FIS is removed.

When performing orotracheal FSI navigating the FIS around the base of the tongue to achieve a satisfactory view of the larynx is one of the major challenges. The FIS has a tendency to stray off the midline, and, frequently, little to no airspace is found between the tongue and the palate through which to navigate the FIS. To mitigate this issue, several devices or techniques can be used. Specialized intubating oral airways can be used to protect the FIS from damage by biting, to prevent the tongue from falling back into the pharynx and obstructing the airspace, and to keep the FIS midline while it is guided to the larynx. Several types of intubating oral airways are available, each with unique design differences, and include the Ovassapian, Berman, and Williams airways. A disadvantage of these devices is that they place pressure on the base of the tongue, potentially causing gagging in awake patients. In both awake patients and those under general anesthesia, gentle traction on the tongue anteriorly is helpful in preventing the tongue from falling back into the pharynx if an intubating airway is not used. This traction can be easily accomplished by hand with the help of 4 × 4-inch gauze pads for traction or with Magill forceps. Care should be taken to not injure the tongue on the bottom teeth. As previously described, LMAs and intubating LMAs can also be used as conduits for oral FSI. Obtaining a laryngeal view during nasal FSI is often easier, as compared with the oral approach, which is due to the fact that the FIS stays midline and the tip of the FIS is usually directed at the glottis as it enters the oropharynx.

Once the FIS has been successfully positioned in the oropharynx, the epiglottis and vocal cords can usually be visualized with a slight anterior deflection of the tip of the FIS The FIS is aimed toward the anterior commissure of the vocal cords and posteriorly flexed to enter into the trachea. The trachea is easily identifiable by the presence of the cartilaginous tracheal rings. The FIS is advanced distally until a point just above the carina, and the ETT is advanced over the FIS while continually visualizing the trachea through the FIS, which provides confirmation that the FIS and ETT have not been accidentally dislodged into the oropharynx or esophagus. Frequently, especially with orotracheal intubation, resistance is met as the tip of ETT reaches the glottic inlet. Often, this resistance has been shown to be attributable to the bevel of the ETT impinging on the right arytenoid.[186] A slight withdrawal of the ETT and a counterclockwise 90-degree turn, orienting the bevel posteriorly, usually resolves this issue. For nasotracheal intubation, a clockwise 90-degree turn, ensuring that the bevel is oriented anteriorly, can prevent the tip of the ETT from impinging on the epiglottis.

Alternatively, the Parker Flex-Tip ETT (Parker Medical, Englewood, CO), which has a bull-nosed tip directed toward the center of the distal lumen, can be used. This ETT has been shown to have a high first-pass success rate when being advanced over a FIS.[187]

After the successful passage of the ETT, proper depth (2 to 3 cm from the carina) is confirmed during the withdrawal of the FIS. On rare occasions, the FIS may prove difficult to remove from the ETT, which may be attributable to the FIS having passed through the Murphy eye rather than the distal lumen or a result of inadequate lubrication of the FIS. In these situations, forceful removal may damage the device; therefore the FIS and ETT should be removed as a unit and the procedure repeated.

Rigid Indirect Laryngoscopes

The first indirect laryngoscopes for intubation were based on modifications of the standard direct laryngoscope and used mirrors or prisms to project an image at an angle from the horizontal, facilitating visualization of the larynx. Modern indirect laryngoscopes based on the direct laryngoscope design that uses optical lenses to project a refracted image of the glottis include the Viewmax (Rüsch, Duluth, GA) and the TruView EVO2 (Truphatek, Netanya, Israel).

One of the most well-studied rigid indirect laryngoscopes is the Bullard Elite (Gyrus ACMI, Southborough, MA). This device features an anatomic L-shape, an attachable metal stylet, and a 3.7-mm working channel that can be used for oxygen insufflation, suction, or instillation of local anesthetic. The Bullard laryngoscope has been shown to be especially useful in patients with limited cervical spine mobility or cervical spine injury.[188,189] The blade's 6.4-mm thickness allows its use in patients with minimal mouth opening. The device is rotated over the base of the tongue from the oropharynx into the laryngopharynx. Once the tip of the Bullard is in the appropriate position in relation to the epiglottis, a lifting force is applied to elevate the epiglottis. Visualization of the larynx is optimized by adjusting the lifting force and the position of the tip of the device.[10]

The Airtraq SP (Prodol Meditec S.A., Guecho, Spain) is a disposable, portable, anatomically shaped, optical laryngoscope that provides a magnified view of the glottis without alignment of the oral, pharyngeal, and laryngeal axes. It includes a guiding channel to hold the ETT and direct it toward the vocal cords. It can be used for a variety of applications, including the known or predicted difficult airway, as well as for awake intubation. The Airtraq laryngoscope has been shown to result in more rapid endotracheal intubation with a reduced incidence of esophageal intubation when compared to DL, especially when used by novices.[190] It is available in two adult and two pediatric sizes, as well as in specific designs for nasotracheal intubation and double-lumen tube placement. The Airtraq Avant is a newer model that features a reusable optic piece that is used in combination with disposable blades.

Lighted Optical Stylets

Lighted optical stylets are rigid or semirigid fiberoptic devices that incorporate the optical and light-transmitting components into a tubular, stainless steel sheath over which the ETT is loaded. A substantial body of evidence supports the use of these optical stylets in patients with limited neck mobility,[191] small mouth opening,[192] abnormal airway anatomy,[193] or anticipated difficult laryngoscopy.

The Bonfils retromolar intubation fiberscope (Karl Storz Endoscopy, Tuttlingen, Germany) is a 40-cm long, rigid optical stylet with a fixed anterior tip curvature of 40 degrees.[194] The proximal eyepiece can be used with the naked eye or connected to a video monitor. It is available with a working channel that can be used for suction, SAYGO local anesthesia,[195] or oxygen insufflation (oxygen flow rates should be limited to 3 L/min to avoid barotrauma).[196] The Shikani optical stylet (Clarus Medical, Minneapolis, MN) is a similar device to the Bonfils fiberscope but with a malleable shaft. The Levitan FPS stylet (Clarus Medical, Minneapolis, MN) is a shorter version of the Shikani stylet intended for use in combination with DL, although usable on its own.[197] The Clarus Video System (Clarus Medical, Minneapolis, MN) is a newer version of the Shikani fiberscope that incorporates a liquid crystal display (LCD) screen.

These optical stylets can be used on their own or in combination with DL or video laryngoscopy.[198] The ETT is mounted on the optical stylet and advanced under direct vision via a midline or right paraglossal route until it passes under the tongue. After indirect visualization of the tip of the stylet passing through the vocal cords (via the eyepiece or video monitor), the ETT is advanced over the stylet into the trachea. When these are not used in conjunction with DL or video laryngoscopy, the left hand of the operator should lift the patient's jaw by gently grasping the mandible and displacing it anteriorly. This maneuver helps create more airspace in the oropharynx and lifts the epiglottis. Optical stylets can be used for awake intubation and have also been used for the transillumination technique (see Lighted stylets).[194,199]

The SensaScope (Acutronic, Hirzel, Switzerland) is a new *hybrid* rigid optical stylet that uses video chip technology. It has an S-shaped curvature and a 3-cm long steerable tip.[200] Visualization is achieved by a connection to a video monitor. The SensaScope is designed to be used in combination with DL and has been successfully used for awake intubation in patients with a predicted difficult airway.[201] The Video RIFL (AI Medical Devices, Williamston, MI) is a similar device with a rigid shaft and a flexible, steerable tip. This device features an LCD monitor attached to the handle that displays the video image.

VIDEO LARYNGOSCOPY

As with flexible bronchoscopes, video chip technology has begun to largely replace fiberoptic technology in rigid indirect laryngoscopes because of the advantages of a higher quality image, increased durability, and reduced maintenance costs. Over the past 10 years, VLs have revolutionized the practice of airway management, and their use may become standard not only for difficult airways, but also for routine airways as well. In fact, video

laryngoscopy is now included in the ASA "Difficult Airway Algorithm" as an alternative approach to intubation and should be considered for patients with a known or predicted difficult airway.[4] A VL is also listed as a suggested piece of equipment on a portable difficult airway cart.[4]

VLs have been shown to result in improved glottic visualization, compared with DL, in both routine airway management and in the predicted difficult airway.[4,202] Although this improved visualization does not necessarily translate into increased success with intubation (particularly in the normal airway), studies have shown improved intubation success with video laryngoscopy in patients with predicted difficult airways .[203,204] VLs are also useful in the unexpected difficult airway; intubation success rates of 94% and 99% have been reported for video laryngoscopy as a rescue modality after failed DL.[205,206] These devices have also been successfully used for awake intubation.[207,208]

Various different VLs have been introduced, each with its own design and specific features. Generally, VLs can be divided into three groups: (1) those whose design is based on the Macintosh blade, (2) those who incorporate highly curved or distally angulated blades, and (3) those that incorporate an ETT-guiding channel.[209] Although no single design has been shown to be superior, there are certain clinical circumstances where one style may be preferable to another. Other features that vary among different VLs include the degree of portability and the size of the video monitor. Many VLs are available in both reusable and single-use models.

VLs based on the Macintosh blade design include the C-MAC laryngoscope (Karl Storz, Tuttlingen, Germany), the McGrath MAC laryngoscope (Aircraft Medical, Edinburgh, UK), and the GlideScope Direct intubation trainer (Verathon, Bothell, WA). These devices can be used for both DL and video laryngoscopy, making them particularly useful for teaching the DL technique. The C-MAC laryngoscope is the most extensively studied of these and is associated with shorter intubation times and greater ease of use, compared with other VLs,[210,211] which is possibly due to laryngoscopists' familiarity with the use of a Macintosh-style blade (Figure 55-25). The technique for using the C-MAC laryngoscope is identical to that of DL with a Macintosh blade; the tip of the VL can be used to lift the epiglottis directly.[212] In contrast to other VLs, most intubations with the C-MAC laryngoscope can be performed without the use of a stylet[213,214]; the use of an oral RAE ETT can facilitate endotracheal intubation.[215]

VLs with a distally angulated or highly curved blade permit a "look around the corner," providing an improved laryngoscopic view without requiring manipulation of the cervical spine. These devices are therefore of particular utility in patients with cervical immobilization, micrognathia, or limited mouth opening.[209] The GlideScope (Verathon, Bothell, WA) is the prototype for this subset of devices. It possesses a 60-degree blade angulation, an antifogging mechanism, a 7-inch LCD monitor, and is available in reusable and single-use models. The McGrath Series 5 laryngoscope is a similar device in that it possesses a distally angulated blade; its primary difference is its greater portability and a disarticulating handle that can be useful in patients with limited mouth opening and limited movement of the head and neck.

Figure 55-25. C-MAC video laryngoscope. *(From Cavus E, Dörges V: Video laryngoscopes. In Hagberg CA, editor:* Benumof and Hagberg's airway management*, ed 3, Philadelphia, 2013, Saunders, p. 544.)*

The D-Blade (Karl Storz, Tuttlingen, Germany) is a highly curved VL blade for use with the C-MAC system. These devices are typically inserted in the mouth midline, without sweeping the tongue from right to left as in DL. Because of the high degree of angulation of the blade, an ETT stylet is almost always necessary; malleable stylets with a 60- to 90-degree bend, articulating stylets, and the GlideRite stylet (a rigid stylet with a 90-degree curve specifically designed for use with the GlideScope) have all been successfully used with these VLs.[216,217] The VL and the styletted ETT should be inserted into the oral cavity under direct vision to avoid oropharyngeal trauma.[218]

Some VLs with highly curved blades have integrated tube-guiding channels to facilitate intubation without the use of a stylet, similar to the Airtraq. The King Vision (King Systems, Noblesville, IN) and the Pentax Airway Scope (AWS; Pentax Medical, distributed by Ambu Inc., Glen Burnie, MD) fall into this category. This type of VL has been shown to be useful in patients with cervical immobilization and has been successfully used for awake intubation.[219,220] The VividTrac (Vivid Medical, Palo Alto, CA) is a new single-use, channeled VL with a Universal Serial Bus (USB) interface that works with any monitor.

INTUBATING INTRODUCERS AND STYLETS

Intubating stylets are generally long, slender devices used to assist in guiding an ETT through the glottis. Malleable ETT stylets are frequently used to create an anterior *hockey stick* curvature to an ETT to facilitate tracheal intubation. ETT introducers can be used to perform a blind intubation when the glottic opening cannot be visualized during laryngoscopy (i.e., a Cormack-Lehane Grade III laryngeal view). Lighted stylets are used to blindly intubate the trachea using the transillumination technique.

Endotracheal Tube Introducers

The original ETT guide was the Eschmann introducer, developed by Venn in 1973.[221] This device, also known

as the *gum elastic bougie*, is long enough to allow advancement of an ETT over its distal end after being placed through the vocal cords. It also possesses an anterior angulation at the distal end (coudé tip) to facilitate maneuvering underneath the epiglottis toward the glottic opening, even when the glottic structures are not visualized. A variety of similar introducers with different sizes and features are available; some are hollow to allow for ventilation if the need arises.

Coudé-tip introducers are particularly useful when only a portion of the laryngeal structures, such as only the tip of the epiglottis, can be visualized. Proper placement of the stylet is indicated by the perception of *tracheal clicks* as the coudé tip passes along the tracheal rings and by a *distal hold-up* as it reaches the small bronchi. An ETT is subsequently advanced over the introducer into the correct position.[222]

Lighted Stylets

Lighted stylets make use of the transillumination technique to blindly intubate the trachea and have been described in the literature as an alternative or aid to DL, particularly in the predicted difficult airway. Lighted stylets may be particularly helpful when the presence of blood or heavy secretions limits visualization of the airway. However, because lighted stylet insertion is a blind technique, it is contraindicated in certain clinical situations, such as neoplasm of the airway or airway trauma. Because increased soft tissue leads to difficulty with transillumination, this technique is less useful in the patient who is morbidly obese.[222]

To perform the transillumination technique, an ETT is preloaded onto the stylet. The left hand of the operator lifts the supine patient's jaw by gently grasping the mandible and displacing it anteriorly to facilitate the insertion of the stylet under the tongue. The stylet should be inserted using a retromolar approach. Once inserted, the stylet should be kept midline and advanced under the tongue. A well-circumscribed *glow* (approximately the size of a half dollar) should appear in the midline of the patient's neck at the level of the cricoid cartilage (Figure 55-26), which indicates correct positioning of the stylet within the trachea. Subsequently, the ETT can be advanced over the stylet into proper position.[222]

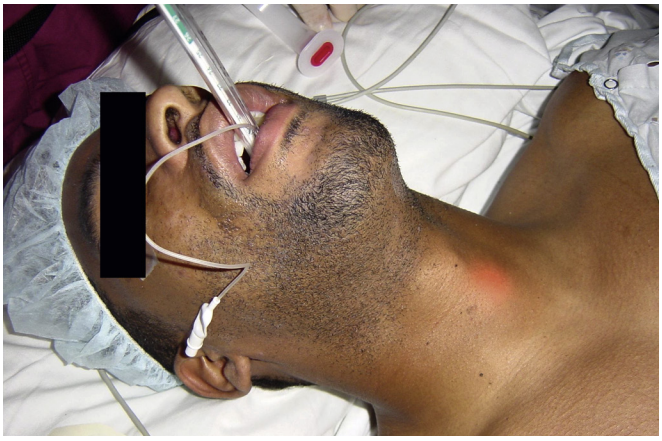

Figure 55-26. When the tip of a lighted stylet is placed at the glottic opening, a well-circumscribed glow can be seen in the anterior neck just below the thyroid prominence.

TRACHEAL INTUBATION THROUGH A SUPRAGLOTTIC AIRWAY DEVICE

The intubating LMA (ILMA), known as the LMA Fastrach (LMA North America, San Diego, CA), was first described by Dr. Archie Brain in 1997; it became available for commercial use in the United States shortly thereafter. The ILMA was designed as a conduit for tracheal intubation to facilitate ventilation between attempts at tracheal intubation. The rigid handle and airway tube enable a rapid and precise control of mask position. An epiglottic elevating bar is designed to elevate the epiglottis as the tube is advanced into the bowl. A disposable, single-use version is available, in addition to the original reusable model. Specialized reusable or single-use tracheal tubes are designed to facilitate atraumatic blind intubation through the ILMA. The tubes are straight, wire-reinforced, and have a soft molded tip designed to prevent impingement on laryngeal structures.

The technique of inserting the ILMA differs in many respects from the insertion of the cLMA, and the learning curve is significant. A *neutral* head position (nonextended head on a support) is recommended. The ILMA handle is used to rotate the mask into the pharynx. Oxygenation, ventilation, and anesthesia are stabilized after insertion. If resistance to ventilation is encountered, then the position of the ILMA is adjusted. The *Chandy maneuver* consists of two separate maneuvers: (1) the ILMA is rotated in the sagittal plane until resistance to bag ventilation is minimal; and then (2) the ILMA is gently lifted from the posterior pharyngeal wall just before passage of the tracheal tube (Figure 55-27). The original, reusable ILMA should be removed soon after tracheal intubation has been verified because its rigidity results in high pressure on adjacent tissues. Although the blind technique has a high rate of success, intubation under vision with a FIS through the ILMA achieves higher first-attempt a overall success rates.

Other SGAs can be used to facilitate endotracheal intubation. The cLMA, although not designed for intubation, can be an effective conduit if used in conjunction with a FIS. Because of the long and narrow airway tube, a microlaryngeal tube should be used. Alternatively, a cLMA can be exchanged for an ETT by using a FIS in conjunction with the Aintree intubation catheter (Cook Critical Care, Bloomington, IN), which is a hollow airway exchange catheter designed to fit over a standard intubating FIS (Figure 55-28). The airQ intubating laryngeal airway (Cookgas, Mercury Medical, Clearwater, FL) is a unique SGA designed for use in both blind and FIS-guided intubation.

RETROGRADE INTUBATION

RI is a well-described technique for orotracheal or nasotracheal intubation that involves guiding an ETT into the trachea with a narrow, flexible guide that has been percutaneously placed through the CTM into the trachea and passed retrograde through the larynx and pharynx,

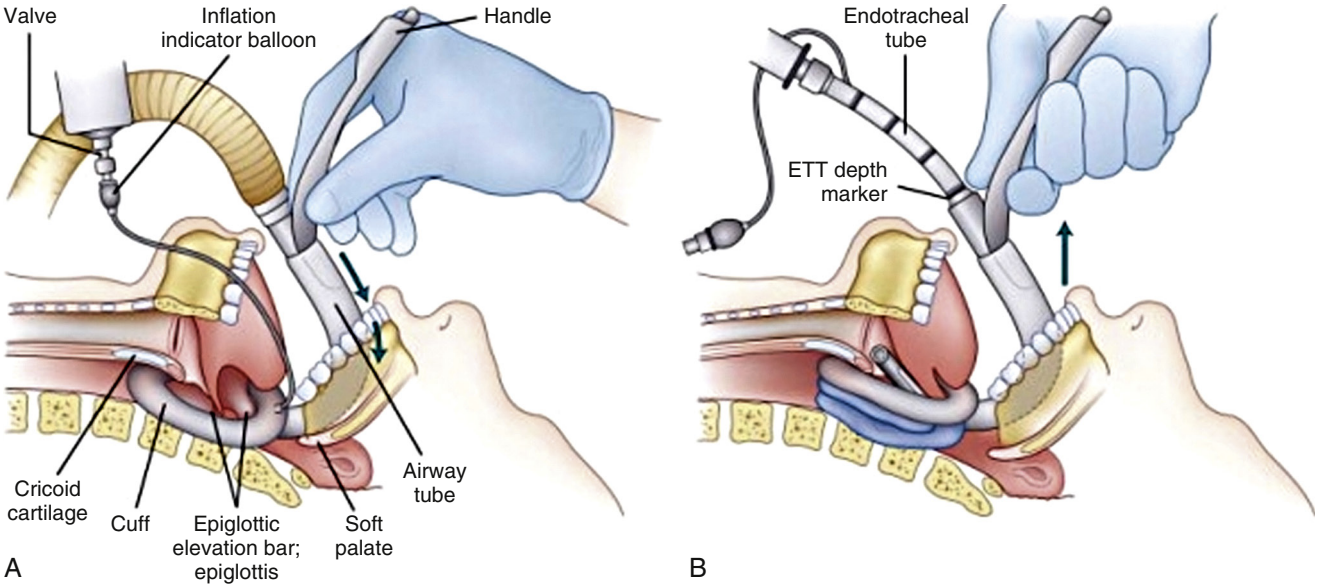

Figure 55-27. The Chandy maneuver consists of two steps. **A,** The first step is important for establishing optimal ventilation. The intubating laryngeal mask airway (ILMA) is slightly rotated in the sagittal plane using the handle until the least resistance to bag ventilation is achieved. **B,** The second step is performed just before blind intubation. The handle is used to lift (but not tilt) the ILMA slightly away from the posterior pharyngeal wall, which facilitates the smooth passage of the endotracheal tube (ETT) into the trachea. *(From Verghese C, Mena G, Ferson DZ, Brain AIJ: Laryngeal mask airway. In Hagberg CA, editor:* Benumof and Hagberg's airway management*, ed 3, Philadelphia, 2013, Saunders, p. 457.)*

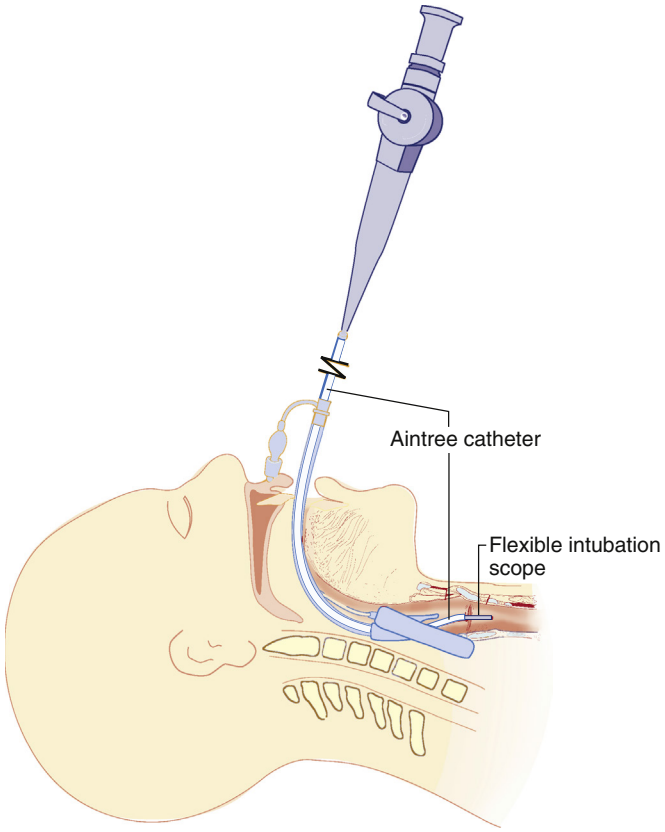

Figure 55-28. Aintree intubating catheter within a flexible intubation scope, inserted through a laryngeal mask airway. *(From Henderson J: Airway management. In Miller RJ, editor:* Anesthesia*, ed 7, Philadelphia, 2009, Churchill Livingstone.)*

exiting the mouth or nose. The guide is typically a steel guidewire, although an epidural catheter can be used. This technique has several modifications, each with its own benefits and disadvantages, and can be successfully used in awake, sedated, obtunded, or apneic patients who have either an anticipated or unanticipated difficult airway.[223] Indications include failure of DL; obstruction of the view of the vocal cords by blood, secretions, or anatomic derangement; and difficult intubation scenarios such as unstable cervical spine, ankylosing spondylitis, maxillofacial trauma, or trismus. RI is also an alternative to FSI in developing countries where the availability of FISs is limited.[223]

The ASA "Difficult Airway Algorithm" describes RI as an alternative approach to difficult intubation in the nonemergent pathway, when intubation is unsuccessful but mask ventilation is adequate. It is suggested that equipment for RI be included in a portable storage unit for difficult airway management. RI can take several minutes to accomplish; therefore this technique is contraindicated in an emergent CICV scenario.[223] Other contraindications are generally relative and include anatomic abnormalities (e.g., malignancy, goiter) that preclude access to the CTM, tracheal stenosis at the level of the CTM, coagulopathy, and local infection.

The ideal position for RI is supine with the neck in extension, allowing easy palpation of the cricoid cartilage and surrounding structures. If this position is not possible, then RI can also be performed with the patient in the sitting position or with the neck in a neutral position. If landmarks are difficult to identify, then ultrasound guidance may be used. The anterior neck should be cleansed before puncture, and aseptic technique should be used. The translaryngeal puncture site can be performed superior or inferior to the cricoid

cartilage. The CTM (superior to the cricoid cartilage) has the advantage of being relatively avascular; however, a puncture at this site allows only 1 cm of space below the level of the vocal cords for the tip of the ETT. A puncture site inferior to the cricoid cartilage, at the cricotracheal ligament, allows the ETT to travel in a straight path with a long length of the ETT below the vocal cords; however, this site is associated with a greater potential for bleeding.[223]

The classic technique for RI involves using a Tuohy needle to puncture the CTM and an epidural catheter as the guide. More commonly, an IV catheter and a steel guidewire are used. The diameter of the guidewire should be small enough to fit through the IV catheter and should be at least twice as long as the ETT to be used; a guidewire with a .038″ diameter (which passes through an 18-gauge IV catheter) and a length of 110 cm is commonly used. Commercial kits are available that include all necessary equipment. Performing a RI with a J-tip, steel guidewire rather than an epidural catheter provides the following advantages: the J-tip of a guidewire is less traumatic to airway; the guidewire has a lower tendency to coil or kink retrieval of the guidewire from the oral or nasal cavity is easier; and the technique is quicker.[223]

Once the patient has been positioned, the operator's nondominant hand stabilizes the trachea by placing the thumb and third digit on either side of the cricoid cartilage. The index finger is used to identify the midline of the CTM and the upper border of the cricoid cartilage. A syringe half-filled with saline is attached to an 18-gauge angiocatheter and advanced at a 90-degree angle to the CTM with the bevel facing cephalad, aspirating for air bubbles to confirm the position inside the trachea. The angle of insertion is slightly lowered, and the needle is removed. At this stage, reconfirmation of a position within the trachea and instillation of a local anesthetic can be performed with a second syringe filled with 2 to 4 mL of 2% or 4% lidocaine. This transtracheal block can provide additional comfort to a patient who is awake or sedated and undergoing RI, or it can reduce the incidence of sympathetic stimulation and laryngospasm in a patient under general anesthesia.

The guidewire is then advanced through the angiocatheter until it exits the mouth or nose. DL can be used to facilitate the wire exiting the mouth, if necessary. The guidewire is clamped with a hemostat at the level of the skin of the neck to prevent migration. Although the ETT can then be directly advanced over the guidewire, a tapered guide catheter (e.g., Arndt airway exchange catheter) is useful to reduce the discrepancy in diameter between the guide-wire and the ETT, which can predispose the ETT to catch on the arytenoids or vocal cords rather than smoothly slide into the trachea. The guide catheter is placed over the portion of the wire exiting the mouth or nose and advanced until it contacts the CTM. The wire is then removed, and an ETT is advanced over the guide catheter (Figure 55-29). Potential complications include bleeding (usually minimal), subcutaneous emphysema, pneumomediastinum, pneumothorax, and injury to the posterior trachea or esophagus.[223]

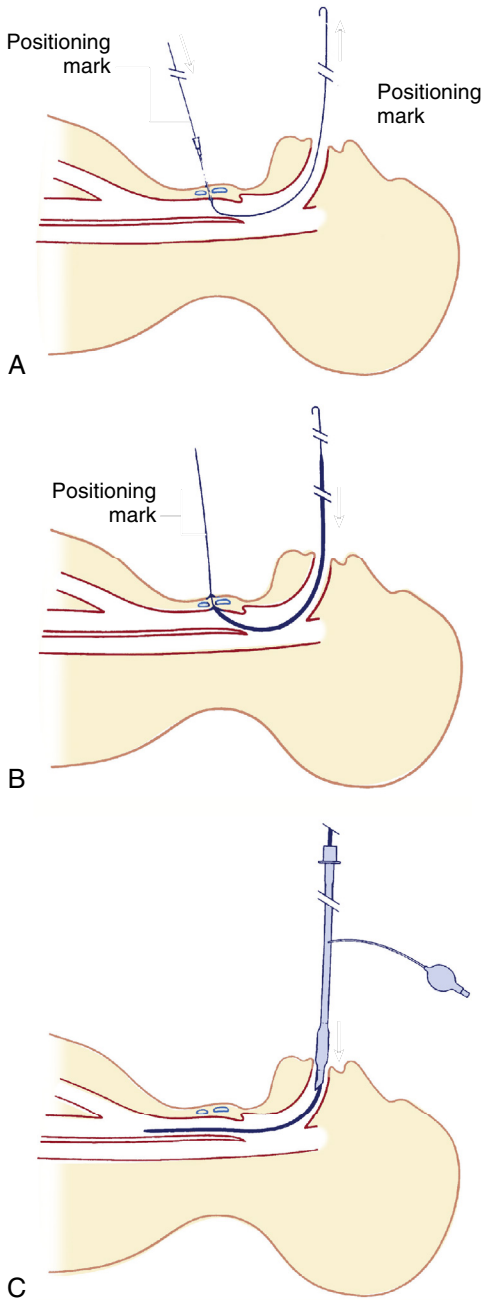

Figure 55-29. The guidewire technique for retrograde intubation. **A,** After the placement of an 18-gauge angiocatheter through the cricothyroid membrane (CTM), the J-tip of the guidewire is inserted in a cephalad direction until it exits the mouth or nose. **B,** The guide catheter is threaded over the guidewire until it contacts the laryngeal access site. The guidewire is then removed from above. **C,** After advancing the guide catheter 2 to 3 cm, the endotracheal tube is advanced into the trachea. *(Courtesy of Cook Critical Care, Bloomington, IN.)*

DOUBLE-LUMEN TUBES AND BRONCHIAL BLOCKERS

Single-lung ventilation is required for certain clinical circumstances, including protective lung isolation from infection or hemorrhage, attaining adequate exposure for surgical procedures (e.g., video-assisted thoracoscopy), and for controlling the distribution of ventilation in the

setting of major bronchial surgery, trauma, or fistula. Double-lumen tubes (DLTs) and bronchial blockers are two options that allow for ventilation of only one lung (also see Chapter 66).

DLTs have a bronchial lumen and a tracheal lumen. They are designated as left sided or right sided, depending on whether the bronchial lumen goes to the left or right main bronchus. Most commonly, a left-sided DLT is used to avoid blockage of the right upper lobe bronchus. DLTs are placed in a similar fashion to the standard ETT, although placement is usually more difficult attributable to their size and stiffness. Video laryngoscopy can facilitate DLT placement.[224] After placing the DLT into the trachea, verification of the location of the bronchial port with a FIS should be determined. The blue bronchial cuff should be positioned just below the carina in the appropriate bronchus. Inflation of the blue bronchial balloon under direct visualization helps verify proper placement. Care should be taken to ensure that the bronchial cuff does not herniate over the carina. Once the DLT is properly placed, isolating a lung is possible by inflating the bronchial cuff and clamping either the tracheal or bronchial connector.

Bronchial blockers are essentially hollow, balloon-tipped catheters that are endobronchially placed to isolate and deflate one lung. In some clinical situations, lung isolation is required, but the use of a DLT is not practical, because of a difficult airway, decreased size of the tracheal lumen, or the need for postoperative mechanical ventilation. In these instances, the use of a modified single-lumen tube with an integrated bronchial blocker (e.g., the Univent [Fuji Systems, Tokyo, Japan]) or the use of a bronchial blocker in conjunction with a standard ETT is appropriate.

PERCUTANEOUS AIRWAYS

Percutaneous (invasive) airways are indicated as a rescue technique when attempts at establishing a noninvasive airway fail. They may also be used as a primary airway in some difficult airway situations when attempts at securing a noninvasive airway are likely to fail, such as a patient with a laryngeal neoplasm and critical airway obstruction. Options for invasive airway access include transtracheal jet ventilation (TTJV), cricothyrotomy, and tracheostomy. Whereas tracheostomy is usually performed by a surgeon, the anesthesia practitioner should become proficient with the techniques for TTJV and cricothyrotomy; the situation will inevitably arise in which an invasive airway will become necessary. An emergent situation is not the time to become familiar with a new technique.

TRANSTRACHEAL JET VENTILATION

Percutaneous TTJV is a relatively quick and effective but invasive method of oxygenation and ventilation in the CICV scenario when more conservative measures fail. The ASA "Difficult Airway Algorithm" lists TTJV as an emergent invasive technique to be used in patients who cannot be conventionally ventilated or intubated.[4] TTJV is widely regarded as a life-saving procedure that can provide adequate, temporary oxygenation and ventilation with less training and complications than a surgical airway, a last resort for obtaining an airway in the algorithm.[225] Nonetheless, TTJV is an invasive technique, and its primary use is as an emergency airway. Occasionally, it is used on an elective basis for laryngeal surgery.

Inspiration during TTJV is achieved by insufflation of pressurized oxygen through a cannula placed by needle cricothyrotomy. Expiration is passive as a result of the elastic recoil of the lungs and the chest wall. Allowing sufficient time for passive expiration to avoid barotrauma from breath stacking is imperative. Expiration occurs through the glottis and depends on a nonobstructed upper airway, which is imperative to avoid barotrauma and resulting pneumothorax. The egress of air through the glottic aperture can also provide bubbles to facilitate the placement of an ETT. In fact, several case reports have demonstrated that after the initiation of TTJV in an airway with little or no visualization of the glottis, successful intubation occurred because of the opening of the glottis and guidance from the bubbles with jet ventilation.[225]

TTJV should not be performed in patients who have sustained direct damage to the cricoid cartilage or larynx or in patients with complete upper airway obstruction. Other relative contraindications to TTJV include coagulopathy, obstructive pulmonary disease, and distorted anatomy in which catheter placement might be difficult.

Typically, a 12- to 16-gauge kink-resistant catheter is used for TTJV. A coil-reinforced 6 Fr catheter (Cook Critical Care, Bloomington, IN) is specifically designed for TTJV to prevent kinking, and its Teflon coating facilitates its passage through the CTM into the trachea. The technique for placement is similar to the technique for RI, with the exception that the needle is inserted with the bevel facing caudally. Confirmation of proper intratracheal placement of the catheter by testing for aspiration of air is imperative before initiating jet ventilation.

The minimum pressure required to drive a jet ventilator is 15 psi. The pipeline pressure for oxygen in hospitals in the United States is approximately 55 psi. Commercially available jet ventilators generally contain pressure regulators to lower the pipeline pressure to provide successful jet ventilation while avoiding higher pressures that might result in barotrauma. In most instances in the operating room, adequate pressure for jet ventilation can be achieved by connecting straight to the pipeline supply. Difficulty usually arises in locations outside of the surgical unit where TTJV may be needed but adequate driving pressure is not available.[225]

A major complication of TTJV is barotrauma with resulting pneumothorax from the use of high-pressure oxygen. To prevent this complication, ensuring that a path for air egress exists and that adequate time for passive expiration is available is an absolute necessity. The lowest possible pressure that will provide adequate oxygenation and ventilation should be used. Other complications associated with TTJV include subcutaneous or mediastinal emphysema, hemorrhage, aspiration, and perforation of the posterior wall of the trachea or esophagus.[225]

CRICOTHYROTOMY

Cricothyrotomy is an invasive technique that provides access to the airway in situations when either noninvasive maneuvers have failed or when it is clinically indicated as a primary plan to secure the airway.[226] Cricothyrotomy is included in the ASA "Difficult Airway Algorithm" as an emergent invasive technique after other rescue maneuvers have failed or are not feasible. Cricothyrotomy equipment should be included in all emergency airway storage units and readily available. Cricothyrotomy is not considered a permanent airway, and, after placement, plans should be made for either the removal of the cricothyrotomy catheter or conversion to a formal tracheostomy.[226]

In children younger than 6 years of age (also see Chapter 93), the cricoid cartilage is the narrowest portion of the airway and the isthmus of the thyroid gland typically reaches the level of the CTM; therefore cricothyrotomy is contraindicated. Needle cricothyrotomy with TTJV is indicated in this pediatric population. Other contraindications to cricothyrotomy include laryngeal fractures, laryngeal neoplasm, subglottic stenosis, coagulopathy, and distorted or unidentifiable neck anatomy.

The two most common techniques for performing a cricothyrotomy are the percutaneous dilational cricothyrotomy and the surgical cricothyrotomy. For the anesthesiologist, the percutaneous technique is usually preferred because the technique is less complicated compared with a surgical cricothyrotomy, and because of the familiarity of using the Seldinger technique for other procedures (e.g., central venous catheterization). Because of the location of the cricothyroid artery and the proximity of the CTM to the vocal folds, puncture or incision of the CTM should be made in the lower third of the membrane and directed posteriorly (Figure 55-30).[226]

A number of commercially available cricothyrotomy kits use the percutaneous dilational technique. The basis for this procedure is the insertion of an airway catheter over a dilator that has been inserted over a guidewire. The patient's neck is extended, and the cricothyroid groove is identified. If landmarks are difficult to identify, then ultrasound guidance may be used. A 1- to 1.5-cm vertical incision is made through the skin overlying the CTM. An 18-gauge needle-catheter attached to a fluid-filled syringe is passed through the incision at a 45-degree angle in the caudal direction with continuous aspiration. Aspiration of free air confirms passage through the CTM. The catheter is advanced over the needle into the trachea. The needle is removed, and the catheter is left in place. The guidewire is inserted caudally to a depth of approximately 2 to 3 cm. The catheter is removed, and the curved dilator with the airway cannula is threaded over the guidewire. The dilator and cannula unit is advanced through the CTM while maintaining control of the guidewire. The dilator and guidewire are removed together while the cannula remains in place. The cuff is inflated, and ventilation is attempted. Proper placement is confirmed by capnography, and the airway cannula is secured in place.[226]

Surgical cricothyrotomy is performed using the technique outlined in Box 55-4. A No. 20 scalpel is preferred because its width is sufficient for inserting a narrow tube without the need for extending the incision, and its length is such that damage to the posterior wall of the trachea is unlikely. This technique is the most rapid and should be used when equipment for the less invasive techniques is unavailable and speed is particularly important.[10]

Complications include hemorrhage, injury to the posterior tracheal wall or esophagus, vocal cord injury, laceration of the thyroid gland, and improper insertion of the cannula. Placement of the airway cannula in the subcutaneous tissue can result in subcutaneous or mediastinal emphysema. Late complications from cricothyrotomy include swallowing dysfunction, infection, voice changes, and tracheal stenosis. Tracheal stenosis has an incidence of approximately 2% to 8% in adults and is more likely if preexisting trauma or infection is present.

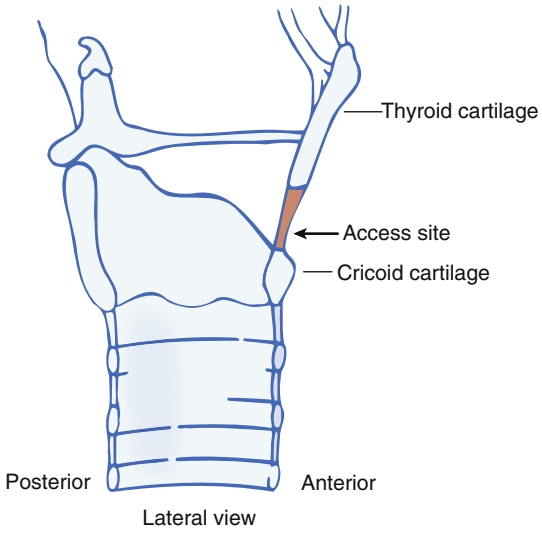

Figure 55-30. Midsagittal anatomy of the larynx and trachea. The access point for percutaneous cricothyrotomy is in the lower third of the cricothyroid membrane. *(Courtesy of Cook Critical Care; Bloomington, IN.)*

BOX 55-4 *Surgical Cricothyrotomy*

EQUIPMENT

- No. 20 scalpel
- Cuffed tracheostomy tube or endotracheal tube (ETT) with a 6- or 7-mm internal diameter

TECHNIQUE

- Step 1: Extend the head and neck, and identify and immobilize the cricothyroid membrane. (Make an initial vertical incision if identification is not possible.)
- Step 2: Make a horizontal stab incision through the skin and cricothyroid membrane. Leave the blade in place until the tracheal hook is in position (step 3).
- Step 3: Apply caudal and outward traction on the cricoid cartilage with the tracheal hook; remove the scalpel.
- Step 4: Insert the tube, and inflate the cuff.
- Step 5: Ventilate with a low-pressure source.
- Step 6: Confirm pulmonary ventilation.

BOX 55-5 ***Complications Associated With Extubation***

- Laryngospasm and bronchospasm
- Upper airway obstruction
- Hypoventilation
- Hemodynamic changes (hypertension, tachycardia)
- Coughing and straining, leading to surgical wound dehiscence
- Laryngeal or airway edema
- Negative-pressure pulmonary edema
- Paradoxical vocal cord motion
- Arytenoid dislocation
- Aspiration

EXTUBATION OF THE TRACHEA

A critical component of airway management is the process of extubation. Although considerable emphasis is placed on the problems that can arise during induction and intubation, the risk for complications can potentially be more frequent during extubation of the trachea.[227] Analysis of the ASA Closed Claims database has shown that although the number of claims for death and brain damage during intubation have decreased since the adoption of the ASA *Practice Guidelines for Management of the Difficult Airway*, the number of claims arising from injury at extubation and during recovery have not decreased.[1] In response to these trends and in the absence of any well-established strategies for the management of tracheal extubation, the Difficult Airway Society (DAS) established a set of guidelines in 2012 to "discuss the problems arising during extubation and recovery" and to "promote a strategic, stepwise approach to extubation."[228]

A number of complications can arise during extubation (Box 55-5); although some of these complications are minor with no long-term sequelae, others can lead to a failed extubation. Failed extubation can result from the failure of oxygenation, failure of ventilation, inadequate clearance of pulmonary secretions, or loss of airway patency.[229] If an airway is not quickly reestablished, then serious complications, including death, may result. As such, the anesthesia practitioner needs to stratify the extubation risk preemptively and establish an extubation plan before attempting extubation. Per the DAS guidelines, risk stratification can be accomplished by considering the following: (1) whether the airway was normal and uncomplicated at induction; (2) whether the airway has become difficult to manage as a result of surgical changes, trauma, or nonsurgical factors; and (3) whether the patient has general risk factors for an unsuccessful extubation.[228]

GENERAL CONSIDERATIONS FOR EXTUBATION OF THE TRACHEA

For both routine and difficult extubation scenarios, an extubation plan must be preemptively formulated, including a plan for reintubation that can be implemented should the patient be unable to maintain an adequate airway after extubation.[4] The decision of whether to extubate the trachea when the patient is fully awake versus a *deep* extubation before the return of consciousness should be made based on the risks and benefits of each technique. The awake patient can more easily maintain a patent airway, attributable to the recovery of awake pharyngeal muscle tone and airway reflexes. Deep extubation avoids coughing and adverse hemodynamic effects but risks upper airway obstruction and hypoventilation. An alternative extubation technique, known as the Bailey maneuver, involves exchanging an ETT for an SGA while the patient is under deep anesthesia.[230] Extubation during a light plane of anesthesia (stage II) can increase the risk for laryngospasm and other airway complications and should be avoided.

General preparations for extubation should include ensuring adequate reversal or recovery from neuromuscular blockade, hemodynamic stability, normothermia, and adequate analgesia. Patients should be preoxygenated with a 100% fraction of inspired oxygen concentration (Fio_2), and alveolar recruitment maneuvers should be considered if appropriate. Suctioning of the pharynx (and the trachea, if indicated), the removal of throat packs, and the placement of a bite block should be performed while the patient is under deep anesthesia.[10] Bite blocks are essential for an awake intubation to prevent biting of the tube during emergence, which can result in airway obstruction and the development of negative-pressure pulmonary edema. Oropharyngeal airways are not recommended for use as a bite block because they can result in dental damage; rather, taped, rolled gauze securely inserted between the molars should be used.[231]

Gastric insufflation with air can increase the risk of pulmonary aspiration after extubation and can impede ventilation. Patients in whom mask ventilation with high pressures is necessary should have an orogastric tube placed and suctioned before extubation.

The sniffing position is the standard position for extubation; its major advantage is that the patient is optimally positioned for airway management, if necessary. Patients who are morbidly obese and other patients at risk for hypoventilation and airway obstruction can benefit from extubation in the head-up position. The lateral decubitus position may be the preferred option when the risk for pulmonary aspiration is high.[10]

Application of positive pressure immediately before cuff deflation may help expel secretions that have collected above the ETT cuff. Inspection of the pilot balloon to ensure complete cuff deflation before extubation is essential; extubation with an inflated cuff can cause vocal cord injury or arytenoid dislocation.

EXTUBATION OF THE DIFFICULT AIRWAY

Many surgical and anesthetic factors can increase extubation risk; a summary of the most pertinent factors is listed in Box 55-6. Although several techniques can be used to manage extubation of the difficult airway, including the Bailey maneuver and remifentanil infusion,[228] the use of an airway exchange catheter (AEC) is most common and recommended by the ASA's Task Force on Management of the Difficult Airway. This hollow reintubation guide is passed through the ETT before extubation and kept in situ until the possible need for reintubation has passed. AECs have the additional capability of maintaining

BOX 55-6 ***Factors Associated With Increased Extubation Risk***

Airway Risk Factors

- Known difficult airway
- Airway deterioration (bleeding, edema, trauma)
- Restricted airway access
- Obesity and obstructive sleep apnea
- Aspiration risk

General Risk Factors

- Cardiovascular disease
- Respiratory disease
- Neuromuscular disease
- Metabolic derangements
- Special surgical requirements

Modified from Popat M, Mitchell V, Dravid R, et al: Difficult Airway Society Guidelines for the management of tracheal extubation, Anaesthesia *67:318-340, 2012.*

oxygenation or monitoring respiration by connection to a capnograph. Smaller AECs (11 Fr) are generally well-tolerated by awake patients, who can breathe, talk, and cough around them. They should be secured with tape in place to prevent accidental dislodgement and labeled to distinguish them from traditional feeding tubes, which can have a similar appearance. Reintubation over an AEC, if necessary, can be facilitated by gentle DL to retract the tongue and oropharyngeal soft tissue.

SUMMARY

Airway management is at the core of safe anesthetic practice. The anesthesia practitioner must have a fundamental knowledge of airway anatomy, physiology, and pharmacology, and well-developed skills in the use of a wide variety of airway devices. Although most airways are straightforward, management of the difficult airway remains one of the most relevant and challenging tasks for anesthesia care providers. Prediction and anticipation of the difficult airway and the formulation of an airway management plan are essential. Many airway problems can be solved with relatively simple devices and techniques; however, experience and good clinical judgment are necessary for their successful application. Newer airway devices with the potential to improve patient outcomes are continually being developed. Anesthesia providers must concurrently develop their skills and learn new techniques to be prepared when difficulty presents itself. Competency-based training with routine assessment of clinical ability with airway techniques is likely in the future for all practitioners involved in airway management. Expertise comes from dedicated practice and a commitment from the practitioner for career-long learning.

Chapter 56

Spinal, Epidural, and Caudal Anesthesia

RICHARD BRULL • ALAN J.R. MACFARLANE • VINCENT W.S. CHAN

Acknowledgment: The editors and publisher would like to thank Dr. David L. Brown for contributing a chapter on this topic to the prior edition of this work. It has served as the foundation for the current chapter.

Key Points

- The distal termination of the spinal cord varies from L3 in infants to the lower border of L1 in adults.
- The speed of neural blockade depends on the size, surface area, and degree of myelination of the nerve fibers exposed to the local anesthetic.
- Blockade of the peripheral (T1-L2) and cardiac (T1-T4) sympathetic fibers is responsible for the decrease in arterial blood pressure (cardiac output and systemic vascular resistance) associated with neuraxial techniques.
- Cerebrospinal fluid volume and local anesthetic baricity are the most important determinants for the spread (i.e., block height) of spinal anesthesia.
- The use of smaller-gauge spinal needles decreases the incidence of post–dural puncture headache.
- Serious neurologic complications associated with neuraxial blockade are rare.
- The use of low-molecular-weight heparin and potent platelet inhibitors increases the risk of epidural hematoma from neuraxial blockade.
- Epidural blood patches are greater than 90% effective in relieving post–dural puncture headache.
- Local anesthetic systemic toxicity results from unintentional administration of the drug into an epidural vein.
- Use of neuraxial blockade can reduce perioperative morbidity and mortality.

PRINCIPLES

Spinal, epidural, and caudal neuraxial blocks result in one or a combination of sympathetic blockade, sensory blockade, or motor blockade depending on the dose, concentration, or volume of local anesthetic administered. Despite these similarities, there are significant technical, physiologic, and pharmacologic differences. Spinal anesthesia requires a small mass (i.e., volume) of drug that is almost devoid of systemic pharmacologic effects to produce rapid (<5 minutes), profound, reproducible sensory analgesia. In contrast, epidural and caudal anesthesia progress more slowly (>20 minutes) after a large mass of local anesthetic that produces pharmacologically active systemic blood levels, which may be associated with side effects and complications unknown to spinal anesthesia. The introduction of combined spinal and epidural techniques blurs some of these differences, but also adds flexibility to clinical care.

PRACTICE

Neuraxial blockade has a wide range of clinical applications for surgery, obstetrics, acute postoperative pain management, and chronic pain relief. Single-injection spinal or epidural anesthesia with local anesthetic is most commonly used for surgery to the lower abdomen, pelvic organs (e.g., prostate), and lower limbs, and for cesarean deliveries. Continuous catheter-based epidural infusions of dilute local anesthetics and opioids are used for obstetric labor analgesia and postoperative pain relief after major surgery (e.g., thoracic, abdominal, lower limb) to provide analgesia for days. Evidence demonstrating that epidural analgesia can reduce cardiovascular and pulmonary morbidity and mortality in high-risk patients undergoing major thoracic and abdominal surgery served to propel the practice of epidural analgesia at the beginning of the millennium.[1] More recently, however, the goals of epidural analgesia have shifted from reduction of morbidity and mortality in high-risk patients to facilitation of fast-track

recovery in otherwise healthy patients undergoing various types of elective inpatient surgical procedures. Caudal blocks are mostly performed for surgical anesthesia and analgesia in children, and for therapeutic analgesia in adults with chronic pain. Indwelling spinal catheters can be applied long term (from months to years) for the treatment of chronic malignant and nonmalignant pain.

HISTORICAL PERSPECTIVES

The first case of spinal anesthesia in humans was performed by August Bier in 1898 using the local anesthetic cocaine.[2] Subsequently, spinal anesthesia was successfully performed using procaine by Braun in 1905, tetracaine by Sise in 1935, lidocaine by Gordh in 1949, chloroprocaine by Foldes and McNall in 1952, mepivacaine by Dhunér and Sternberg in 1961, and bupivacaine by Emblem in 1966. Spinal anesthesia using ropivacaine and levobupivacaine was introduced in the 1980s. The year 1901 marked the first reported use of intrathecal morphine described by Racoviceanu-Pitesti, as well as the first description of caudal anesthesia reported by Cathleen. Lumbar epidural anesthesia in humans was first described by Pagés in 1921, the loss-of-resistance technique by Dogliotti in the 1930s, continuous caudal for obstetrics by Hingson in 1941, and lumbar epidural catheterization for surgery by Curbelo in 1947.[3] The use of epidural morphine analgesia was first reported by Behar in 1979.

Despite the extensive experience using neuraxial techniques throughout the past century, several events caused major setbacks along the way, including the Woolley and Roe case detailing paraplegia after spinal anesthesia in 1954,[4] the reports of persistent neurologic deficits and adhesive arachnoiditis with spinal chloroprocaine in the early 1980s, and cauda equina syndrome with continuous spinal lidocaine anesthesia in the early 1990s.[5] More recently, the potential for catastrophic epidural hematoma with newer potent anticoagulants (e.g., low-molecular-weight heparin [LMWH]) and antiplatelet agents (e.g., clopidogrel) has caused concern.[6]

ANATOMY

The spinal cord is continuous with the brainstem proximally and terminates distally in the conus medullaris as the filum terminale (fibrous extension) and the cauda equina (neural extension). This distal termination varies from L3 in infants to the lower border of L1 in adults because of differential growth rates between the bony vertebral canal and the central nervous system.

Surrounding the spinal cord in the bony vertebral column are three membranes (from innermost to outermost): the pia mater, the arachnoid mater, and the dura mater (Fig. 56-1). The cerebrospinal fluid (CSF) resides in the space between the pia mater and the arachnoid mater, termed the *subarachnoid* (or *intrathecal*) *space*. The pia mater is a highly vascular membrane that closely invests the spinal cord and brain. Approximately 500 mL of CSF is formed daily by the choroid plexuses of the cerebral ventricles, with 30 to 80 mL occupying the subarachnoid

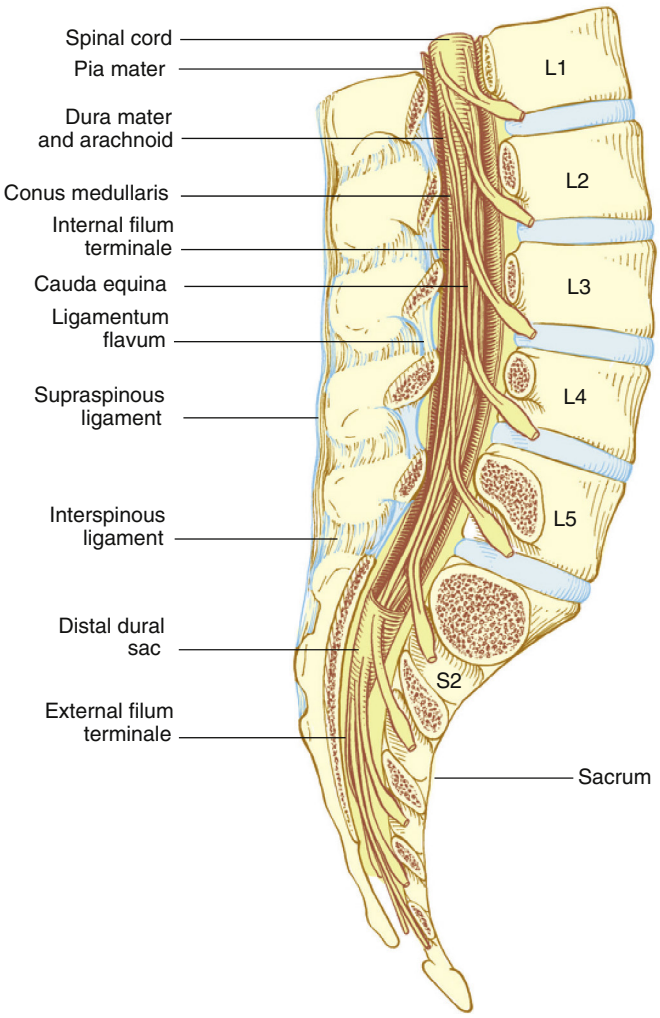

Figure 56-1. Spinal cord anatomy. Notice the termination of the spinal cord (i.e., conus medullaris) at L1-L2 and termination of the dural sac at S2.

space from T11-T12 downward. The arachnoid mater is a delicate, nonvascular membrane that functions as the principal barrier to drugs crossing into (and out of) the CSF and is estimated to account for 90% of the resistance to drug migration.[7] As Liu and McDonald[8] and Bernards[9] emphasize, the functional proof of the arachnoid's role as the primary barrier to flow is the observation that spinal CSF resides in the subarachnoid, and not the subdural, space. The outermost layer is the dura.

Surrounding the dura mater is the epidural space, which extends from the foramen magnum to the sacral hiatus and surrounds the dura mater anteriorly, laterally, and posteriorly. The epidural space is bound anteriorly by the posterior longitudinal ligaments, laterally by the pedicles and intervertebral foramina, and posteriorly by the ligamentum flavum. Contents of the epidural space include the nerve roots and fat, areolar tissue, lymphatics, and blood vessels including the well-organized Batson venous plexus.

Posterior to the epidural space is the ligamentum flavum (the so-called yellow ligament), which also extends from the foramen magnum to the sacral hiatus. Although classically portrayed as a single ligament, it is actually

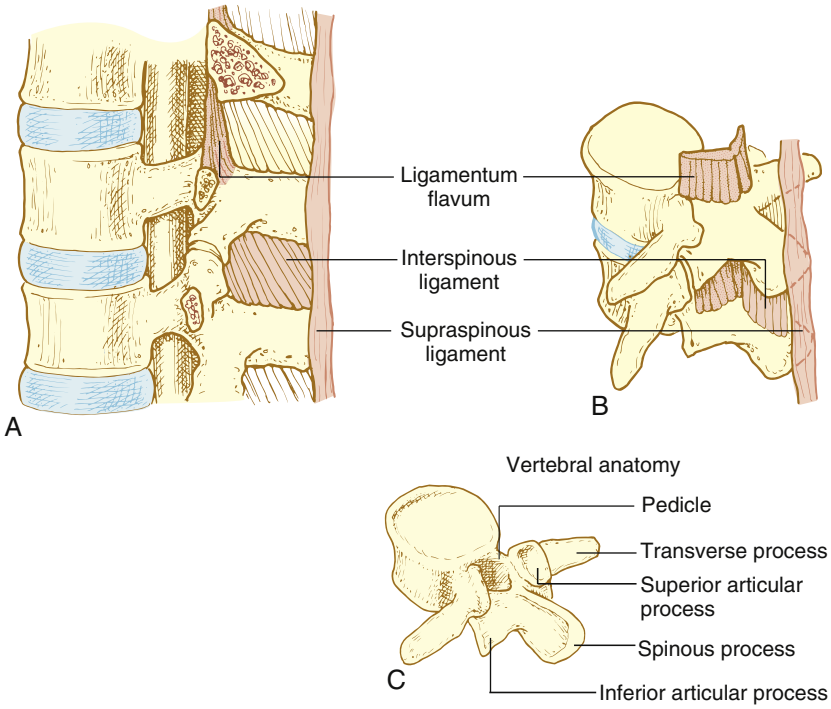

Figure 56-2. Vertebral anatomy. **A,** Sagittal view. **B,** Oblique view of the lumbar vertebrae showing the ligamentum flavum thickening in the caudad extent of the intervertebral space and in the midline. **C,** Oblique view of a single lumbar vertebra.

comprised of two ligamenta flava—the right and the left—which join in the middle and form an acute angle with a ventral opening (Fig. 56-2).[10,11] The ligamentum flavum is not uniform from skull to sacrum, nor even within an intervertebral space. Ligament thickness, distance to the dura, and skin-to-dura distance vary with the area of the vertebral canal. The vertebral canal is triangular and largest in area at the lumbar levels, and it is circular and smallest in area at the thoracic levels. The two ligamenta flava are variably joined (fused) in the midline, and this fusion or lack of fusion of the ligamenta flava even occurs at different vertebral levels in individual patients.[10] Immediately posterior to the ligamentum flavum are the lamina and spinous processes of vertebral bodies or the interspinous ligaments. Extending from the external occipital protuberance to the coccyx posterior to these structures is the supraspinous ligament, which joins the vertebral spines (see Fig. 56-2).

There are 12 thoracic vertebrae, 5 lumbar vertebrae, and a sacrum. The vertebral arch, spinous process, pedicles, and laminae form the posterior elements of the vertebra, and the vertebral body forms the anterior element. The vertebrae are joined together anteriorly by the fibrocartilaginous joints with the central disks containing the nucleus pulposus, and posteriorly by the zygapophyseal (facet) joints. The thoracic spinous process is angulated steeply caudad as opposed to the almost horizontal angulation of the lumbar spinous process. This is a clinically important distinction for needle insertion and advancement in the thoracic versus lumbar levels.

The sacral canal contains the terminal portion of the dural sac, which typically ends at S2. Variation is found in this feature as well, with the termination of the dural sac being lower in children. In addition to the dural sac, the sacral canal contains a venous plexus, which is part of the valveless internal vertebral venous plexus. The volume of the caudal canal in adults, excluding the foramina and dural sac, is about 10 to 27 mL. Perhaps this wide variability in volume accounts for some of the variation in block height with caudal anesthesia (Fig. 56-3).[12]

BLOOD SUPPLY

Blood is supplied to the spinal cord from one anterior spinal artery (originating from the vertebral artery), two posterior spinal arteries (originating from the inferior cerebellar artery), and the segmental spinal arteries (originating from the intercostal and lumbar arteries).[13] The spinal arteries enter the spinal canal at each intervertebral foramen and give off branches to both the nerve roots and the medullary branches to the spinal cord; one of the major branches is the artery of Adamkiewicz, variably entering between T7 and L4 on the left, which supplies the lower thoracic and upper lumbar regions. The anterior two thirds of the spinal cord is supplied by the anterior arterial branches and the posterior one third by the posterior branches. The anterior and deep portion of the cord (gray matter) is most prone to ischemia (leading to anterior horn motor neuron injury, or anterior spinal syndrome) because there are fewer anterior medullary feeder vessels than posterior feeder vessels. Likewise, the midthoracic part of the spinal cord (from T3 to T9) is most at risk where segmental medullary feeder vessels are rare. Venous drainage of the spinal cord follows a similar distribution as the spinal arteries. There are three longitudinal anterior spinal veins and three posterior spinal veins that communicate with the segmental anterior and posterior radicular veins before draining into the internal vertebral venous plexus in the medial and lateral components of the epidural space. There are no veins in the posterior epidural space except those caudal to the L5-S1 disk.

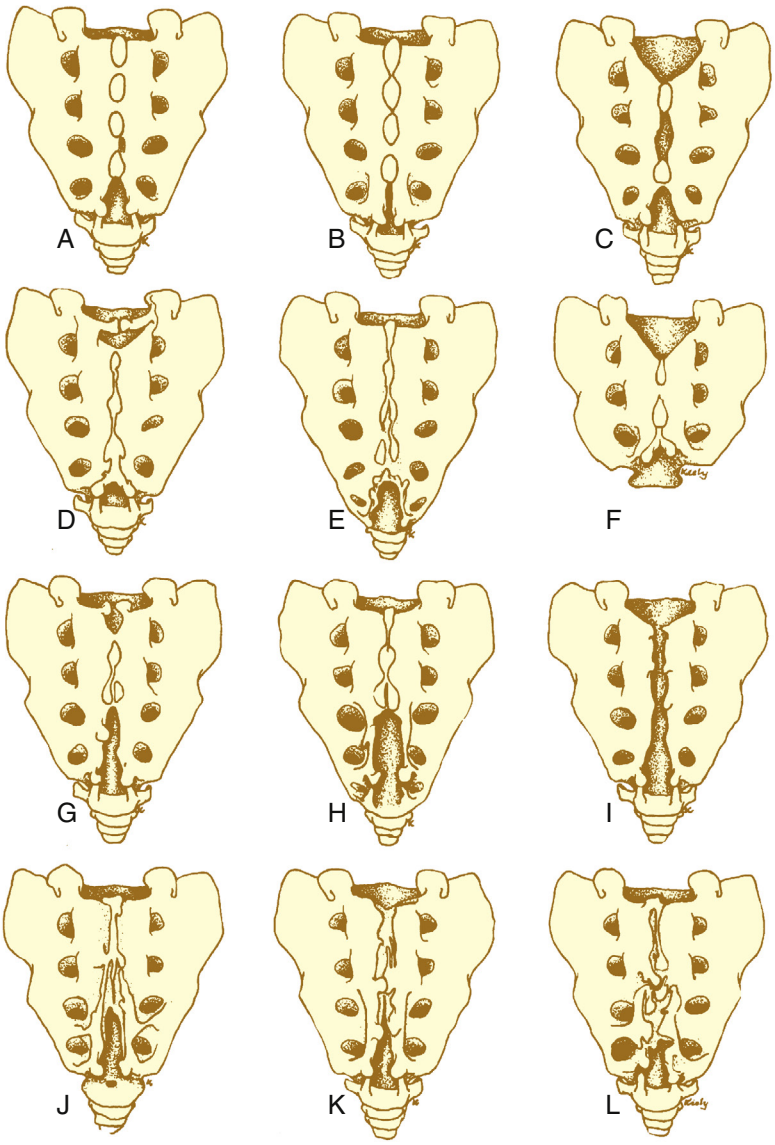

Figure 56-3. Anatomic variants of the sacrum and sacral hiatus. **A,** Normal. **B,** Longitudinal slitlike hiatus. **C,** Second midline hiatus. **D,** Transverse hiatus. **E,** Large hiatus with absent cornua. **F,** Transverse hiatus with absent coccyx, two prominent cornua, and two proximal "decoy hiatuses lateral to the cornua." **G-I,** Large midline defects contiguous with the sacral hiatus. **J-L,** Enlarged longitudinal hiatuses, each with an overlying decoy hiatus. *(From Willis RJ: Caudal epidural block. In Cousins MN, Bridenbaugh PO, editors:* Neural blockade in clinical anesthesia and management of pain*, ed 2, Philadelphia, 1988, JB Lippincott, p 365.)*

ANATOMIC VARIATIONS

NERVE ROOTS

The spinal nerve roots are not uniform in size and structure. Specifically, Hogan and Toth[14,15] have shown that there is considerable interindividual variability in nerve root size. These differences may help to explain the interpatient differences in neuraxial block quality when equivalent techniques are used on seemingly similar patients. Another anatomic relationship may affect neuraxial blocks; although generally larger than the ventral (motor) roots, the dorsal (sensory) roots are often blocked more easily. This apparent paradox is explained by organization of the dorsal roots into component bundles, which creates a much larger surface area on which the local anesthetics act, possibly explaining why larger sensory nerves are blocked more easily than smaller motor nerves.[8]

CEREBROSPINAL FLUID

Lumbosacral CSF has a constant pressure of approximately 15 cm H_2O, but its volume varies by patient, in part because of differences in body habitus and weight.[16] It is estimated that CSF volume accounts for 80% of the variability in peak block height and regression of sensory and motor blockade. Nevertheless, except for body weight (less CSF in subjects with high body mass index [BMI]), the volume of CSF does not correlate with other anthropomorphic measurements available clinically.[17] (see Factors Affecting Block Height, later in the chapter)

EPIDURAL SPACE

Hogan's[10] study of frozen cryomicrotome cadaver sections suggests that the epidural space is more segmented and less uniform than previously believed from indirect anatomic analysis. Another study by Hogan[18] has also

shown in cadavers that the spread of solution after epidural injection into the tissues of the epidural space is nonuniform, and he postulated that this accounts for the clinical unpredictability of epidural drug spread. This lack of uniformity also extends to age-related differences. There is evidence that adipose tissue in the epidural space diminishes with age,[19] and this decrease in epidural space adipose tissue may dominate the age-related changes in epidural dose requirements (see Chapter 80).

MECHANISM OF ACTION

Local anesthetic binding to nerve tissue disrupts nerve transmission, resulting in neural blockade. For spinal and epidural anesthesia, the target binding sites are located within the spinal cord (superficial and deep portions) and on the spinal nerve roots in the subarachnoid and epidural spaces. The spinal nerve roots and dorsal root ganglia are considered the most important sites of action. Nerves in the subarachnoid space are highly accessible and easily anesthetized, even with a small dose of local anesthetic, compared with the extradural nerves, which are often ensheathed by dura mater (the "dural sleeve"). The speed of neural blockade depends on the size, surface area, and degree of myelination of the nerve fibers exposed to the local anesthetic. Anatomic studies show that the S1 and L5 posterior roots are the largest and thus most resistant to blockade during epidural anesthesia.[15] Smaller nerves are more sensitive to the effects of local anesthetics because of their relatively high membrane surface area to axon unit volume ratio. For example, the small preganglionic sympathetic fibers (B fibers, 1 to 3 μm, minimally myelinated) are most sensitive to local anesthetic blockade. Among the sensory nerves, the C fibers (0.3 to 1 μm, unmyelinated), which conduct cold temperature sensation, are blocked more readily or earlier than the A-delta fibers (1 to 4 μm, myelinated), which conduct pinprick sensation. The A-beta fibers (5 to 12 μm, myelinated), which conduct touch sensation, are the last to be affected among the sensory fibers. The larger A-alpha motor fibers (12 to 20 μm, myelinated) are more resistant than any of the sensory fibers. Regression of blockade ("recovery") follows in the reverse order: motor function followed first by touch, then pinprick, and finally cold sensation.[20] Another manifestation of relative sensitivity or susceptibility to the effects of local anesthetics is the observed differences in the peak block height (highest or most cephalad level of anesthesia) according to each sensory modality, which is termed *differential sensory block*. For example, the level of anesthesia to cold sensation (also an approximate level of sympathetic blockade) is most cephalad and is on average one to two spinal segments higher than the level of pinprick anesthesia, which in turn is one to two segments higher than the level of touch anesthesia.[21]

DRUG UPTAKE

When local anesthetic is injected directly into the subarachnoid space during spinal anesthesia, it diffuses through the pia mater and penetrates through the spaces of Virchow-Robin (extensions of the subarachnoid space accompanying the blood vessels that invaginate the spinal cord from the pia mater) to reach the deeper dorsal root ganglia.[22] Furthermore, a portion of the subarachnoid drug diffuses outward through the arachnoid and dura mater to enter the epidural space,[23] whereas some is taken up by the blood vessels of the pia and dura maters.[24]

Drug penetration and uptake is directly proportionate to the drug mass, CSF drug concentration, contact surface area, lipid content (high in spinal cord and myelinated nerves), and local tissue vascular supply, but is inversely related to nerve root size. The concentration of local anesthetic in the CSF is highest at the site of subarachnoid injection in the case of spinal anesthesia (generally L2-L4 levels).

For epidural anesthesia, drug uptake is more complex. Some of the injected local anesthetic will move from the epidural space through the meninges into the CSF to exert its neural blocking effect, whereas some will be lost through vascular absorption into the capillary vessels and into the systemic circulation and uptake into epidural fat. The bioavailability of local anesthetics found in the CSF after epidural administration is low (<20%).

DRUG DISTRIBUTION

Diffusion is the primary mechanism of local anesthetic distribution in the CSF from areas of high concentration (i.e., at the site of injection) toward other segments of the spinal cord with low drug concentration.[25] Rostral spread after the administration of a small local anesthetic dose, often evident within 10 to 20 minutes, is related to the CSF circulation time. Longitudinal oscillations generated by the pulsations of the arteries in the skull are believed to be responsible for CSF bulk flow. This likely facilitates the cephalad distribution of local anesthetic from the lumbar subarachnoid space to the basal cisterns within 1 hour of injection.

Drug distribution in the epidural space is more complex, with possible contributions from one, some, or all of the following mechanisms: (1) crossing the dura mater into the subarachnoid space, (2) rostral and caudal (longitudinal) spread within the epidural space, (3) circumferential spread within the epidural space, (4) exit of the epidural space through the intervertebral foramina, (5) binding to epidural fat, and (6) vascular absorption into the epidural vessels. Longitudinal spread of local anesthetic by bulk flow within the epidural space may occur after the administration of a larger dose (i.e., volume). Factors that may enhance the distribution of local anesthetic within the epidural space are small caliber (greater spread in the thoracic space), increased epidural space compliance, decreased epidural fat content, decreased local anesthetic leakage through the intervertebral foramina (e.g., elderly and spinal stenosis), and increased epidural pressure (e.g., pregnancy).[26] Drug is also preferentially distributed from areas of high to low concentration. Finally, the direction of drug spread varies with the vertebral level—that is, epidural spread is mostly cephalad in the lumbar region, caudad after a high thoracic injection, and mostly cephalad spread after a low thoracic injection.[26]

DRUG ELIMINATION

Regression of neural blockade results from a decline in the CSF drug concentration, which in turn is caused by nonneural tissue uptake and, most importantly, vascular absorption. Time for block regression is also inversely correlated with CSF volume.[27] Drug is absorbed by the vessels in the pia mater or the epidural vessels through back diffusion before entering the systemic circulation. No drug metabolism takes place in the CSF. The rate of elimination is also dependent on the distribution of local anesthetic; greater spread will expose the drug to a larger area for vascular absorption and thus a shorter duration of action. Lipid-soluble local anesthetics (e.g., bupivacaine) bind to epidural fat to form a depot that can slow vascular absorption.

PHYSIOLOGIC EFFECTS

Safe conduct of spinal, epidural, and caudal anesthesia requires an appreciation of their physiologic effects. Neuraxial anesthesia evokes blockade of the sympathetic and somatic (sensory and motor) nervous systems, along with compensatory reflexes and unopposed parasympathetic activity.[28] The physiologic effects of epidural anesthesia are similar to those of spinal anesthesia, with the exception that local anesthetic blood levels reach concentrations sufficient enough to produce systemic effects on their own.

CARDIOVASCULAR

The effects of neuraxial blocks on blood pressure are similar in some ways to the combined use of intravenous α_1- and β-adrenergic blockers on cardiac output: decreased stroke volume and heart rate (see Chapter 20) caused by blockade of the peripheral (T1-L2) and cardiac (T1-T4) sympathetic fibers as well as adrenal medullary secretion. The decrease in arterial blood pressure is believed to be more gradual and of less magnitude with epidural than with spinal anesthesia of comparable levels. However, when tetracaine (10 mg) spinal anesthesia was compared with lidocaine (20 to 25 mL of a 1.5% solution) epidural anesthesia, there was a larger decrease in arterial blood pressure (approximately 10%) with the epidural technique than with the spinal anesthetic.[29] Of prime importance, the extent to which arterial blood pressure decreases with either technique depends on multiple factors, including patient age and intravascular volume status.

Stroke Volume

Sympathectomy usually decreases stroke volume. Venous and arterial vasodilation reduces preload (venous return) and afterload (systemic vascular resistance), respectively. Because of the large amount of blood that resides in the venous system (approximately 75% of the total blood volume), the venodilation effect predominates, owing to the limited amount of smooth muscle in venules; in contrast, the vascular smooth muscle on the arterial side of the circulation retains a considerable degree of autonomous tone. Cardiac output is thought to be either maintained or slightly decreased during the onset of spinal anesthesia. Yet a biphasic response, characterized by an early transient increase followed by an eventual decrease in cardiac output,[30] has been observed. This initial increase is caused by a greater magnitude of decline in the systemic vascular resistance than by venous return, especially in elderly patients with preexisting hypertension and high baseline systemic vascular resistance (also see Chapter 80).

The vasodilatory changes after neuraxial blockade that can affect cardiac output depend on each patient's baseline sympathetic tone (i.e., higher sympathetic tone in the elderly equates to a greater hemodynamic change) and the extent of the sympathectomy (i.e., the height of the block). The extent of the sympathectomy is typically described as extending for two to six dermatomes above the sensory block level with spinal anesthesia and at the same level with epidural anesthesia.[31] If normal cardiac output is maintained, systemic vascular resistance should decrease only 15% to 18% after neuraxial blockade in healthy normovolemic patients, even with nearly total sympathectomy. In elderly patients with cardiac disease, systemic vascular resistance may decrease almost 25% after spinal anesthesia, whereas cardiac output decreases only 10%.[32] Determination of baseline autonomic nervous system activity (e.g., blood pressure variability signaled by low-frequency band power and near-infrared spectroscopy reduction) has been found to predict the risk of hypotension in the elderly.[30]

Heart Rate

Heart rate may decrease during a high neuraxial block as a result of blockade of the cardioaccelerator fibers arising from T1-T4.

Heart rate may also decrease in the presence of extensive peripheral sympathectomy (T5-L2), with venous pooling in the lower extremity and the abdominal and pelvic viscera. Although hypotension will trigger a compensatory baroreceptor sympathetic response (vasoconstriction and increased heart rate) above the level of blockade, the reduction in venous return and right atrial filling causes a decrease in signal output from intrinsic chronotropic stretch receptors located in the right atrium and great veins,[31] leading to a marked increase in parasympathetic activity (vagal tone). The two opposing responses are usually in check with a minimal change in heart rate (or a slight reduction). However, when neuraxial anesthesia is extended to the T1 level, blockade of the cardioaccelerator fibers in addition to a marked reduction in venous return may result in severe bradycardia and even asystole because of unopposed parasympathetic activity. However rare, the likelihood of cardiac arrest appears to be more likely in young, healthy, and conscious patients.[33] The Bezold-Jarisch reflex may be a possible cause of profound bradycardia and circulatory collapse after spinal anesthesia, especially in the presence of hypovolemia, when a small end-systolic left ventricular volume may trigger a mechanoreceptor-mediated bradycardia.[34]

Coronary Blood Flow

When coronary artery blood flow and myocardial metabolism were determined in humans during spinal anesthesia

to T4 in hypertensive and normotensive patients, decreases in coronary blood flow (153 to 74 mL/100 g per minute) paralleled the decrease in mean arterial blood pressure (119 to 62 mm Hg), and the percent extraction of myocardial oxygen was unchanged (75% to 72%). Extraction of oxygen was unchanged because myocardial work, as expressed by myocardial use of oxygen, paralleled the decrease in mean arterial blood pressure and coronary blood flow (16 to 7.5 mL/100 g per minute).[35] A high thoracic block in patients with ischemic heart disease can be beneficial, with improvement in global and regional myocardial function and reversal of ischemic changes likely a result of reduced myocardial oxygen demand and left ventricular afterload.[36] Both infarction size and ischemia-induced arrhythmias improved in coronary occlusion experiments in animals, with no apparent vasodilatory effect on the coronary vessels.[37] These data support the observations by Stanley and co-workers[38] but still do not provide a patient-by-patient indication of the organ most at risk for flow-related ischemia.

Treatment

The clinical question of what level of decrease in arterial blood pressure after a neuraxial block is acceptable without a significant decrease in organ perfusion (e.g., brain, liver, gut) remains to be answered, although some human and animal data are available (see respective sections). Once arterial blood pressure decreases to a level at which treatment is believed to be necessary, ephedrine, a mixed adrenergic agonist, provides more appropriate therapy for the noncardiac circulatory sequelae of neuraxial block than does a pure α-adrenergic agonist (see Chapters 16 and 20), unless the patient has a specific and defined arterial blood pressure requirement.[39] That the decrease in arterial blood pressure after neuraxial block can be minimized by the administration of crystalloids intravenously is probably not a valid concept. Specifically, 250- to 2000-mL preblock hydration regimens may temporarily increase preload and cardiac output but do not consistently increase arterial blood pressure or prevent hypotension.[8] Useful techniques to prevent hypotension include the repeated low-dose local anesthetic boluses through a continuous spinal catheter,[40] small-dose unilateral spinal anesthesia, and selective small-dose spinal anesthesia.

CENTRAL NERVOUS SYSTEM

Spinal anesthesia–induced hypotension may decrease regional cerebral blood flow (CBF) in elderly patients and those with preexisting hypertension. In a study of elderly patients who had hypotension during bupivacaine spinal anesthesia, Minville and colleagues demonstrated a significant but transient decrease of middle cerebral artery blood flow velocity and an increase in cerebral vascular resistance, both of which suggest a decrease in cerebral perfusion.[41] There was no change in cognitive function after surgery in any of these patients. Both CBF and velocity decline as a result of changes in the cerebral vasculature, especially in the elderly. Whether cerebral autoregulation is impaired in the elderly is still debatable (see Chapter 80).

Kety and colleagues[42] demonstrated that producing spinal anesthesia to the midthoracic levels with procaine, even in patients with essential hypertension, results in a decrease in mean arterial blood pressure of 26% (155 to 115 mm Hg) accompanied by a 12% (52 to 46 mL/100 g per minute) decrease in CBF. When the level of spinal anesthesia was purposely increased to produce higher levels of block (T4) in normotensive and hypertensive patients, CBF was unchanged in the normotensive group (45 to 46 mL/100 g per minute), whereas a 19% decrease occurred in the apparently untreated hypertensive patients (46.5 to 37.5 mL/100 g per minute).[43]

RESPIRATORY

Alterations in pulmonary variables in healthy and even in elderly patients during neuraxial block are usually of little clinical consequence.[44] A decrease in vital capacity follows a reduction in expiratory reserve volume related to paralysis of the abdominal muscles necessary for forced exhalation rather than a decrease in phrenic or diaphragmatic function.[45] Blockade of the intercostal and abdominal muscles during neuraxial anesthesia is adequately compensated by unaltered function of the diaphragm and other accessory respiratory muscles (e.g., sternomastoid, scalenes), especially for forceful inspiration and expiration.[46] Nonetheless, neuraxial block should be used cautiously in the setting of severe respiratory disease because paralysis of the intercostal and abdominal muscles is common. However rare, respiratory arrest associated with spinal anesthesia is often unrelated to phrenic or inspiratory dysfunction but rather to hypoperfusion of the respiratory centers in the brainstem. Supportive evidence for this concept is observed after resuscitation, when apnea almost always disappears as soon as pharmacologic and intravascular fluid therapies have restored cardiac output and arterial blood pressure.

Pregnancy

In young healthy pregnant women undergoing cesarean delivery, spinal bupivacaine, ropivacaine, and levobupivacaine affect pulmonary function minimally (a reduction of 3% to 6% for forced vital capacity [FVC] and 6% to 13% for peak expiratory flow rate [PEFR]), irrespective of the peak sensory block level.[47] However, in overweight pregnant women, vital capacity declines even more (24% vs 11%) and recovers more slowly compared with normal-weight pregnant women after hyperbaric spinal bupivacaine administration (see also Chapter 77).[48]

Obesity (Also see Chapter 71)

The impact of spinal anesthesia on lung volume variables is significantly reduced compared with general anesthesia[49] but is significantly more in overweight patients than in normal-weight patients.[48] The magnitude of decline in vital capacity is proportional to the BMI value (vital capacity –19% for BMI 30 to 40 kg/m^2 versus –33% for BMI >40 kg/m^2).[50] Importantly, however, for obese patients undergoing laparotomy surgery, thoracic epidural anesthesia lessens the extent of decline in postoperative vital capacity and hastens recovery when compared with parenterally administered opioids.[49]

GASTROINTESTINAL

Neuraxial blockade from T6 to L1 disrupts splanchnic sympathetic innervation to the gastrointestinal tract, resulting in a contracted gut and hyperperistalsis. Nausea and vomiting may be associated with neuraxial block in as much as 20% of patients and they are primarily related to gastrointestinal hyperperistalsis caused by unopposed parasympathetic (vagal) activity.[51] Atropine is effective in treating nausea associated with high (T5) subarachnoid anesthesia.[52]

Thoracic epidural anesthesia (TEA) has a direct blood pressure–dependent effect on intestinal perfusion.[53] TEA improves anastomotic mucosal blood flow in patients undergoing esophagectomy when mean arterial blood pressure is minimally altered but worsens local perfusion when arterial blood pressure is decreased by about 50%. In colorectal surgery, TEA decreases anastomotic blood flow but improves gastric and transverse colonic blood flow.[54] Correction of systemic hypotension by vasopressor therapy (e.g., norepinephrine) has been found to reverse impaired colonic perfusion. TEA may also reduce the rate of anastomotic leak after emergency laparotomy, esophageal surgery,[55] and other gastrointestinal interventions.[56]

A reduction in hepatic blood flow parallels the reduction in mean systemic arterial pressure in the setting of spinal anesthesia.[57] Although lumbar epidural anesthesia also results in a decline in hepatic perfusion despite colloid preloading in young and elderly patients, hepatic perfusion can increase, though mildly (<10%), with TEA after major abdominal surgery.[57]

RENAL

Despite a predictable decrease in renal blood flow accompanying neuraxial blockade, this decrease is of little physiologic importance.[58,59] One aspect of genitourinary function of clinical importance is the belief that neuraxial blocks are a frequent cause of urinary retention, which delays discharge of outpatients and necessitates bladder catheterization in inpatients (see Complications–Urinary Retention, later in the chapter). However, this belief is questionable. For example, in orthopedic patients undergoing hip replacement, bladder catheterization was no more frequent after spinal or epidural anesthesia than it was after general anesthesia and opioid analgesics. In any case, excessive volumes of intravenous crystalloid solutions should not be given to patients undergoing spinal anesthesia. The requirement for voiding before discharge in low-risk ambulatory surgery patients after short-acting spinal or epidural anesthetics should be encouraged.[60]

INDICATIONS

At the most basic level, neuraxial blockade is indicated when the surgical procedure can be accomplished with a spinal level of anesthesia that does not produce adverse patient outcomes. The level of anesthesia or analgesia required is of prime importance because the physiologic effects of a high-level block may be untenable.

NEURAXIAL ANESTHESIA

When considering neuraxial anesthesia, the nature and duration of surgery, patient comorbidities, the ease of spinal insertion (i.e., positioning and spinal pathology), and the relative benefits and risks to the individual are important. Spinal anesthesia is most commonly used for patients who require surgical anesthesia for procedures of known duration that involve the lower extremities, perineum, pelvic girdle, or lower abdomen. Descriptions of spinal anesthesia as the primary surgical anesthetic have more recently expanded to include lumbar spine surgery,[61] as well as upper abdominal procedures, such as laparoscopic cholecystectomy.[62] Spinal anesthesia may be useful when patients wish to remain conscious or when comorbidities such as severe respiratory disease or a difficult airway increase the risks of using general anesthesia. Epidural anesthesia can also be used for the lower extremities, perineum, pelvic girdle, or lower abdomen, but by virtue of intermittent or continuous catheter-based local anesthetic delivery, the duration of surgical anesthesia is not necessarily finite as it is with single-injection spinal anesthesia. Continuous catheter-based spinal anesthesia is arguably less conventional than either single-shot spinal anesthesia or catheter-based epidural anesthesia, but may be especially useful when insertion of an epidural catheter is challenging[63] or in the setting of severe cardiac disease when the reliability of a single-shot spinal anesthetic must be combined with more hemodynamically stable incremental dosing.

NEURAXIAL ANALGESIA

Local anesthetics (as well as other additives, discussed later) applied to the neuraxis in subanesthetic doses can provide potent, long-lasting analgesia for a variety of indications, including intraoperative analgesia, acute postsurgical pain,[64] and severe chronic pain associated with malignancy. The use of intrathecal and/or epidural opioids either alone or in combination with local anesthetics can provide excellent quality pain relief[65,66] and are an analgesic mainstay in labor and delivery,[67,68] during and after hip[69] or knee replacement,[70] in laparotomy,[71] in thoracotomy,[72] and increasingly even in cardiac surgery.[73,74] Some of the most important benefits of epidural analgesia are realized in patients with preexisting respiratory disease undergoing abdominal surgery.[75] Neuraxial analgesia may have other beneficial outcomes beyond analgesia and these are reviewed later.

CONTRAINDICATIONS

ABSOLUTE

There are few absolute contraindications to neuraxial blockade. Some of the most important include patient refusal, localized sepsis, and an allergy to any of the drugs planned for administration. A patient's inability to maintain stillness during needle puncture, which can expose the neural structures to traumatic injury,[76] as well as raised intracranial pressure, which may theoretically predispose

to brainstem herniation,[77] should also be considered absolute contraindications to a neuraxial technique.

RELATIVE

Relative contraindications must be weighed against the potential benefits of neuraxial blockade. Relative contraindications can be approached by system.

Neurologic

Myelopathy or Peripheral Neuropathy. The proof that neuraxial anesthesia or analgesia in the setting of preexisting neurologic deficit can worsen the extent of injury (so-called double-crush phenomenon) is absent.[78-80] Chronic low back pain without neurologic deficit is not a contraindication to neuraxial blockade. The association between neuraxial techniques and the exacerbation of back pain symptoms is not documented.

Spinal Stenosis. Patients with spinal stenosis may be at increased risk of neurologic complications after neuraxial blockade,[81] but the relative contribution of surgical factors and natural history of the spinal pathology itself is unknown.

Spine Surgery. Previous spine surgery does not predispose patients to an increased risk of neurologic complications after neuraxial blockade.[81,82] However, depending on postsurgical anatomy and the presence of scar tissue, adhesions, hardware, and/or bone grafts, needle access to the CSF, or epidural space and/or epidural catheter insertion may be challenging or impossible. In addition, the resultant spread of local anesthetic in the CSF or epidural space can be unpredictable and incomplete.

Multiple Sclerosis. Patients with multiple sclerosis (MS) may be more sensitive to neuraxial local anesthetics and thus exhibit a prolonged duration of motor and sensory blockade; however, any association between neuraxial anesthesia and exacerbation of MS symptoms is not based in evidence.[83,84]

Spina Bifida. Depending on the severity of the neural tube defect, patients with spina bifida may have a tethered cord and the ligamentum flavum may be absent, thereby increasing the potential for traumatic needle injury to the spinal cord. The spread of local anesthetic in the CSF and epidural space (if present) can be highly variable.

If a neuraxial technique is undertaken in any of these circumstances, a careful evaluation of neurologic status must first be undertaken and noted along with documentation of the discussion of the risks and benefits.

Cardiac (Also see Chapter 67)

Aortic Stenosis or Fixed Cardiac Output. The unpredictable speed and extent to which systemic vascular resistance is reduced after spinal anesthesia may cause many providers to avoid spinal anesthesia in preload-dependent patients and try to prevent a dangerous decrease in coronary perfusion. This concern is borne of theoretic risk and a great deal of caution rather than evidence.[85] Clinical practice mandates that neuraxial anesthesia be considered individually for each patient with aortic stenosis in the context of their own disease severity, left ventricular function, and case urgency. A catheter-based neuraxial anesthetic, whether it is an epidural or intrathecal catheter, allows for the repeated administration of small doses of local anesthetic, with potentially more control over hemodynamic changes, and may be a logical alternative choice.

Hypovolemia. An extension of patients who are preload-dependent, hypovolemic patients may exhibit an exaggerated hypotensive response to the vasodilatory effects of neuraxial blockade.

Hematologic

Thromboprophylaxis. Borne of the catastrophic cases of spinal hematoma causing paralysis associated with the introduction and use of LMWH in the United States (U.S. FDA public health advisory: reports of epidural or spinal hematomas with the concurrent use of low molecular weight heparin and spinal/epidural anesthesia or spinal puncture. U.S. Department of Health and Human Resources, 1997), the American Society of Regional Anesthesia and Pain Medicine (ASRA) first published a practice advisory to guide the provision of neuraxial techniques in patients receiving antithrombotic or thrombolytic therapy in 2004. Now in its third iteration and addressing a myriad of novel potent oral anticoagulants, the ASRA practice advisory[6] is an invaluable resource for providers performing neuraxial techniques in this challenging and ever-growing patient population. A summary of the ASRA guidelines, along with those of other professional societies is reproduced in Table 56-1.

Inherited Coagulopathy. The safety of neuraxial techniques in patients with common bleeding diatheses is not well documented. Hemorrhagic complications after neuraxial techniques in patients with known hemophilia, von Willebrand disease, or idiopathic thrombocytopenic purpura appear infrequently when factor levels are more than 0.5 IU/mL for factor VIII, von Willebrand factor, and ristocetin cofactor activity, or when the platelet count is greater than $50 \times 10^9/L^1$ before block performance.[86] The minimum safe factor levels and platelet count for neuraxial blockade remain undefined in both the obstetric and general populations.[86]

Infection

Theoretic concerns based on animal data and laboratory and case reports in humans[87-89] suggest iatrogenic seeding of the neuraxis in the setting of a systemic infection. Some providers avoid neuraxial techniques in febrile patients. A definitive causative relationship between existing systemic infection and meningitis or epidural abscess after a neuraxial technique has never been shown. In fact, a lumbar puncture is a critical component of the investigation of fever of unknown origin, yet there are no definitive data linking lumbar puncture to increased risk of neuraxial infection in this setting.[90] Although the profound vasodilation may be sufficient reason to avoid neuraxial techniques in patients with profound bacteremia or septic shock, the theoretic risk of seeding the

intrathecal or epidural spaces by performing neuraxial techniques in patients with untreated systemic infection further supports using another technique. Yet patients with evidence of systematic infection may safely undergo neuraxial anesthesia once antibiotic therapy has been initiated and the patient has demonstrated a response to the antibiotics.[90]

TABLE 56-2 DERMATOMAL LEVEL REQUIRED FOR VARIOUS COMMON SURGICAL PROCEDURES

Type of surgery	Dermatomal Level
Upper abdominal surgery	T4
Ceserean delivery	T4
Transurethral resection of prostate	T10
Hip surgery	T10
Foot and ankle surgery	L2

SPINAL ANESTHESIA

FACTORS AFFECTING BLOCK HEIGHT

The dermatomal level required for various surgical procedures is outlined in Table 56-2. The provider must recall that intraabdominal structures such as the peritoneum (T4), bladder (T10), and uterus (T10) have a spinal segment innervation that may be much more cephalad compared with that of the corresponding skin incision used to operate on these structures.

TABLE 56-3 **FACTORS AFFECTING LOCAL ANESTHETIC DISTRIBUTION AND BLOCK HEIGHT**

	More Important	Less Important	Not Important
Drug factors	Dose Baricity	Volume Concentration Temperature of injection Viscosity	Additives other than opioids
Patient factors	CSF volume Advanced age Pregnancy	Weight Height Spinal anatomy Intraabdominal pressure	Menopause Gender
Procedure factors	Patient position Epidural injection post spinal	Level of injection (hypobaric more than hyperbaric) Fluid currents Needle orifice direction Needle type

CSF, Cerebrospinal fluid.

Drug, patient, and procedural factors can all affect the distribution of local anesthetic spread within the intrathecal space, some of which are more clinically relevant than others.[25,91] Many of these factors are not controllable by the anesthesiologist, leading to significant interpatient variability (Table 56-3).

Drug Factors

The adjustable factors for any given local anesthetic solution are dose, volume, concentration, temperature, and baricity. Baricity and dose are most important.

Baricity. Baricity is the ratio of the density of a local anesthetic solution to the density of CSF. Density is defined as the mass per unit volume of solution (g/mL) at a specific temperature. Density may be compared between different substances by calculating the specific gravity, which is the ratio of the density of a solution to the density of water. Because density varies inversely with temperature, the baricity of a local anesthetic solution is conventionally defined at 37° C. The density of CSF is 1.00059 g/L.[92] Local anesthetic solutions that have the same density as CSF are termed *isobaric*, those that have a higher density than CSF are termed *hyperbaric*, and those with a lower density than CSF are termed *hypobaric*. The spread of hyperbaric solutions is more predictable,[93] with less interpatient variability.[94] To make a drug hyperbaric to CSF, it must be denser than CSF, with a baricity appreciably more than 1.0000 or a density appreciably more than 1.00059. The reverse is true for making a drug hypobaric to the CSF. Dextrose and sterile water are commonly added to render local anesthetic solutions either hyperbaric or hypobaric, respectively. The clinical importance of baricity is the ability to influence the distribution of local anesthetic spread based on gravity. Hyperbaric solutions will preferentially spread to the dependent regions of the spinal canal, whereas hypobaric solutions will spread to nondependent regions. Isobaric solutions tend not to be influenced by gravitational forces.[95] Anesthesiologists can capitalize on this phenomenon by altering the position of the patient. For example, the administration of hyperbaric local anesthetic to patients in the lateral decubitus position will result in a preferential anesthetic effect on the dependent side, whereas the opposite is true for the administration of a hypobaric solution. A thoughtful understanding of the natural curvatures of the vertebral column can help predict local anesthetic spread in patients placed in the horizontal supine position immediately after intrathecal administration. Hyperbaric local anesthetics injected, while sitting, at the L3-4 or L4-5 interspace will spread with gravity from the height of the lumbar lordosis down toward the trough of the thoracic kyphosis in the horizontal supine position, resulting in a higher level of anesthetic effect than isobaric or hypobaric solutions.[91] Hyperbaric solutions are also useful in small doses for a saddle block and to achieve unilateral anesthesia. CSF and local anesthetic density change with temperature. Plain bupivacaine 0.5%, for example, may be isobaric at 24° C but is slightly hypobaric at 37° C. A small volume of drug at room temperature injected intrathecally quickly equilibrates after injection and increases to the temperature of the CSF. Nevertheless, increasing temperature decreases density of a solution and warming of local anesthetic solution to body temperature, therefore making it more hypobaric, increases the block height in patients who remain seated for several minutes after injection.[96]

Dose, Volume, and Concentration. The dose, volume, and concentration are inextricably linked (Volume × Concentration = Dose), but dose is the most reliable determinant of local anesthetic spread (and thus block height) when compared with either volume or concentration for isobaric and hypobaric local anesthetic solutions.[97,98] Hyperbaric local anesthetic injections are primarily influenced by baricity.

The choice of local anesthetic itself does not influence spread if all other factors are controlled. Additive drugs, other than opioids, also do not affect spread. However, opioids do seem to increase mean spread,[91,99] possibly as a result of pharmacologic enhancement at the extremes of the spread where the local anesthetic block alone would have been subclinical.[100,101]

Patient Factors

Patient characteristics that may influence block height include patient height, weight, age, sex, pregnancy, anatomic configuration of the spine, and the CSF properties

(volume and composition). Within the range of "normal-sized" adults, patient height does not seem to affect the spread of spinal anesthesia. This is likely because the length of the lower limb bones rather than the vertebral column contributes most to adult height. A correlation has been found between the vertebral column length and local anesthetic spread[102] and, at extremes of height, consideration should be given to altering the dose accordingly.

The CSF volume is an important patient-related factor that significantly influences peak block height and regression of sensory and motor blockade.[17] Lumbosacral CSF has a fairly constant pressure of approximately 15 cm H_2O but its volume varies from patient to patient, in part because of differences in body habitus and weight.[16] In a small sample of patients, block height varied indirectly with CSF volume.[17] Unfortunately, CSF volume does not correlate well with anthropomorphic measurements available clinically other than body weight.[17] In theory, the increased abdominal mass in obese patients, and possible increased epidural fat, may decrease the CSF volume and therefore increase the spread of local anesthetic and block height. This has indeed been demonstrated using hypobaric solutions,[103,104] which are characterized by more variable spread anyway, but not hyperbaric solutions[103,105] (see Chapter 71).

CSF density can also vary between and within individuals depending on sex, menopausal status, and pregnancy[92] (see Chapter 77). The density of CSF is lower in women compared with men, premenopausal compared with postmenopausal women, and pregnant compared with nonpregnant women. Although this may affect relative baricity of local anesthetics, the clinical variation in spread is probably unimportant.

Advanced age is associated with increased block height[106,107] (see Chapter 80). In older patients, CSF volume decreases, whereas its specific gravity increases. Further, the nerve roots appear more sensitive to local anesthetic in the aged population.

Gender can theoretically affect block height by several mechanisms. CSF density is higher in males, thereby reducing the baricity of local anesthetic solution and possibly limiting the extent of cephalad spread. In the lateral position, the broader shoulders of males relative to their hips make the lateral position slightly more head-up. The reverse is true in females who have a slightly head-down tilt in the lateral position compared with males. Despite this, there is little objective data that males have a slightly less cephalad spread than females in the lateral position.

Variations of the spine may be an important contributor to block height. Scoliosis, although it possibly makes insertion of the needle more difficult, will have little effect on local anesthetic spread if the patient is turned supine. Kyphosis, however, in a supine patient may affect the spread of a hyperbaric solution. Spread of local anesthetic is enhanced by changes in the lumbar lordosis during pregnancy, as well as by the volume and density of CSF, by twin pregnancies compared with singletons, by intraabdominal pressure increases (possibly), and by a progesterone-mediated increase in neuronal sensitivity.

Procedure Factors

Patient position, needle type and alignment, and the level of injection are each procedure-related factors that can affect block height. Combined with the baricity and local anesthetic dose, patient position is the most important factor in determining the block height. Position should not affect the spread of a truly isobaric solution.[95] Intrathecal local anesthetic appears to stop spreading 20 to 25 minutes after injection, thus positioning of the patient is most important during this time period, but particularly in the initial few minutes. However, marked changes in patient posture up to two hours after injection can still result in significant changes in the block level, probably because of bulk movement of CSF.[108,109] Although a 10-degree head-up tilt can reduce the spread of hyperbaric solutions without hemodynamic compromise,[110] a head-down tilt does not always increase the spread of hyperbaric bupivacaine.[111] Flexion of the hips in combination with the Trendelenburg position flattens the lumbar lordosis and has been shown to increase cephalad spread of hyperbaric solutions.[112] A "saddle block" where only the sacral nerve roots are anesthetized can be achieved by using a small dose of hyperbaric local anesthetic while the patient remains in the sitting position for up to 30 minutes. When larger hyperbaric doses are administered, however, the block can still extend cephalad despite maintaining the sitting position for a prolonged period of time.[113] The reverse holds true for hypobaric solutions, where block height is greater (than hyperbaric solutions) if they are administered in a sitting position.[114]

The specific needle type and orientation of the orifice may affect block quality. With hypobaric solutions, cephalad alignment of the orifice of Whitacre, but not Sprotte, needles produces greater spread.[115-117] The orientation of the needle orifice does not appear to affect the spread of hyperbaric solutions. When directing the needle orifice to one side (and using hyperbaric anesthetic), a more marked unilateral block is achieved again when using a Whitacre, rather than a Quincke, needle.[118]

The level of injection affects block height. Most studies have demonstrated that, even when the difference is only one interspace more cephalad, the block height is greater[119-122] when using isobaric bupivacaine. The level of injection does not appear to influence the spread of hyperbaric solutions.[123,124] Injection rate and barbotage (repeated aspiration and reinjection of CSF) of isobaric and hyperbaric solutions have not consistently been shown to affect block height.[91] A slower injection may actually increase spread, and this is perhaps also safer because forceful injection may cause the syringe to disconnect from the needle. Other maneuvers that do not appear to affect block height are coughing and straining after local anesthetic injection. This is related to the physics of injecting drugs into a closed column of CSF, which instantaneously transmits pressure changes throughout the CSF column, such as those that occur with coughing or straining.[25] The injection of local anesthetic or even saline into the epidural space after a spinal anesthetic increases the block height. This is discussed separately in the combined spinal-epidural section.

DURATION

The duration of a spinal anesthetic depends on how this variable is defined. For example, the duration of surgical anesthesia is less than the time for complete block resolution. In addition, surgical anesthesia depends on the surgical site because anesthesia is more prolonged at the lower lumbar and sacral levels than at those more cephalad from where the block regresses first. Duration is affected primarily by the dose,[97,125] the intrinsic properties of the local anesthetic (which affect elimination from the subarachnoid space), and the use of additives (if applicable). The latter two are described later. Hyperbaric solutions have a shorter duration of action than isobaric solutions.[125]

PHARMACOLOGY

The clinical effects of intrathecal local anesthetics are mediated by drug uptake and distribution within the CSF and elimination. These in turn are dictated in part by the p*K*a, lipid solubility, and protein binding of the local anesthetic solution. Rather than their pharmacologic structure (i.e., amide or ester), it is the duration of action—short-acting (i.e., procaine, chloroprocaine, articaine), intermediate-acting (i.e., lidocaine, prilocaine, mepivacaine), and long-acting (i.e., tetracaine, bupivacaine, levobupivacaine, ropivacaine)—that is most often used to classify local anesthetics in the clinical setting. The choice and dose of local anesthetic depend on both the expected duration and the nature (location, ambulatory) of surgery. Table 56-4 shows a range of local anesthetics used for spinal anesthesia with corresponding doses, onset times, and durations of action.

Short- and Intermediate-Acting Local Anesthetics

Procaine. Procaine is a short-acting ester local anesthetic and one of the oldest spinal anesthetics, having originally replaced cocaine as the drug of choice for spinal anesthesia in the early twentieth century. Procaine itself was then replaced by lidocaine, but with concerns about lidocaine and transient neurologic symptoms (TNS), procaine has recently been reexamined as an alternative fast-acting local anesthetic. However, it is not commonly used because of a more frequent failure rate than lidocaine, significantly more nausea, and a slower time to recovery.[135] If used, it is often administered as a hyperbaric drug in a dose ranging between 50 and 200 mg in a 10% concentration.

Chloroprocaine. Chloroprocaine is an ultra–short-acting ester local anesthetic that was introduced in the 1950s. Its initial popularity stemmed from its rapid metabolism by pseudocholinesterase, which translated into minimal systemic or fetal effects in the setting of epidural labor analgesia. However, its reputation as a spinal anesthetic has been tarnished because of reports of neurologic injury associated with the preservative once used in older preparations of the drug[136-139] (see Complications, discussed later). Recently, interest in chloroprocaine has increased for use in spinal anesthesia for ambulatory surgery (see Chapter 89). Modern, preservative-free preparations of chloroprocaine administered in small doses (30 to 60 mg) produce reliable, short-duration spinal anesthesia,[126] with a faster recovery time than procaine, lidocaine, and bupivacaine.[140-144] TNS can occur with modern chloroprocaine preparations, albeit at a considerably lesser rate (0.6%) than lidocaine (14%).[145-147]

Articaine. Articaine is a relatively novel amide local anesthetic that also has an ester linkage. The ester linkage allows for metabolism by nonspecific cholinesterases. It has been widely used since 1973 for dental nerve blocks with a good safety profile. Intrathecal articaine has not been extensively investigated, but studies do suggest that doses of 50 to 80 mg with or without glucose appear to

TABLE 56-4 **DOSE, BLOCK HEIGHT, ONSET TIMES, AND DURATION OF COMMONLY USED SPINAL ANESTHETICS**

Local Anesthetic Mixture	Dose (mg)		Duration (min)		Onset (min)
	To T10	*To T4*	*Plain*	*Epinephrine (0.2 mg)*	
Lidocaine 5% (with/without dextrose)*	40-75	75-100	60-150†	20%-50%	3-5
Mepivacaine 1.5% (no dextrose)	30-45‡	60-80§	120-180¶	—	2-4
Chloroprocaine 3% (with/without dextrose)	30-40	40-60	40-90‖	N/R	2-4

provide rapid-onset spinal anesthesia for about 1 hour, with a recovery profile faster than bupivacaine.[148,149]

Lidocaine. Lidocaine is a hydrophilic, relatively poorly protein-bound amide local anesthetic. It has a rapid onset and intermediate duration and is used in doses of 50 to 100 mg for shorter procedures that can be completed in 1.5 hours or less. It was traditionally prepared as a 5% solution in 7.5% dextrose; this preparation has been associated with both permanent nerve injury and transient neurologic symptoms (TNS, see Complications, discussed later). Despite efforts to reduce the concentration of both the drug and dextrose,[150,151] the use of intrathecal lidocaine declined and has not yet recovered.

Prilocaine. Prilocaine is an amide local anesthetic based on the structure of lidocaine. Prilocaine was introduced in 1965 and has an intermediate duration of action that may lend itself to use in the ambulatory surgery setting.[152] A dose of 40 to 60 mg of 2% hyperbaric prilocaine can provide a block to T10 for 100 to 130 minutes, whereas as little as 20 mg combined with fentanyl has been successfully used for ambulatory arthroscopic knee surgery.[153] Prilocaine is rarely associated with TNS.[152,154,155] In large doses (>600 mg), prilocaine can result in methemoglobinemia. This should not be an issue with doses used for spinal anesthesia, but it has been reported after epidural infusions.[156]

Mepivacaine. Mepivacaine is another short-acting amide local anesthetic. It was first introduced for spinal anesthesia in 1962 and was initially prepared as a hyperbaric solution. The use of spinal mepivacaine has declined because the incidence of TNS after hyperbaric mepivacaine was similar to that of lidocaine,[147] although TNS was less frequent with the isobaric preparation of mepivacaine.[157-159] Doses of 30 to 80 mg with and without additives have been used (see Table 56-4) and, when compared with lidocaine, mepivacaine has a slightly longer duration of action.[160]

Long-Acting Local Anesthetics

Tetracaine. Tetracaine is an ester local anesthetic with a rate of metabolism one tenth that of chloroprocaine. It is packaged either as niphanoid crystals (20 mg) or as an isobaric 1% solution (2 mL, 20 mg). When niphanoid crystals are used, a 1% solution is obtained by adding 2 mL of preservative-free sterile water to the crystals. Mixing 1% solution with 10% dextrose produces a 0.5% hyperbaric preparation that may be used for perineal and abdominal surgery in doses of 5 and 15 mg, respectively. Tetracaine is usually combined with a vasoconstrictor additive because the duration of tetracaine alone can be unreliable. Although such combinations can provide up to 5 hours of anesthesia,[161-164] the addition of phenylephrine in particular has been associated with TNS.[165]

Bupivacaine. Bupivacaine was introduced in 1963 and is a highly protein-bound amide local anesthetic with a slow onset because of its relatively high p*K*a. It is appropriate for procedures lasting up to 2.5 to 3 hours (see Table 56-4).[166,167] Bupivacaine is available as 0.25%, 0.5%, and 0.75% clear isobaric solutions and also as a hyperbaric 0.5% (in Europe) and 0.75% solution containing 80 mg/mL glucose. At room temperature, plain bupivacaine is actually slightly hypobaric compared with CSF. Recovery profiles using small doses appear to be similar to that of lidocaine[168-170] and thus low-dose bupivacaine is used in ambulatory procedures. A recent systematic review[171] concluded that 4 to 5 mg of hyperbaric bupivacaine combined with unilateral positioning was adequate for short knee arthroscopy procedures. Bupivacaine is rarely associated with TNS.

Levobupivacaine. Levobupivacaine is the pure S (–) enantiomer of racemic bupivacaine. Although it is used in similar doses to bupivacaine and has a similar onset and duration, levobupivacaine potency appears to be slightly less than bupivacaine.[129] Nevertheless, the majority of clinical studies using identical doses of levobupivacaine and bupivacaine have found no significant difference in clinical efficacy for spinal anesthesia.[129,172-174] The main advantage of levobupivacaine is that it is less cardiotoxic than bupivacaine,[175,176] which is more of a theoretic than a real risk in the setting of spinal anesthesia.

Ropivacaine. Ropivacaine was introduced in 1996 and is another highly protein-bound amide local anesthetic. It is structurally related to bupivacaine, with the same p*K*a (8.1) and so it is also characterized by slow onset and a long duration of action. Compared to bupivacaine, the proposed advantages of spinal ropivacaine were less cardiotoxicity and greater motor-sensory block differentiation, resulting in less motor block. Subsequently, the potency of ropivacaine was found to be 0.6 that of bupivacaine.[179-181] When ropivacaine is given in an equivalent dose to bupivacaine, there is slightly less motor block and earlier recovery with ropivacaine.[8,182-184]

Spinal Additives

Whether administered into the CSF in conjunction with a local anesthetic or alone, a variety of medications may exert a direct analgesic effect on the spinal cord and nerve roots, or prolong the duration of sensory and motor blockade. As such, the coadministration of these agents often allows for a reduction in the required dose of local anesthetic, with the advantage of motor block sparing and faster recovery while still producing the same degree of analgesia.

Opioids. The effects of opioids within the CSF are complex, because of a combination of direct spinal cord dorsal horn opioid receptor activation, cerebral opioid receptor activation after CSF transport, and peripheral and central systemic effects after vascular uptake. The effect at each of these sites depends on both the dose administered and the physicochemical properties of the opioid, particularly lipid solubility. Highly lipid-soluble drugs such as fentanyl and sufentanil have a more rapid onset and shorter duration of action than more hydrophilic opioids. In addition to increasing uptake into neural tissue, greater lipid solubility results in rapid uptake into both blood vessels (with a resultant systemic effect) and fatty tissue. The spread of lipophilic opioids within the CSF is there-

fore more limited than hydrophilic opioids such as morphine, which demonstrate greater spread as a result of slower uptake and elimination from the CSF. As a result, hydrophilic opioids have a greater risk of late respiratory depression, which is one of the rare but most serious consequences of intrathecal opioid administration. The extent of neural tissue and vascular uptake also affects the potency of intrathecal opioids. For example, the relative intrathecal to intravenous potency of morphine is 200 to 300 to 1, whereas for fentanyl and sufentanil it is only 10 to 20 to 1.[185] In addition to respiratory depression, intrathecal opioids have other side effects including nausea and vomiting, pruritus, and urinary retention. These are discussed later in the Complications section.

Hydrophilic Opioids. Preservative-free morphine is the most widely used hydrophilic opioid in spinal anesthesia. It has a slow onset but provides analgesia for up to 24 hours.[186] Adequate analgesia is achieved with 100 μg, with minimal side effects for cesarean deliveries, whereas the most efficacious dose for major orthopedic surgery is less clear.[187] For hip or knee replacement surgery, side effects tend to increase without a corresponding improvement in analgesia with intrathecal morphine doses of 300 μg or more. Doses as high as 500 μg may be used for major abdominal surgery or thoracotomies, where it is becoming increasingly common to administer spinal opioids alone as a simple alternative to epidural local anesthetic–based analgesia. The magnitude of the analgesic response and the optimal dose remain unclear. Overall, the beneficial effects of intrathecal morphine seem most marked in abdominal surgery, and within the first 24 hours in particular.[186,188]

Diamorphine is available for use in the United Kingdom only. It is a lipid-soluble prodrug that crosses the dura faster than morphine and is cleared from the CSF more quickly than morphine. Once in the dorsal horn of the spinal cord, it is converted to morphine and 6-monoacetyl morphine, both of which are μ-agonists with a relatively long duration of action. It is recommended for use in doses of 0.3 to 0.4 mg for cesarean delivery[189] and is widely used instead of morphine in the United Kingdom.

There are only limited data related to the use of hydromorphone for spinal analgesia. It is more commonly used epidurally, as discussed later. Limited data suggest that intrathecal hydromorphone 50 to 100 μg provides comparable analgesia with similar side effects to 100 to 200 μg of morphine, with a similar duration of action. However, it has not undergone full neurotoxicity screening and does not provide any advantage compared with morphine.[190]

Meperidine is an opioid of intermediate lipid solubility, but it also has some local anesthetic properties and has been used as the sole intrathecal agent (doses ranging from 0.5 to 1.8 mg/kg) in both obstetric and general surgery.[191,192] Smaller doses are used in combination with local anesthetics. Both 10 mg and 20 mg improve analgesia compared with placebo after cesarean delivery,[193] although side effects were more frequent with the larger dose. However, this drug is used infrequently because of the availability of other opioids and its unknown neurotoxicity profile.

Lipophilic Opioids. Fentanyl and sufentanil are used frequently in obstetrics for labor analgesia and cesarean delivery as discussed elsewhere (also w 77). Sufentanil 2 to 10 μg and fentanyl 25 μg provide comparable analgesia in early labor.[194-197] In transurethral prostatectomy surgery, when combined with low-dose bupivacaine, sufentanil 5 μg provides superior analgesia compared with fentanyl 25 μg.[198] Fentanyl in doses of 10 to 30 μg is commonly used in ambulatory surgery because of its rapid onset time of 10 to 20 minutes and relatively short duration of 4 to 6 hours. Although the local anesthetic dose can be reduced and analgesia prolonged,[199] the addition of fentanyl to bupivacaine may increase side effects and delay discharge.[171]

Vasoconstrictors. Vasoconstrictors, such as epinephrine and phenylephrine, prolong the duration of sensory and motor blockade when added to local anesthetics. The mechanism of action is reduced systemic local anesthetic uptake caused by an α_1-mediated vasoconstriction. Epinephrine may also enhance analgesia via a direct α_2-mediated effect. Traditionally, epinephrine 0.1 to 0.6 mg, was thought to prolong tetracaine spinal anesthesia, but not bupivacaine or lidocaine spinal anesthesia.[22] This theory was postulated because of differences in the vasodilatory action of the local anesthetic drugs; plain lidocaine and bupivacaine cause vasodilation, whereas plain tetracaine does not. However, lidocaine spinal anesthesia can be prolonged by epinephrine when measured by both two-dermatome regression in the lower thoracic dermatomes and by occurrence of pain at the operative site for procedures carried out at the level of the lumbosacral dermatomes.[200,201] Similarly, bupivacaine spinal duration may be increased, but because of the already long duration, epinephrine is not generally added to bupivacaine. There is a concern that potent vasoconstrictive action places the blood supply of the spinal cord at risk. However, there are no human data supporting this theory, and in animal studies,[164,202-204] administering either subarachnoid epinephrine (0.2 mg) or phenylephrine (5 mg) does not decrease spinal cord blood flow. Phenylephrine 2 to 5 mg prolongs both lidocaine and tetracaine spinal anesthesia to a similar extent as epinephrine.[201,205] Bupivacaine spinal anesthesia is not prolonged by phenylephrine.[206,207] Concepcion and co-workers[208] compared epinephrine (0.2 and 0.3 mg) and phenylephrine (1 and 2 mg) added to tetracaine and did not find any differences in duration between the two vasoconstrictors. Caldwell and associates[163] used larger doses of vasoconstrictors, epinephrine at 0.5 mg and phenylephrine at 5 mg, and showed that phenylephrine prolonged tetracaine spinal anesthesia significantly more than did epinephrine. The addition of phenylephrine has declined in popularity because of its association with TNS.[165,209]

α_2-Agonists. Clonidine, dexmedetomidine, and epinephrine all act on prejunctional and postjunctional α_2 receptors in the dorsal horn of the spinal cord. Activation of presynaptic receptors reduces neurotransmitter release, whereas postjunctional receptor activation results in hyperpolarization and reduction of pulse transmission.[210] In doses of 15 to 225 μg, clonidine prolongs the duration of sensory and motor blockade by

approximately 1 hour and improves analgesia, reducing morphine consumption by up to 40%.[211-215] It appears to cause less urinary retention than morphine but, as with intravenous clonidine administration, spinal clonidine can also cause hypotension. A systematic review concluded that the hypotension associated with spinal clonidine was not dose-related and that the risk of bradycardia with clonidine was not increased.[216] Sedation can also occur with spinal clonidine, peaking within 1 to 2 hours and lasting up to 8 hours.[210] Dexmedetomidine is approximately 10-fold more α_2-selective than clonidine is.[217] As little as 3 μg of dexmedetomidine can prolong motor and sensory block without hemodynamic compromise.[218,219]

Other Drugs. Neostigmine in doses of 10 to 50 μg has analgesic effects after intrathecal administration.[220,221] Intrathecal neostigmine has been shown to prolong motor and sensory blockade and reduce postoperative analgesic requirements. Neostigmine inhibits the breakdown of acetylcholine, therefore increasing acetylcholine concentration, which itself is antinociceptive. It also appears to stimulate the release of nitric oxide in the spinal cord. Its benefits, however, are limited by nausea, vomiting, bradycardia, and, in higher doses, lower extremity weakness,[222,223] and is therefore not in widespread use.[224] Midazolam is a γ-aminobutyric acid receptor agonist that in doses of 1 to 2 mg appears to increase sensory and motor block and decrease analgesic requirements postoperatively, without the adverse effects observed with α_2 agonists or opioids. Early work raised concerns of spinal cord toxicity, but more recent studies suggest that it is safe.[225] Ketamine, adenosine, tramadol, magnesium, and nonsteroidal antiinflammatory drugs have also all been administered intrathecally, but further work is required to establish whether these drugs have any clinical value.

Technique

Technique should be classified into a series of steps (i.e., the four Ps): preparation, position, projection, and puncture.

Preparation. Informed consent must be obtained, with adequate documentation of the discussion of risk (see Complications, discussed later). Resuscitation equipment must always be readily available whenever a spinal anesthetic procedure is performed. The patient should have adequate intravenous access and be monitored with pulse oximetry, noninvasive arterial blood pressure, and electrocardiogram. Pre-prepared packs are now commonly used and often contain fenestrated drapes, swabs and towels, syringes, needles, filters, spinal needles, sterilizing solution, and local anesthetic for skin infiltration. When the local anesthetic for subarachnoid injection is chosen, the duration of block should be matched with both the surgical procedure and patient variables (see Table 56-4).

The most important characteristics of a spinal needle are the shape of the tip and the needle diameter. Needle tip shapes fall into two main categories: those that cut the dura and those with a conical, pencil-point tip. The former include the Pitkin and the Quincke-Babcock needle,

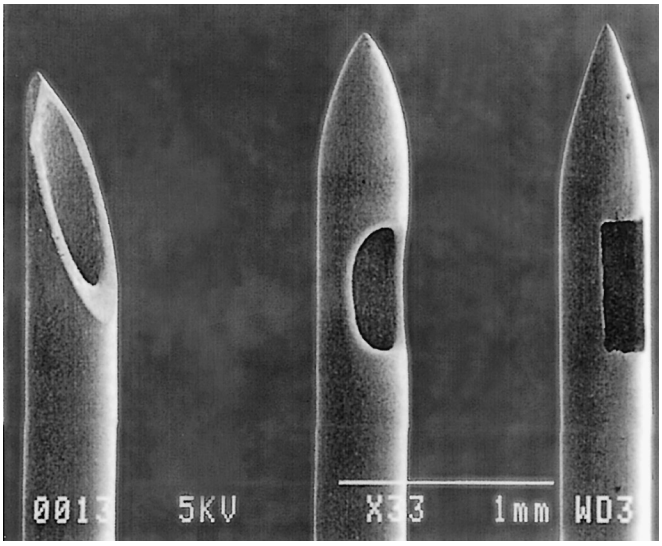

Figure 56-4. Scanning electron micrographs of spinal needle tip designs: Quincke (*left*), Sprotte (*middle*), and Whitacre (*right*). *(Adapted from Puolakka R, Andersson LC, Rosenberg PH: Microscopic analysis of three different spinal needle tips after experimental subarachnoid puncture,* Reg Anesth Pain Med *25:163, 2000.)*

and the Whitacre and Sprotte needles belong to the latter group (Fig. 56-4). The orifice of the Whitacre needle is smaller. If a continuous spinal technique is chosen, use of a Tuohy or other thin-walled needle can facilitate passage of the catheter. The use of small needles reduces the incidence of post–dural puncture headache from 40% with a 22-G needle to less than 2% with a 29-G needle. The use of larger needles, however, improves the tactile sense of needle placement, and so although 29-G needles result in a very low rate of post–dural puncture headache, the failure rate is increased.[226,227] Pencil-point needles provide better tactile sensation of the different layers encountered during needle insertion but, more importantly, they reduce the incidence of post–dural puncture headache. Pencil-point needles of 25, 26, and 27 G probably represent the optimal needle choice. An introducer needle can assist with guidance of smaller-gauge spinal needles in particular. Special Luer lock needles and syringes for spinal kits are now also available. These have been designed to prevent inadvertent intrathecal injection but still rely on the correct drug being drawn up into the "special" connector syringe (Fig. 56-4).

Sterility is an issue of utmost importance. One of the most common organisms responsible for postspinal bacterial meningitis is *Streptococcus viridans,* which is an oral commensal, emphasizing the purpose of wearing a mask as part of a full aseptic technique. Hands and forearms must be washed and all jewelry removed. A variety of solutions may be used to clean the back, such as chlorhexidine or alcohol (alone or in combination), or iodine solutions. Chlorhexidine and alcohol together have been concluded to be most effective.[229-231] If chlorhexidine is used, it is important that the solution is allowed to dry completely before skin puncture because chlorhexidine is neurotoxic.

Position (Also see Chapter 41). The three primary patient positions include the lateral decubitus, sitting, and prone

positions, each of which has advantages in specific situations. The superiority of any one particular position is unclear. In the obstetric population, there have been small studies demonstrating that block operator performance was faster in the sitting position, albeit this benefit was offset by a slower onset time compared with the lateral decubitus position[232] (see Chapter 77). Current consensus guidelines state that neuraxial blocks should be undertaken with the patient awake,[76] except in those circumstances where the physician and patient conclude that benefit outweighs the risk. General anesthesia or heavy sedation can prevent a patient from recognizing warning signs of pain or paresthesia if the needle is in close proximity to nervous tissue.

A patient in the lateral decubitus position facilitates the administration of sedative medication if required, is less dependent on a well-trained assistant than for a patient in the sitting position, and is arguably more comfortable. Patients are placed with their back parallel to the edge of the operating table nearest the anesthesiologist, thighs flexed onto the abdomen, with the neck flexed to allow the forehead to be as close as possible to the knees in an attempt to "open up" the vertebral spaces. The assistant may still be invaluable during this positioning by encouraging and assisting the patient in assuming the ideal lateral decubitus position. Because of the differing proportional sizes of hips and shoulders, the spine may slope down toward the head in females, with the opposite occurring in males. The patient should be positioned so that spread of hypobaric, isobaric, or hyperbaric solution to the operative site is optimized.

Identification of the midline may be easier when the patient is placed in the sitting position, especially when obesity or scoliosis renders midline anatomy difficult to examine. When placing patients in this position, a stool can be provided as a footrest and a pillow placed in the lap, or a specially designed stand may be used. The assistant helps to maintain the patient in a vertical plane while flexing the patient's neck and arms over the pillow, relaxing the shoulders, and asking the patient to "push out" the lower back to open up the lumbar vertebral spaces. Care must be taken not to oversedate a patient in this position. Hypotension may also be more common for a person in the sitting position.

The prone position is rarely used but may be chosen when the patient is to be maintained in that position (often with the jack-knife modification) during the surgical procedure. Such cases may include rectal, perineal, or lumbar procedures. The anesthesiologist may have to aspirate for CSF because CSF pressure is minimized when insertion of the lumbar needle is carried out in this position.

Projection and Puncture. The midline approach relies on the ability of patients and assistants to minimize lumbar lordosis and allow access to the subarachnoid space between adjacent spinous processes, usually at the L2-L3, L3-L4, or the L4-L5 space. The spinal cord ends at the level of L1-L2 and so needle insertion above this level should be avoided. The intercristal line is the line drawn between the two iliac crests and traditionally corresponds to the level of the L4 vertebral body or the L4-L5 interspace, but the reliability of this landmark is questionable as demonstrated by recent ultrasonography studies.[233] Once the appropriate space has been selected, a subcutaneous skin wheal of local anesthetic is developed over this space, and the introducer is inserted at a slight cephalad angle of 10 to 15 degrees through skin, subcutaneous tissue, and supraspinous ligament to reach the substance of the interspinous ligament. The introducer is grasped with the palpating fingers and steadied while the other hand is used to hold the spinal needle like a dart, and the fifth finger is used as a tripod against the patient's back to prevent patient movement and unintentional insertion to a level deeper than intended. The needle, with its bevel parallel to the midline, is advanced slowly to heighten the sense of tissue planes traversed and to prevent skewing of nerve roots, until the characteristic change in resistance is noted as the needle passes through the ligamentum flavum and dura. On passing through the dura, there is often a slight "click" or "pop" sensation. The stylet is then removed, and CSF should appear at the needle hub. The smaller the needle diameter, the longer the wait for CSF flow, particularly if the patient is not in the sitting position. If the CSF does not flow, the needle might be obstructed and rotation in 90-degree increments can be undertaken until CSF appears. If CSF does not appear in any quadrant, the needle should be advanced a few millimeters and rechecked in all four quadrants. If CSF still has not appeared and the needle is at a depth appropriate for the patient, the needle and introducer should be withdrawn and the insertion steps should be repeated. A common reason for failure is insertion of the needle off the midline (Fig. 56-5).

After CSF is freely obtained, the dorsum of the anesthesiologist's nondominant hand steadies the spinal needle against the patient's back while the syringe containing the therapeutic dose is attached to the needle. CSF is again freely aspirated into the syringe, and the anesthetic dose is injected at a rate of approximately 0.2 mL/sec. After completion of the injection, 0.2 mL of CSF can be aspirated into the syringe and reinjected into the subarachnoid space to reconfirm location and clear the needle of the remaining local anesthetic.

The paramedian approach exploits the larger "subarachnoid target" that exists if a needle is inserted slightly lateral to the midline (Fig. 56-6). The paramedian approach may be especially useful in the setting of diffuse calcification of the interspinous ligament. The most common error when using the paramedian technique is that the needle entry site is placed too far off midline, which makes the vertebral laminae barriers to insertion of the needle. In the paramedian approach, a skin wheal is raised 1 cm lateral and 1 cm caudad to the corresponding spinous process. A longer needle (e.g., 3 to 5 cm) is then used to infiltrate deeper tissues in a cephalomedial plane. The spinal introducer and needle are next inserted 10 to 15 degrees off the sagittal plane in a cephalomedial plane (see Fig. 56-6). Similar to the midline approach, the most common error is to angle the needle too far cephalad on initial insertion. Nevertheless, if the needle contacts bone, it is redirected slightly in a cephalad direction. If bone is again contacted, but at a deeper level, the slight cephalad angulation is continued because it is likely that

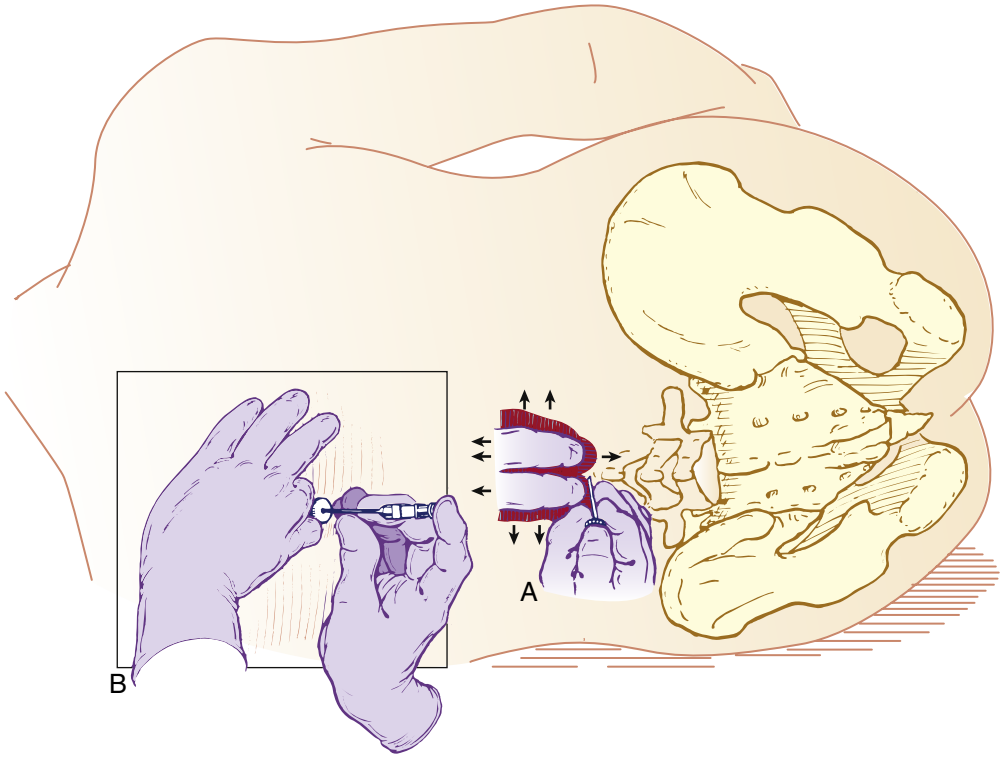

Figure 56-5. Insertion of the spinal needle. **A,** The palpating fingers are "rolled" in a side-to-side and a cephalad-to-caudad direction to identify the interspinous space. **B,** During needle insertion, the needle should be stabilized in a tripod fashion while placed in the hand, similar to a dart being thrown.

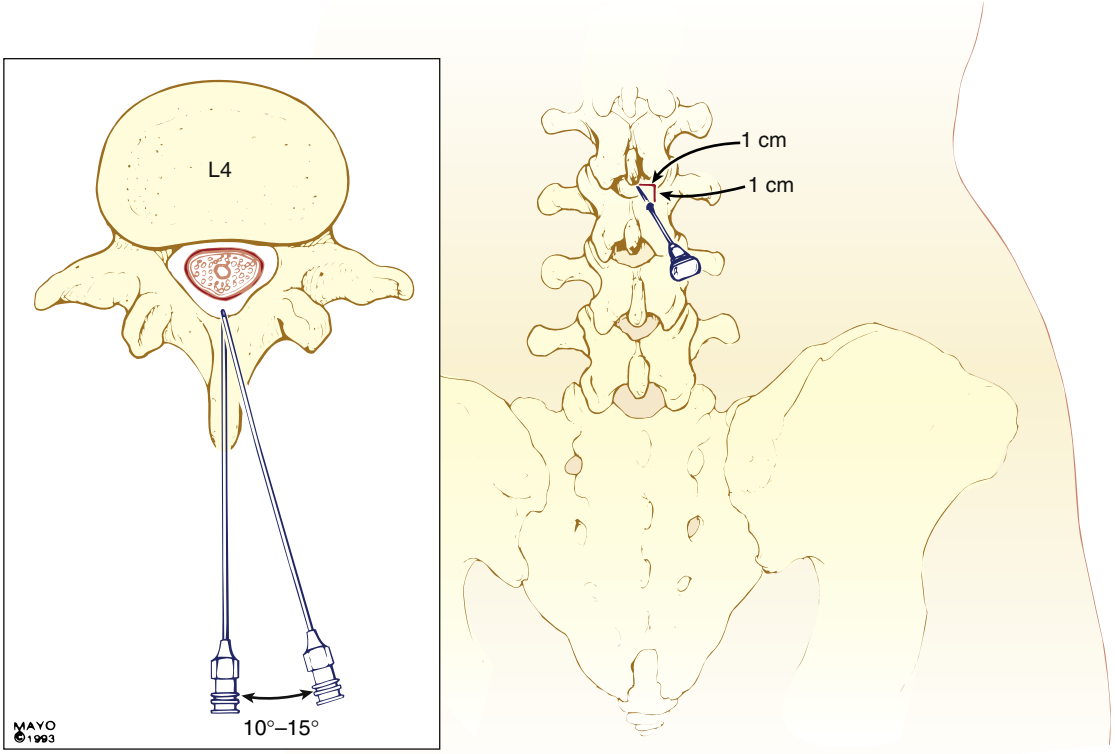

Figure 56-6. Vertebral anatomy of the midline and paramedian approaches to centroneuraxis blocks. The midline approach highlighted in the *inset* requires anatomic projection in only two planes: sagittal and horizontal. The paramedian approach shown in the *inset* and in the posterior view requires an additional oblique plane to be considered, although the technique may be easier in patients who are unable to cooperate in minimizing their lumbar lordosis. The paramedian needle is inserted 1 cm lateral and 1 cm caudad to the caudad edge of the more superior vertebral spinous process. The paramedian needle is inserted approximately 15 degrees off the sagittal plane, as shown in the inset. *(Courtesy of the Mayo Foundation, Rochester, Minn.)*

the needle is being "walked up" the lamina. As in the midline approach, the characteristic feel of the ligaments and dura is possible, but only once the ligamentum flavum is reached because the needle is this time not passing through the supraspinous and interspinous ligaments. After CSF is obtained, the block is carried out in a manner similar to that described for the midline approach.

SPECIAL SPINAL TECHNIQUES

Continuous Spinal Anesthesia

Continuous spinal anesthesia allows incremental dosing of local anesthetic and therefore predictable titration of the block to an appropriate level, with better hemodynamic stability than a single-shot spinal.[40] It is useful in controlling arterial blood pressure in such patients with severe aortic stenosis or pregnant women with complex cardiac disease. In obstetrics, it may also be used in patients with morbid obesity and where previous spinal surgery may hinder epidural spread. Spinal catheters also serve as an alternative to the combined spinal-epidural (CSE) technique for prolonged cases and have been used in selected patients for laparotomies where general anesthesia may be too great a risk.[234] If a continuous spinal anesthetic is undertaken, a needle with a laterally facing opening may be used to perform the lumbar puncture (Fig. 56-7). A midline or paramedian approach may be used, with some experts suggesting that use of the paramedian approach facilitates insertion of the catheter.[235] The catheter should be threaded 2 to 3 cm into the subarachnoid space and the needle withdrawn over the catheter. The catheter must never be withdrawn back into the needle shaft in case a piece of the catheter is sheared off and left in the subarachnoid space. Care must also be taken to ensure that the catheter is not inserted more deeply into the subarachnoid space when the needle is withdrawn over the catheter. Spinal microcatheters exist, but these have been associated with cauda equina syndrome,[5] probably because of lumbosacral pooling of local anesthetic. Catheter-over-the-needle devices are also available for use with continuous spinal anesthesia, with the advantage of minimizing leakage of CSF around the catheter,[236] but these may be more difficult to insert.[236] Finally, epidural doses of local anesthetic should not be infused or "bloused" into spinal catheters, and strict attention must also be paid to sterile technique.

Unilateral Spinal Anesthesia and Selective Spinal Anesthesia

The terms *unilateral spinal anesthesia* and *selective spinal anesthesia* overlap slightly, but both refer to small-dose techniques that capitalize on baricity and patient positioning to hasten recovery. A recent systematic review found that a dose of 4 to 5 mg of hyperbaric bupivacaine with unilateral positioning was adequate for knee arthroscopy.[171] This technique has also been used for unilateral inguinal hernia repair with a dose of 8 mg bupivacaine. In selective spinal anesthesia, minimal local anesthetic doses are used with the goal of anesthetizing only the sensory fibers to a specific area.[237,238] These doses are discussed in more detail in the chapter on anesthesia for ambulatory surgery (see Chapter 89).

BLOCK MONITORING

Once the spinal anesthetic has been administered, the onset, extent, and quality of the sensory and motor blocks must be assessed while heart rate and arterial blood pressure are also being monitored for any resultant sympathetic blockade. There are many methods of assessing sensory block, but cold sensation and pinprick representing C- and A-delta fibers, respectively, are used more

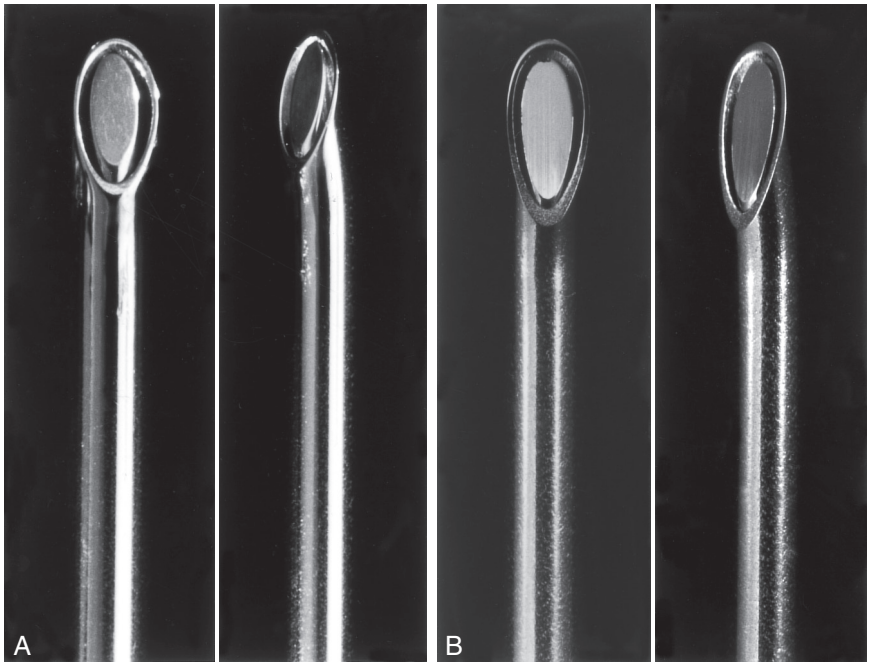

Figure 56-7. Examples of continuous spinal needles, including a disposable, 18-G Hustead **(A)** and a 17-G Tuohy **(B)** needle. Both have distal tips designed to direct the catheters inserted through the needles along the course of the bevel opening; 20-G epidural catheters are used with these particular needle sizes.

often than mechanical stimuli such as touch, pressure, and von Frey hairs, which reflect the A-beta nerves. Loss of sensation to cold usually occurs first, verified using an ethyl chloride spray, ice, or alcohol, followed by the loss of sensation to pinprick, verified using a needle that does not pierce the skin.[20] Finally, loss of sensation to touch occurs. Dermatomal block height also varies with the method of assessment, but in general, peak height is measured most cephalad using loss of cold, and is measured lower with pinprick, and lowest with touch.[239] Assessing dermatomal block height assumes that absence of sensation to these stimuli equates to blockade of the nociceptive fibers, but this is not necessarily the case.[240] Other electrical and experimental chemical methods of assessing pain have been used but gentle pinprick remains the simplest.[91,241] Motor block may also be measured in a variety of ways. The modified Bromage scale (Box 56-1) is most commonly used, although this represents only lumbosacral motor fibers.[242] Electromyography and pulmonary function tests have been used to measure abdominal and thoracic motor function, but these are neither practical nor specific.

In practice, the combination of sympathetic block with an adequate sensory level and motor block (inability to straight-leg raise ensures at least that lumbar nerves are blocked) are used to confirm spinal efficacy. Ensuring that the level of block using cold or pinprick is two to three segments above the expected level of surgical stimulus is commonly considered adequate.

EPIDURAL ANESTHESIA

FACTORS AFFECTING EPIDURAL BLOCK HEIGHT

The epidural space is a collapsible, distensible reservoir through which drugs spread and are removed by diffusion, vascular transport, and leakage. Spread of anesthetic within the epidural space, and subsequent block height, is related to a variety of factors, not all of which can be manipulated by the anesthesiologist (Table 56-5).[26]

BOX 56-1 *Modified Bromage Scale*

- 0: No motor block
- 1: Inability to raise extended leg; able to move knees and feet
- 2: Inability to raise extended leg and move knee; able to move feet
- 3: Complete block of motor limb

Drug Factors

The volume and total mass of injectate are the most important drug-related factors that affect block height after the administration of local anesthetic in the epidural space. As a general principle, 1 to 2 mL of solution should be injected per segment to be blocked. Although additives such as bicarbonate, epinephrine, and opioids influence onset, quality, and duration of analgesia and anesthesia, these do not affect spread.

Patient Factors

Age can influence epidural block height.[26] There appears to be a stronger correlation with age and block height in thoracic epidurals, with one study suggesting that 40% less volume is required in the elderly (see Chapter 80).[243] Possible reasons include decreased leakage of local anesthetic through intervertebral foramina, decreased compliance of the epidural space in the elderly resulting in greater spread, or an increased sensitivity of the nerves in the elderly. As with spinal anesthesia, it appears that only the extremes of patient height influence local anesthetic spread in the epidural space. Weight is not well correlated with block height in the settings of either lumbar or thoracic epidural anesthesia.[244] Less local anesthetic is required to produce the same epidural spread of anesthesia in pregnant patients. Although this may be in part a result of engorgement of epidural veins secondary to increased abdominal pressure, the effect also occurs in early pregnancy.[245]Also, continuous positive airway pressure increases the height of a thoracic epidural block.[246,247]

Procedure Factors

The level of injection is the most important procedural-related factor that affects epidural block height. In the upper cervical region, spread of injectate is mostly caudal, in the midthoracic region spread is equally cephalad and caudal, and in the low thoracic region spread is primarily cephalad.[248] After a lumbar epidural, spread is more cephalad than caudal. Some studies suggest that the total number of segments blocked is less in the lumbar region compared with thoracic levels for a given volume of injectate. Patient position has been shown to affect spread of lumbar epidural injections, with preferential spread and faster onset to the dependent side in

TABLE 56-5 **FACTORS AFFECTING EPIDURAL LOCAL ANESTHETIC DISTRIBUTION AND BLOCK HEIGHT**

	More Important	Less Important	Not Important
Drug Factors	Volume Dose	Concentration	Additives
Patient Factors	Elderly age Pregnancy	Weight Height Pressure in adjacent body cavities	
Procedure Factors	Level of injection	Patient position	Speed of injection Needle orifice direction

the lateral decubitus position.[249] The sitting and supine positions do not affect epidural block height. However, the head-down tilt position does increase spread in obstetric patients.[250] Needle bevel direction and speed of injection also do not appear to influence the spread of a bolus injection.

PHARMACOLOGY

Local anesthetics for epidural use may be classified into short-, intermediate-, and long-acting drugs. A single bolus dose of local anesthetic in the epidural space can provide surgical anesthesia ranging from 45 minutes up to 4 hours depending on the type of local anesthetic administered and the use of any additives (Table 56-6). Most commonly, an epidural catheter is left in situ so that local anesthetic–based anesthesia or regular analgesia can be extended indefinitely.

Short-Acting and Intermediate-Acting Local Anesthetics

Procaine. Similar to spinal anesthesia, procaine is not commonly used for epidural anesthesia. Five-percent procaine has a slow onset and the resultant block can be unreliable and of poor quality.

Chloroprocaine. Chloroprocaine is available preservative free in 2% and 3% concentrations for epidural injection, with the latter preferable for surgical anesthesia because the former may not produce muscle relaxation. The 3% preparation has an onset time of 10 to 15 minutes and a duration of up to 60 minutes. Adding epinephrine prolongs the block for up to 90 minutes. Before the development of preservative-free preparations, large volumes (>25 mL) of chloroprocaine had been associated with deep, aching, burning lumbar back pain.[251] This was thought to be secondary to the ethylenediaminetetraacetic acid that chelated calcium and caused a localized hypocalcemia. In addition, chloroprocaine can antagonize the effects of epidural morphine.[242] This may be a result of opioid receptor antagonism by either the chloroprocaine or a metabolite. Antagonism of an intracellular messenger and decreased morphine availability caused by a reduction in perineural pH are also proposed mechanisms. However, morphine and chloroprocaine seem like an illogical combination because the beneficial ultra-short duration of action of chloroprocaine is offset by the addition of morphine.

Articaine. Articaine is not widely used for epidural anesthesia and has not been studied extensively. When 2% articaine was compared with epidural lidocaine in one study, it had a similar latency, spread, duration, and motor block.[252] It has also been used for obstetric epidural analgesia.[148]

Lidocaine. Lidocaine is available in 1% and 2% solutions; it has an onset time of 10 to 15 minutes and a duration of up to 120 minutes, which can be extended to 180 minutes with the addition of epinephrine. Unlike spinal anesthesia, TNS is not commonly associated with epidural lidocaine.[253]

Prilocaine. Prilocaine is available in 2% and 3% solutions. The 2% solution produces a sensory block with minimal motor block. Onset time is approximately 15 minutes, with a duration of approximately 100 minutes. When compared with lidocaine, prilocaine has a more marked sensory blockade and a longer duration (different from Cousins).[242] In large doses, prilocaine is associated with methemoglobinemia.[156,254]

Mepivacaine. Mepivacaine is available as 1%, 1.5%, and 2% preservative-free solutions. The 2% preparation has an onset time similar to lidocaine of approximately 15 minutes, but a slightly longer duration (up to 200 minutes with epinephrine), making it a preferred option by some centers for surgery of an intermediate duration.

Long-Acting Local Anesthetics

Tetracaine. Tetracaine is not widely used for epidural anesthesia because of unreliable block height and, in larger doses, systemic toxicity.

Bupivacaine. Bupivacaine is available in 0.25%, 0.5%, or 0.75% preservative-free solutions. The onset time is around 20 minutes with a duration of up to 225 minutes, which is prolonged only slightly by the addition of epinephrine (to 240 minutes). More dilute concentrations such as 0.125% to 0.25% can be used for analgesia. However, disadvantages include cardiac and central nervous system toxicity and the potential for motor block

TABLE 56-6 **COMPARATIVE ONSET TIMES AND ANALGESIC DURATIONS OF LOCAL ANESTHETICS ADMINISTERED EPIDURALLY IN 20- TO 30-ML VOLUMES**

Drug	Concentration (%)	Onset (min)	Duration (min)	
			Plain	1:200,000 Epinephrine
2-Chloroprocaine	3	10-15	45-60	60-90
Lidocaine	2	15	80-120	120-180
Mepivacaine	2	15	90-140	140-200
Bupivacaine	0.5-0.75	20	165-225	180-240
Etidocaine	1	15	120-200	150-225
Ropivacaine	0.75-1.0	15-20	140-180	150-200
Levobupivacaine	0.5-0.75	15-20	150-225	150-240

Data from Cousins MJ, Bromage PR: Epidural neural blockade. In Cousins MJ, Bridenbaugh PO, editors: Neural blockade in clinical anesthesia and management of pain. *Philadelphia, 1988, JB Lippincott, pp 255.*

from larger doses. Solutions of 0.5% and 0.75% are used to provide surgical anesthesia. Liposomal bupivacaine is currently under investigation for epidural use. An epidural bolus of liposomal 0.5% bupivacaine provided similar onset but longer-lasting analgesia to boluses of plain bupivacaine.[255] It does not appear to be more toxic than plain bupivacaine or to have a differing cardiac safety profile. The benefit, as with extended-release morphine (discussed later), is the lack of need for an epidural catheter. Conversely, such extended-release boluses are less titratable if for any reason the epidural needs to be terminated early.

Levobupivacaine. Levobupivacaine can be used as an epidural local anesthetic in 0.5% to 0.75% concentrations for surgical anesthesia, whereas analgesia can be achieved with concentrations of 0.125% to 0.25%. Levobupivacaine administered epidurally has the same clinical characteristics as bupivacaine.[129,256,257] The advantage of levobupivacaine is that it is less cardiotoxic compared with bupivacaine.[175,258]

Ropivacaine. Ropivacaine is available in 0.2%, 0.5%, 0.75%, and 1.0% preservative-free preparations. For surgical anesthesia, 0.5% to 1.0% is used, whereas 0.1% to 0.2 % is used for analgesia. Ropivacaine is associated with a superior safety profile compared with bupivacaine.[259,260] Data from animal models suggest that bupivacaine has a 1.5 to 2.5 lower seizure threshold than ropivacaine. Ropivacaine is also less cardiotoxic. When compared with bupivacaine and levobupivacaine, ropivacaine at equivalent concentrations has a relatively similar clinical profile. Ropivacaine has a slightly shorter duration of action and less motor block, although the reduced motor block may in fact reflect different potencies of the drugs rather than a true motor-sparing effect of ropivacaine. Epidurally administered ropivacaine is 40% less potent than bupivacaine.[179,180,261]

Epidural Additives

Vasoconstrictors. Epinephrine reduces vascular absorption of local anesthetics in the epidural space. The local anesthetics vary in their responsiveness to epinephrine. The effect is the most with lidocaine,[262] mepivacaine, and chloroprocaine (up to 50% prolongation), with a lesser effect with bupivacaine, levobupivacaine, and etidocaine, and a limited effect with ropivacaine, which already has intrinsic vasoconstrictive properties (see Table 56-6). Epinephrine itself may also have some analgesic benefits because it is absorbed into the CSF, where it can act on dorsal horn α_2 receptors.[263] Phenylephrine has been used in epidural anesthesia less widely than in spinal anesthesia, perhaps because it does not reduce peak blood levels of local anesthetic as effectively as epinephrine does during epidural use.[264]

Opioids. Opioids synergistically enhance the analgesic effects of epidural local anesthetics, without prolonging motor block. A combination of local anesthetic and opioid reduces the dose-related adverse effects of each drug independently. The analgesic benefits of neuraxial opioids must be balanced against the dose-dependent side effects. As with intrathecal opioids, there appears to be a therapeutic ceiling effect above which only side effects increase. Opioids may also be used alone, particularly when there are concerns regarding hemodynamic instability. Epidural opioids work by crossing the dura and arachnoid membrane to reach the CSF and spinal cord dorsal horn. Lipophilic opioids, such as fentanyl and sufentanil, partition into epidural fat and therefore are found in lower concentrations in CSF than hydrophilic opioids, such as morphine and hydromorphone. Fentanyl and sufentanil are also readily absorbed into the systemic circulation, and several studies suggest that this is the principal analgesic mechanism.[265,266]

Epidural morphine is administered as a bolus of 1 to 5 mg, with an onset time of 30 to 60 minutes and duration of up to 24 hours. The optimal dose that balances analgesia while minimizing side effects is 2.5 to 3.75 mg.[267] Alternatively, morphine can be administered continuously in doses of 0.1 to 0.4 mg/hr through an epidural catheter. Hydromorphone is more hydrophilic than fentanyl but more lipophilic than morphine. It can be administered as a bolus of 0.4 to 1.5 mg, with onset at 15 to 30 minutes and a duration of 18 hours. Hydromorphone used as an infusion is delivered at rates between 5 and 20 μg/hr. The onset of epidural fentanyl and sufentanil is 5 to 15 minutes and lasts only 2 to 3 hours. Bolus doses of 10 to 100 μg may be used to provide analgesia. Diamorphine is available in the United Kingdom and used in doses of 2 to 3 mg as epidural boluses, or approximately 0.05 mg/mL in an infusion.

Depodur is an extended-release liposomal formulation of morphine used as a single-shot lumbar epidural dose, thereby avoiding issues and side effects of a continuous local anesthetic infusion and indwelling catheters, particularly in patients receiving anticoagulants. When administered before surgery (or after clamping of the cord in cesarean deliveries), Depodur can provide up to 48 hours of pain relief.[268,269] A dose of 10 to 15 mg is recommended for lower abdominal surgery, and 15 mg is recommended for major lower limb orthopedic surgery.

α_2-Agonists. Epidural clonidine can prolong sensory block to a greater extent than motor block. The mechanism appears to be mediated by the opening of potassium channels and subsequent membrane hyperpolarization[270] rather than an α_2-agonist effect. The addition of clonidine reduces both epidural local anesthetic and opioid requirements.[271-273] Other benefits of clonidine may include a reduced immune stress and cytokine response.[274] Epidural clonidine does have a variety of side effects including hypotension, bradycardia, dry mouth, and sedation. The cardiovascular effects may be greatest when clonidine is administered in the epidural space at the thoracic level.[275] In preliminary studies, epidural dexmedetomidine has also been shown to reduce intraoperative anesthetic requirements, improve postoperative analgesia, and prolong both sensory and motor block.[276]

Other Drugs. Conflicting reports exist regarding the benefit of epidural ketamine and whether it is neurotoxic.[277-279] Epidural neostigmine provides labor analgesia before local anesthetic infusion without causing respiratory depression,

hypotension, or motor impairment.[280] Midazolam, tramadol, dexamethasone, and droperidol have also been studied but are not commonly used.

Carbonation and Bicarbonate. Many local anesthetic preparations have a pH between 3.5 and 5.5 for chemical stability and bacteriostasis. At these low pHs, a higher proportion of the drug is in the ionized form and is therefore unable to cross nerve membranes to reach the internal binding site on sodium channels. Both carbonation of the solution and adding bicarbonate have been used in an attempt to increase the solution pH, and therefore the non-ionized free-base proportion of local anesthetic. Although carbonation may theoretically increase the speed of onset and quality of the block by producing more rapid intraneural diffusion and more rapid penetration of connective tissue surrounding the nerve trunk,[281,282] available data suggest that there are no clinical advantages for carbonated solutions.[235,283]

EPIDURAL TECHNIQUE

Preparation

Patient preparation as previously described for spinal anesthesia must equally be applied to epidural anesthesia, namely consent, monitoring, and resuscitation equipment, intravenous access, and choosing the patient and drugs appropriately depending on comorbidities and the nature of surgery. Sterility is arguably even more important than spinal anesthesia because a catheter is often left in situ. The extent of the surgical field must be understood so that the epidural may be inserted at the appropriate level—that is, the lumbar, low-, mid-, or high-thoracic, or less commonly, cervical.[26] A variety of epidural needles have been used for epidural anesthesia, but Tuohy needles are most common (Fig. 56-8). These needles are usually 16 to 18 g in size and have a 15- to 30-degree curved, blunt "Huber" tip designed to both reduce the risk of

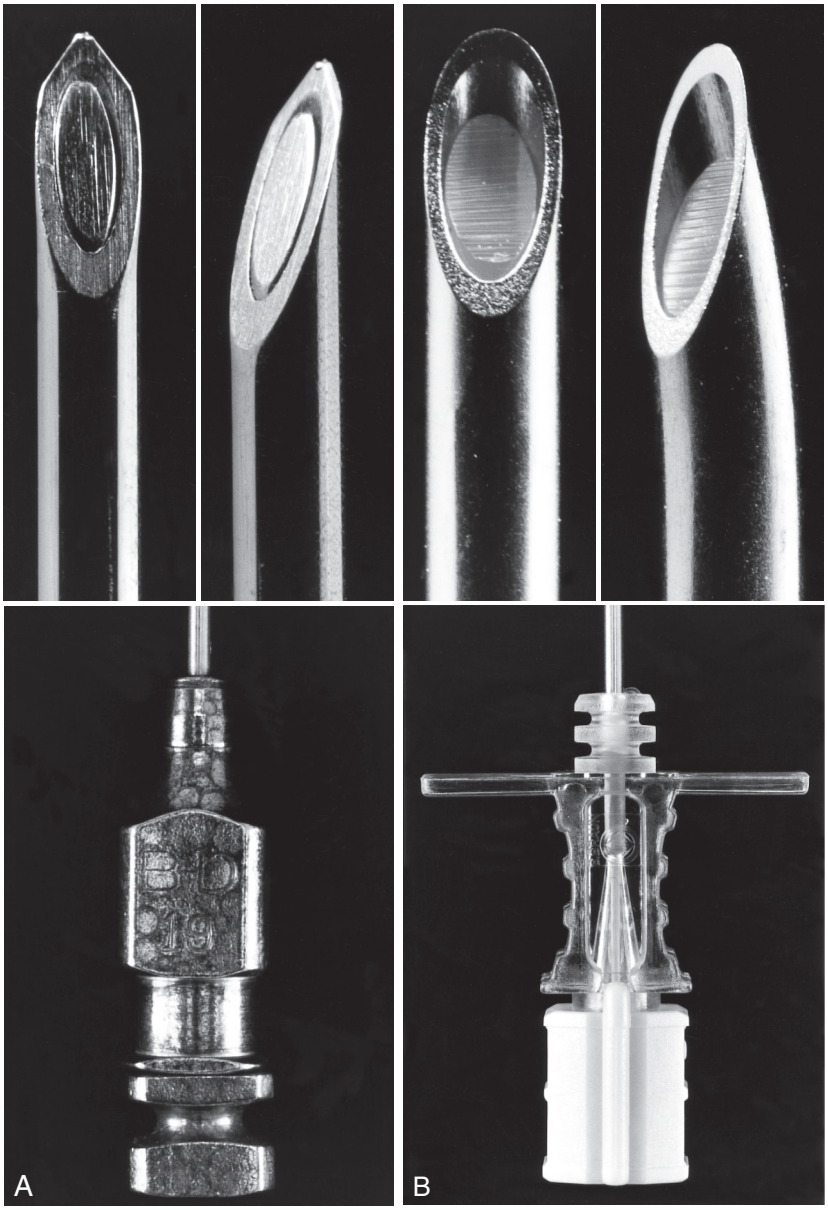

Figure 56-8. Epidural needles with catheter assortment. **A,** A 19-G reusable Crawford epidural needle. **B,** A 19-G disposable Tuohy needle.

Continued

accidental dural puncture and guide the catheter cephalad. The needle shaft is marked in 1-cm intervals so that depth of insertion can be identified. The catheter is made of a flexible, calibrated, durable, radiopaque plastic with either a single end hole or multiple side orifices near the tip. Several investigators have found that multiple-orifice catheters are superior, with a reduced incidence of inadequate analgesia.[284-286] However, the use of multiorifice catheters in pregnant women resulted in a more frequent incidence of epidural vein cannulation.[287]

The method of identifying the epidural space must also be predetermined. Most practitioners use a loss-of-resistance technique to either air or saline, rather than the hanging drop technique, both of which are described later. If a loss-of-resistance technique is used, an additional decision about the type of syringe (i.e., glass versus low-resistance plastic and Luer-Lok versus friction hub) is required.

Position

The sitting and lateral decubitus positions necessary for epidural puncture are the same as those for spinal anesthesia (see also Chapter 77). As before, inadequate positioning of the patient can complicate an otherwise meticulous technique. Shorter insertion times occur in the sitting position for thoracic epidurals compared with the lateral decubitus position, but ultimately, success rates are comparable.[288] As with spinal anesthesia, epidurals are performed with the patient awake.[76]

TABLE 56-7 **SUGGESTED EPIDURAL INSERTION SITES FOR COMMON SURGICAL PROCEDURES**

Nature of Surgery	Suggested Level of Insertion	Remarks
Hip surgery Lower extremity Obstetric analgesia	Lumbar L2-L5	
Colectomy, Anterior resection Upper abdominal surgery	Lower thoracic T6-T8	Spread more cranial than caudal
Thoracic	T2-T6	Midpoint of surgical incision

Modified from Visser WA, Lee RA, Gielen MJM: Factors affecting the distribution of neural blockade by local anesthetics in epidural anesthesia and a comparison of lumbar versus thoracic epidural anesthesia, Anesth Analg *107:708-721, 2008.*

Projection and Puncture

The level of needle insertion depends on the location of surgery (Table 56-7). Important surface landmarks include the intercristal line (corresponding to the L4-L5 interspace), the inferior angle of the scapula (corresponding to the T7 vertebral body), the root of the scapular spine (T3), and the vertebra prominens (C7). Ultrasonography may be useful to identify the correct thoracic space[233]; it is less commonly used for thoracic

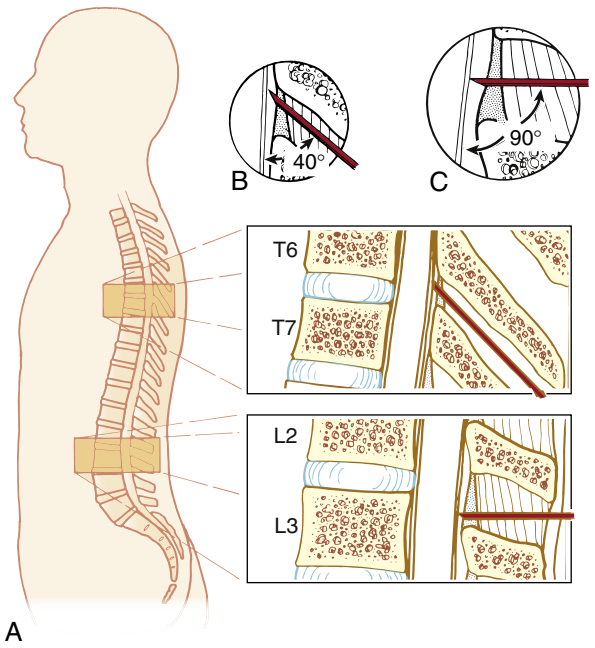

Figure 56-9. A, Lumbar and thoracic epidural technique. The increased angle of needle insertion during thoracic epidural cannulation may provide a slightly longer distance of "needle travel" before entering the subarachnoid space. In contrast to lumbar epidural cannulation **(B),** the distance traveled is modified by a more perpendicular angle of needle insertion **(C).**

epidural insertion, however, because the acoustic shadows make visualization of landmarks such as the ligamentum flavum and intrathecal space more difficult.[289] A variety of different needle approaches exist: midline, paramedian, modified paramedian (Taylor approach), and caudal.

A midline approach is commonly chosen for lumbar and low thoracic approaches. After local anesthetic infiltration of the skin, the nondominant hand can be rested on the back of the patient, with the thumb and index finger holding the needle hub or wing. The angle of approach should be only slightly cephalad in the lumbar and low-thoracic regions, whereas in the midthoracic region, the approach should be more cephalad because of the significant downward angulation of the spinous processes (Fig. 56-9). In a controlled fashion, the needle should be advanced with the stylet in place through the supraspinous ligament and into the interspinous ligament, at which point the stylet can be removed and the syringe attached. If it is in the correct location, the needle should rest firmly in the tissues. Some advocate needle placement in the ligamentum flavum for both the loss-of-resistance and hanging-drop methods before attaching the syringe, but this may be difficult, particularly for novices; however, this may allow an improved appreciation of epidural anatomy for the operator. If the needle is merely inserted into the supraspinous ligament and then loss-of-resistance or hanging-drop insertion is begun, there is an increased chance of false loss-of-resistance, possibly because of defects in the interspinous ligament.[290] Such false-positive rates can be as high as 30%.

Air or saline are the two most common noncompressible media used to detect a loss-of-resistance when identifying the epidural space. Each involves intermittent (for air) or constant (for saline) gentle pressure applied to the bulb of the syringe with the dominant thumb while the needle is advanced with the nondominant hand. A combination of air and saline may also be used, incorporating 2 mL of saline and a small (0.25 mL) air bubble. Usually the ligamentum flavum is identified as a tougher structure with increased resistance, and when the epidural space is subsequently entered, the pressure applied to the syringe plunger allows the solution to flow without resistance into the epidural space. There are reports that air is less reliable in identifying the epidural space, results in a higher chance of incomplete block, and may also cause both pneumocephalus (which can result in headaches) and venous air embolism in rare cases. If air is chosen, the amount of air injected after loss-of-resistance should therefore be minimized. A recent meta-analysis suggested that there was no difference in adverse outcome in the obstetric population when air or saline was used.[291] Another meta-analysis found that fluid inserted through the epidural needle before catheter insertion reduces the risk of epidural vein cannulation by the catheter.[287] One proposed disadvantage of using saline is that it may be more difficult to readily detect an accidental dural puncture.

An alternative method of identifying the epidural space is the hanging-drop technique. After the needle is placed into the ligamentum flavum, a drop of solution such as saline is placed within the hub of the needle. When the needle is advanced into the epidural space, the solution should be "sucked in." The theory behind this maneuver has traditionally been attributed to subatmospheric pressure in the epidural space, although recent experimental evidence in the cervical region suggests that using negative-pressure methods are poorly reliable and only useful in the sitting position.[292] The subatmospheric pressure has been related to expansion of the epidural space as the needle pushes the dura away from the ligamentum flavum.[293] The negative intrathoracic pressure may influence the pressure in the epidural space in the thoracic region and should be maximal during inspiration. Timing needle advancement to coincide with inspiration may be difficult, however.

When a lumbar midline approach is used, the depth from skin to the ligamentum flavum commonly reaches 4 cm, with the depth in most (80%) patients being between 3.5 and 6 cm; it can be longer or shorter in obese or very thin patients, respectively. Ultrasonography may be useful to predict the depth before needle insertion.[233] In the lumbar region, the ligamentum flavum is 5 to 6 mm thick in the midline. When a thoracic approach is chosen, needle control is of equal or greater importance because injury to the spinal cord is possible if the needle is advanced too far, although there are no data to suggest that approaching the epidural space at the lumbar level is any more or less safe than at the thoracic level. This may be partly because those using the thoracic technique are most often anesthesiologists with considerable experience in lumbar epidural anesthesia.[294] In addition, the increased angle of needle insertion in the thoracic region

may theoretically provide an element of safety in that the more acute angle necessary to gain access to the epidural space provides some margin of safety (see Fig. 56-9).

When the epidural space is identified, the depth of the needle at the skin should be noted. The syringe can then be removed and a catheter gently threaded to approximately the 15- to 18-cm mark to ensure a sufficient length has entered the epidural space. The needle can then be carefully withdrawn, and the catheter is withdrawn to leave 4 to 6 cm in the space. Catheter space less than 4 cm in length in the epidural space may increase the risk of catheter dislodgement and inadequate analgesia, whereas threading more catheter may increase the likelihood of catheter malposition or complications.[295-298]

As described earlier, a false loss-of-resistance can occur and is one of the causes of a failed block. The Tsui test may be used to confirm the epidural catheter position.[299] This test stimulates the spinal nerve roots with a low electrical current conducted through normal saline in the epidural space and an electrically conducting catheter. A metal-containing catheter must be used, with the cathode lead of the nerve stimulator connected to the catheter via an electrode adapter, whereas the anode lead is connected to an electrode on the patient's skin. At currents of approximately 1 to 10 mA, corresponding muscle twitches (i.e., intercostal or abdominal wall muscles for thoracic epidural catheters) can be used to identify catheter tip location. Subarachnoid and subdurally positioned epidural catheters elicit motor responses at a much lower threshold current (<1 mA), because the stimulating catheter is in very close or direct contact with highly conductive CSF.[300,301]

When the catheter is positioned at the desired depth, it must be secured to the skin. Commercial fixation devices exist, and some are superior to tape alone.[302] Tunneling can reduce catheter migration and improve lasting block success.[303] However, tunneling has not been compared with noninvasive catheter fixation devices in a well-designed study.

Paramedian Approach

The paramedian approach is particularly useful in the mid- to high thoracic region, where the angulation of the spine and the narrow spaces render the midline approach problematic. The needle should be inserted 1 to 2 cm lateral to the inferior tip of the spinous process corresponding to the vertebra above the desired interspace. The needle is then advanced horizontally until the lamina is reached and then redirected medially and cephalad to enter the epidural space. The Taylor approach is a modified paramedian approach via the L5-S1 interspace, which may be useful in trauma patients who cannot tolerate or are not able to maintain a sitting position. The needle is inserted 1 cm medial and 1 cm inferior to the posterior superior iliac spine and is angled medially and cephalad at a 45- to 55-degree angle.

Before initiating an epidural local anesthetic infusion, a test dose may be administered. The purpose of this is to exclude intrathecal or intravascular catheter placement. A small volume of lidocaine 1.5% with epinephrine is traditionally used for this purpose. A recent systematic review found reasonable evidence that 10 to 15 μg of epinephrine alone in nonpregnant adult patients was the best pharmacologic method of detecting intravascular placement, using endpoints of an increase in systolic blood pressure more than 15 mm Hg or an increase in heart rate more than 10 beats/min. The optimal method of detecting intrathecal or subdural placement, however, could not be ascertained.[304]

COMBINED SPINAL-EPIDURAL

Combined spinal-epidural anesthesia was first described in 1937 but has subsequently been modified over the past 30 years[305-310] and the CSE technique is now seeing increasing popularity. A CSE allows flexibility in a number of clinical settings because the more rapid onset of spinal block compared with epidural anesthesia allows the operative procedure to begin earlier, whereas the epidural catheter still provides both effective postoperative analgesia and allows anesthesia to be extended as the spinal resolves. This is particularly useful during labor, where opioid and a small dose of local anesthetic may be injected through a small spinal needle to provide rapid analgesia, whereas the epidural catheter can be used thereafter for both analgesia and surgical anesthesia if an operative delivery becomes necessary. Another significant advantage of CSE in general is the ability to use a low dose of intrathecal local anesthetic, with the knowledge that the epidural catheter may be used to extend the block if necessary. The addition of either local anesthetic or saline alone to the epidural space via the catheter compresses the dural sac and increases the block height. This latter technique is called epidural volume extension (EVE) and has been shown in cesarean delivery to provide a comparable sensory block to larger doses of intrathecal local anesthetic (with no epidural volume extension) but with significantly faster motor recovery.[311] The principle of using a lower dose of spinal anesthetic and titrating the epidural dose after the spinal anesthetic to reach the appropriate block height is a reduction in side effects,[312] with faster recovery, which can in turn potentially hasten discharge. This sequential technique also provides greater hemodynamic stability for high-risk patients using a lower initial mass of drug for spinal anesthetic, with subsequent gradual extension of the block if necessary using the epidural.

TECHNIQUE

The CSE technique most commonly involves placement of the epidural needle first, followed by either a "needle through needle" technique to reach the subarachnoid space or an altogether separate spinal needle insertion at either the same or different interspace. Some but not all studies have demonstrated greater success and lower failure rates with the separate needle insertion technique.[313-316] This method has the potential advantage of being able to confirm that the epidural catheter is functional before spinal anesthesia is administered, which, although it is time consuming, may be advantageous if the epidural catheter is to be relied upon for anesthesia when the spinal component resolves. Conversely, this method theoretically risks shearing the epidural catheter

that is already in situ. If a needle-through-needle technique is chosen, special CSE kits are available with long spinal needles, some of which can be locked in place for the subarachnoid injection.

CAUDAL ANESTHESIA

Caudal anesthesia is popular in pediatric anesthesia (see Chapter 93), but the technique also can be used in adults, although it is unpredictable when upper abdominal or thoracic spread is required. Its indications in adults therefore are essentially the same as those for lumbar epidural anesthesia, although it may be particularly useful when sacral anesthetic spread is desired (e.g., perineal, anal, rectal procedures), where a spinal surgery scar may prevent a lumbar anesthetic technique and, more commonly, in chronic pain and cancer pain management (see Chapter 64). The use of fluoroscopic guidance and, more recently, ultrasonography can help guide correct needle placement and reduce the rate of a failed block.[317] Ultrasonography is of even greater benefit in children because the lack of bony ossification allows visualization of both local anesthetic spread and the position of caudal epidural catheters.[318,319]

PHARMACOLOGY

The local anesthetics used are similar to those described for epidural anesthesia and analgesia. However, in adults approximately twice the lumbar epidural dose is required to achieve a similar block with the caudal approach. The spread is also variable, making this technique in adults unreliable for procedures above the umbilicus.

TECHNIQUE

Patient preparation as described before for spinal and epidural anesthesia must be equally applied to caudal anesthesia, namely consent, monitoring and resuscitation equipment, intravenous access, and the same asepsis precautions. Caudal anesthesia requires identification of the sacral hiatus. The sacrococcygeal ligament (i.e., extension of ligamentum flavum) overlies the sacral hiatus between the two sacral cornua. To facilitate locating the cornua, the posterior superior iliac spines should be located and, by using the line between them as one side of an equilateral triangle, the location of the sacral hiatus should be approximated (Fig. 56-10). Ultrasonography can also be used to identify these landmarks,[317-319] as can fluoroscopy. Three positions (see Chapter 41) are available for caudal anesthesia, with the prone position most often chosen in adults, the lateral decubitus position most chosen in children, and the knee-chest position the most infrequently used. The lateral decubitus position is used in children because it is easier to maintain a patent airway in this position than in the prone position, and the landmarks are more easily palpable than they are in adults (see Chapter 92). This consideration is valuable because caudal anesthesia is often combined with general anesthesia in pediatric patients to decrease the amount of volatile agent used intraoperatively or to provide postoperative analgesia. In contrast, a caudal block is often administered during preoperative sedation in adults and when the prone position is applicable. When placing a patient in the prone position, a pillow should be inserted beneath the iliac crests to rotate the pelvis and make cannulation of the caudal canal easier. An additional aid is to spread the lower extremities about 20 degrees with the heels rotated laterally, which minimizes gluteal muscle contraction and eases needle insertion.

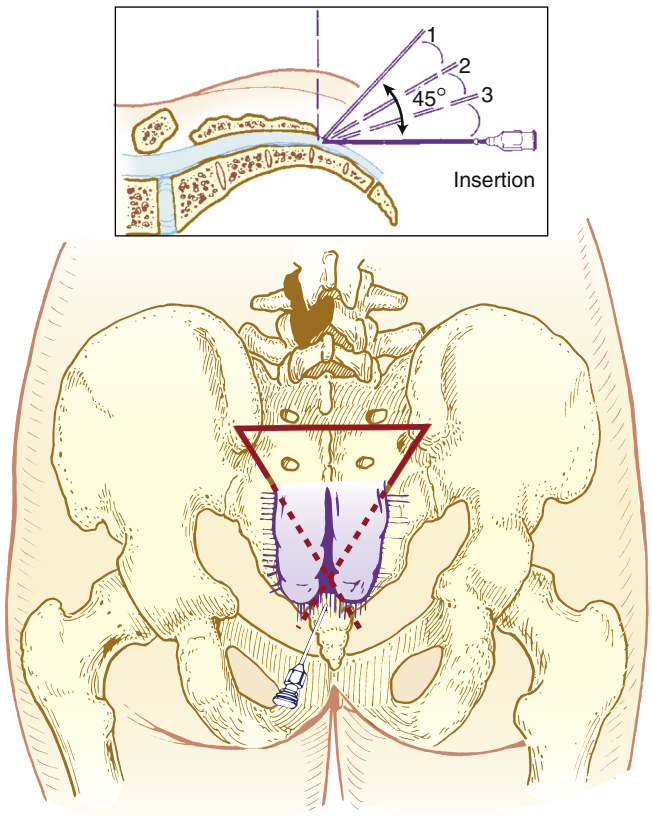

Figure 56-10. Caudal technique. Palpating fingers locate the sacral cornua by using the equilateral triangle. Needle insertion is completed by insertion and withdrawal in a stepwise fashion (*inset,* so-called 1-2-3 insertion) until the needle can be advanced into the caudal canal and the solution can be injected easily (without creation of a subcutaneous "lump" of fluid).

After the sacral hiatus is identified, the index and middle fingers of the palpating hand are placed on the sacral cornua, and after local infiltration, the caudal needle (or Tuohy needle if a catheter is to be placed) is inserted at an angle of approximately 45 degrees to the sacrum. While the needle is advanced, a decrease in resistance to needle insertion should be appreciated as the needle enters the caudal canal. The needle is advanced until bone (i.e., the dorsal aspect of the ventral plate of the sacrum) is contacted and then is slightly withdrawn, and the needle is redirected so that the angle of insertion relative to the skin surface is decreased. In male patients, this angle is almost parallel to the coronal plane; in female patients, a slightly steeper angle (15 degrees) is necessary. During redirection of the needle, loss-of-resistance is sought to confirm entry into the epidural space, and the needle advanced no more than approximately 1 to 2 cm into the caudal canal. In adults, the tip should never be advanced

beyond the S2 level (approximately 1 cm inferior to the posterior superior iliac spine), which is the level to which the dural sac extends. Additional advancement of the needle increases the risk of dural puncture, and unintentional intravascular cannulation becomes more likely. One method of increasing the likelihood of correct caudal needle placement is to inject 5 mL of saline rapidly through the caudal needle while palpating the skin overlying the sacrum. If no midline bulge is detected, the needle is probably positioned correctly. In contrast, if a midline bulge is detected during saline injection, the needle is positioned incorrectly.

After ensuring correct needle position and before injection of the therapeutic dose of caudal anesthetic, aspiration should be performed and a test dose administered because, as in lumbar epidural anesthesia, a vein or the subarachnoid space can be entered unintentionally.

COMPLICATIONS

The physiologic effects of neuraxial blocks may be misinterpreted as complications; however, clear distinction should be made between the physiologic effects of the neuraxial technique and complications, which imply some harm to the patient.[320] The material risks associated with neuraxial anesthesia must be intimately understood and respected because catastrophic injury is not unknown and serves to remind us that a person's nervous system is at the other end of the needle.[321]

NEUROLOGIC

Serious neurologic complications associated with neuraxial anesthesia are rare. As such, prohibitively large numbers of patients are required for study to estimate the frequency of these events. The true incidence of most neurologic injury after neuraxial anesthesia is unknown.

Paraplegia

The frequency of paraplegia related to neuraxial anesthesia is reported to be approximately 0.1 per 10,000,[322,323] and the mechanism of such a severe injury is likely multifactorial and difficult to identify for certain.[324] Although injury resulting from direct needle trauma to the spinal cord[325-329] may be self-evident, historical cases highlight the fundamental danger that accompanies the injection of a foreign substance into the CSF. The highly publicized cases of Woolley and Roe, two healthy, middle-aged men who became paraplegic after spinal anesthesia by the same anesthesiologist using the same drug on the same day for minor surgery at the same hospital in the United Kingdom in 1947, arguably set back the practice of spinal anesthesia for decades despite evidence that contamination by the descaling liquid used to cleanse the procedure tray had most likely been responsible.[4] Another example of catastrophic injury related to intrathecal injectate was the chloroprocaine neurotoxicity experience in the early 1980s, during which several patients developed adhesive arachnoiditis, cauda equina syndrome, or permanent paresis thought to be related to a combination of low pH and the antioxidant sodium bisulfite preservative used in early (and discontinued) preparations of the short-acting ester local anesthetic chloroprocaine.[136-139,330]

Profound hypotension or ischemia of the spinal cord can be important contributing factors in cases of paraplegia associated with neuraxial anesthesia. Anterior spinal artery syndrome, characterized by painless loss of motor and sensory function, is associated with anterior cord ischemia or infarction with sparing of proprioception, which is carried by the posterior column. The anterior cord is believed to be especially vulnerable to ischemic insult because of its single and tenuous source of arterial blood supply (the artery of Adamkiewicz). Ischemia caused by any one or a combination of profound hypotension, mechanical obstruction, vasculopathy, or hemorrhage can contribute to irreversible anterior cord damage.[331-333]

Cauda Equina Syndrome

The rate of cauda equina syndrome is approximately 0.1 per 10,000 and invariably results in permanent neurologic deficit.[322] The lumbosacral roots of the spinal cord may be particularly vulnerable to direct exposure of large doses of local anesthetic, whether it is administered as a single injection of relatively highly concentrated local anesthetic (e.g., 5% lidocaine)[334] or prolonged exposure to a local anesthetic through a continuous catheter.[5,335,336] The U.S. Food and Drug Administration withdrew approval for spinal catheters smaller than 24 G in size in 1992 because of concerns about a perceived association between the small-bore catheters and the development of cauda equina syndrome.[337] Although small-bore catheters can reduce the risk of headache, they can predispose to pooling of local anesthetic around the lumbosacral nerve roots, possibly because of slow injectate flow through the fine-bore catheter, thereby exposing them to high concentrations of local anesthetic. However, small-bore spinal catheters are being used effectively in Europe, and they are beginning to reappear in the United States, although it has taken nearly 15 years for them to emerge from the regulatory cloud of the early 1990s.[338]

Epidural Hematoma

Bleeding within the vertebral canal can cause ischemic compression of the spinal cord and lead to permanent neurologic deficit if not recognized and evacuated expeditiously. Many risk factors have been associated with the development of an epidural hematoma, including difficult or traumatic needle or catheter insertion,[339] coagulopathy, elderly age, and female gender.[340] Radicular back pain, prolonged blockade longer than the expected duration of the neuraxial technique, and bladder or bowel dysfunction are features commonly associated with a space-occupying lesion within the vertebral canal and should prompt magnetic resonance imaging on an urgent basis. Before the recently published United Kingdom National Health Service (NHS) audit, the largest contemporary studies report rates of epidural hematoma of less than 0.06 per 10,000 after spinal anesthesia, whereas the rates of epidural hematoma after epidural blockade may be as much as tenfold higher.[294,341-345] The United Kingdom NHS audit arguably provides the most accurate rates of neurologic complications associated with neuraxial anesthesia in contemporary practice. This unique prospective nationwide audit found five cases of epidural hematoma among 707,455 neuraxial

techniques (0.07 per 10,000), all of which occurred among 97,925 perioperative epidural techniques (0.5 per 10,000) performed over the course of 1 year.[323]

Nerve Injury

In 1955, Vandam and Dripps[346] were the first to capture data prospectively on nerve injury from more than 10,000 patients who underwent spinal anesthesia. No severe neurologic injuries occurred in this population. In 1969, Dawkins[347] published the classic review of neurologic complications after 32,718 epidural anesthetics and reported the frequency of transient and permanent nerve injury to be 0.1% and 0.02%, respectively. Despite interim advances in practice and research methodology, some of the largest contemporary studies available[341,344,348-350] suggest that the rate of neurologic injury related to neuraxial anesthesia is mostly unchanged compared with that reported nearly a half century ago. Most notable from these contemporary data are that epidural (including CSE) anesthesia is likely associated with a more frequent rate of radiculopathy or peripheral neuropathy compared with spinal anesthesia,[322] and that neuraxial anesthesia performed in adults for the purposes of perioperative anesthesia or analgesia is apparently associated with a higher likelihood of neurologic complications compared with that performed in the obstetric, pediatric, and chronic pain settings.[323,341,342,351,352] The rate of permanent nerve injury after neuraxial blockade is even more difficult to determine because methods of investigation and diagnosis, determination of causation, and reporting of outcomes are highly variable within the literature.[353] The United Kingdom NHS audit found the overall rate of permanent nerve injury to be 7 in 707,455 or 0.1 per 10,000,[323] which is remarkably similar to studies published a half century earlier by Dawkins. Three cases of nerve injury occurred among 293,050 epidurals (0.1 per 10,000), 3 among 324,950 spinal anesthetics (0.1 per 10,000), and 1 among 41,875 CSEs (0.2 per 10,000), mostly in young, healthy patients. Procedure-related risk factors traditionally associated with nerve injury after neuraxial anesthesia in the perioperative setting include radicular pain or paresthesia occurring during the procedure.[321,344,354,355]

Post–Dural Puncture Headache

A relatively common complication of neuraxial anesthesia is post–dural puncture headache. As the name implies, post–dural puncture headache is believed to result from unintentional or intentional puncture of the dura membrane in the setting of neuraxial anesthesia or after myelography and diagnostic lumbar puncture. There are two possible explanations for the cause of the headache, neither of which has ever been proven. First, the loss of CSF through the dura is proposed to cause traction on pain-sensitive intracranial structures as the brain loses support and sags. Alternatively, the loss of CSF initiates compensatory yet painful intracerebral vasodilation to offset the reduction in intracranial pressure.[356] The characteristic feature of a post–dural puncture headache is a frontal or occipital headache that worsens with the upright or seated posture and is relieved by lying supine. Associated symptoms can include nausea, vomiting, neck pain, dizziness, tinnitus, diplopia, hearing loss, cortical blindness, cranial nerve palsies, and even seizures. In more than 90% of cases, the onset of characteristic post–dural puncture headache symptoms will begin within 3 days of the procedure,[357] and 66% start within the first 48 hours.[358] Spontaneous resolution usually occurs within 7 days in the majority (72%) of cases, whereas 87% of cases resolve by 6 months.[359]

Post–dural puncture headache can occur in the setting of either spinal or epidural anesthesia, the former associated with certain modifiable risk factors during intentional dural puncture and the latter associated with unintentional puncture of the dura by advancing the Tuohy needle. Orienting a needle bevel parallel with the axis of the spine, such that the longitudinal fibers of the dura would more likely be separated than cut, results in a lower incidence of postspinal puncture headache.[360] This clinical observation has been supported by laboratory investigations[361] showing that simulated spinal puncture with cone-shaped (pencil-point) spinal needle tips produces slower transdural loss of fluid than a similar puncture with cutting tipped needles does. Indeed a meta-analysis has shown that noncutting needle tip designs have a lower frequency of post–dural puncture headache than do cutting spinal needle tip designs.[362] Other studies suggest that the collagen layers of the dura are oriented in a multidirectional fashion, not always in a cephalocaudad direction, and are variable in thickness, leading to the suggestion that damage to the longitudinal cells of the arachnoid membrane is more likely to be influenced by the type of bevel and may even be the predominant factor affecting post–dural puncture headache.[9] Reports vary as to whether the incidence of post–dural puncture headache is increased with the combined spinal-epidural technique compared with epidural alone.[363,364]

Aside from the type of needle tip (cutting versus pencil-point) and the bevel direction, there are additional risk factors common to the performance of both spinal and epidural anesthesia that contribute to the likelihood of developing a post–dural puncture headache. These risk factors are listed in Box 56-2.[365]

Conservative management for post–dural puncture headache includes supine positioning, hydration, caffeine, and oral analgesics. Sumatriptan has also been used with varying effect but is not without side effects.[366,367]

BOX 56-2 ***Relationships Among Variables and Post–Spinal Puncture Headache***

Factors That Can Increase the Incidence of Headache After Spinal Puncture

- Age: Younger, more frequent
- Sex: Females > males
- Needle size: Larger > smaller
- Needle bevel: Less when the needle bevel is placed in the long axis of the neuraxis
- Pregnancy: More when pregnant
- Dural punctures: More with multiple punctures

Factors That Do Not Increase the Incidence of Headache After Spinal Puncture

- Insertion and use of catheters for continuous spinal anesthesia
- Timing of ambulation

Epidural blood patch is the definitive therapy for postdural puncture headache.[368] This therapy was introduced by Gormley[369]; its safety and efficacy have been well-documented, and contemporary practice has validated that a single epidural blood patch continues to have a greater than 90% initial improvement rate[370] and persistent resolution of symptoms in 61% to 75% of cases.[371]

Epidural blood patch is ideally performed 24 hours after dural puncture and after the development of classic post–dural puncture headache symptoms. The efficacy of prophylactic epidural blood patching is not supported by evidence.[372,373] By injecting radionuclide-labeled red blood cells epidurally, Szeinfeld and co-workers[374] demonstrated that approximately 15 mL of blood will spread over a mean distance of nine spinal segments, and that the direction of spread was preferentially cephalad relative to the level of blood injection. As a result, these authors recommend inserting the blood patch needle at or caudad to the level of the previous culprit dural puncture. These findings have since been validated by magnetic resonance imaging of epidural blood patch spread.[375] A recent multinational, multicenter, randomized, blinded trial suggested that 20 mL of blood is a reasonable starting target volume.[376] A second epidural blood patch may be performed 24 to 48 hours after the first in the case of ineffective or incomplete relief of symptoms.

Transient Neurologic Symptoms

Traditionally associated with lidocaine, TNS have been described after intrathecal administration of every local anesthetic used for spinal anesthesia. TNS, previously known as transient radicular irritation,[377] is usually characterized by bilateral or unilateral pain in the buttocks radiating to the legs or, less commonly, isolated buttock or leg pain. Symptoms occur within 24 hours of the resolution of an otherwise uneventful spinal anesthetic and are not associated with any neurologic deficits or laboratory abnormalities.[378] The pain can range from mild to severe and typically resolves spontaneously in 1 week or less.[379] The likelihood of TNS is highest after intrathecal lidocaine and mepivacaine and is far less frequent with bupivacaine.[147,159,380] The phenomenon is related to the concentration of lidocaine,[147] the addition of dextrose or epinephrine, or solution osmolarity. The type of needle can influence the likelihood of TNS, with the rate reduced by a double-orifice needle,[381] possibly because single-orifice needles increase the risk of injecting anesthetic caudally in the thecal sac. TNS is not commonly associated with epidural procedures but has occurred with epidural lidocaine and other local anesthetics.[253,382] Finally, TNS occurs more commonly in patients who are placed in the lithotomy position for surgery. Nonsteroidal antiinflammatory drugs are the first line of treatment, but pain can be severe and may even require opioids.

CARDIOVASCULAR

Hypotension

Hypotension may be considered a complication of neuraxial blockade if the patient faces harm. In the setting of spinal anesthesia, hypotension (defined as systolic blood pressure <90 mm Hg) is more likely to occur with a variety of factors including peak block height greater than or equal to T5, age older than or equal to 40 years, baseline systolic blood pressure less than 120 mm Hg, combined spinal and general anesthesia, spinal puncture at or above the L2-L3 interspace, and the addition of phenylephrine to the local anesthetic.[51] Hypotension (defined as a reduction in mean arterial blood pressure >30%) is independently associated with chronic alcohol consumption, history of hypertension, BMI, and the urgency of surgery.[383] Nausea is a common symptom of hypotension in the setting of neuraxial anesthesia, as are vomiting, dizziness, and dyspnea. Although prevention of hypotension caused by vasodilatation by a prophylactic ("preloading") infusion of colloid or crystalloid during the performance of the neuraxial block ("coloading") has been reported,[384] this is no longer recommended as a routine practice.[384]

Bradycardia

The development of severe bradycardia after spinal anesthesia has long been recognized as an important risk of spinal anesthesia.[385,386] Bradycardia stems from blockade of the thoracic sympathetic fibers (preganglionic cardiac accelerator fibers originating at T1-T5), as well as reflexive slowing of the heart rate as vasodilation reduces the venous return to the right atrium where stretch receptors respond by a compensatory slowing of the heart rate. Factors that may increase the likelihood of exaggerated bradycardia (40 to 50 beats/min) include baseline heart rate less than 60 beats/min, age younger than 37 years, male gender, nonemergency status, β-adrenergic blockade, and prolonged case duration. Severe bradycardia (<40 beats/min) is associated with a baseline heart rate less than 60 beats/min and male gender.[387]

Cardiac Arrest (Also see Chapter 108)

In a review of closed insurance claims, Caplan and associates[388] identified 14 cases of sudden cardiac arrest in healthy patients receiving spinal anesthesia. The etiology of sudden cardiac arrest after spinal anesthesia is not understood. Whether these catastrophic events represented lack of vigilant monitoring and treatment as opposed to some mysterious physiologic explanation is not known.[389] The latter notwithstanding, it is clear that hypoxemia and oversedation are complicit in the severe bradycardia and asystole that can occur suddenly during well-conducted spinal anesthesia.[390,391] Curiously, these rare events seem to be preferentially associated with spinal anesthesia rather than epidural techniques. In their inaugural survey of French anesthesiologists, Auroy and colleagues reported the rate of cardiac arrest to be 6.4 per 10,000 after spinal anesthesia compared with 1 per 10,000 for all other neuraxial and peripheral regional anesthesia techniques combined.[344] In their larger follow-up survey of all anesthesiologists in France, Auroy and colleagues[350] reported 10 cases of cardiac arrest after 35,439 spinal anesthetics (2.5 per 10,000) and none after 5,561 epidural techniques. Most recently, Cook and colleagues uncovered three cases of cardiovascular collapse among 707,425 neuraxial blocks (0.04 per 10,000) during their nationwide audit, two of

which were during spinal anesthesia and one in the setting of CSE.[323]

RESPIRATORY

Neuraxial opioids are commonly added to local anesthetic solutions to improve the quality and duration of neuraxial anesthesia and analgesia. The risk of respiratory depression associated with neuraxial opioids is dose-dependent, with a reported frequency that approaches 3% after the administration of 0.8 mg of intrathecal morphine.[392] Respiratory depression may stem from rostral spread of opioids within the CSF to the chemosensitive respiratory centers in the brainstem.[65] With lipophilic anesthetics, respiratory depression is generally an early phenomenon occurring within the first 30 minutes; respiratory depression has never been described more than 2 hours after the administration of intrathecal fentanyl or sufentanil.[225] With intrathecal morphine, there is a risk of late respiratory depression, occurring as much as 24 hours after injection. Respiratory monitoring for the first 24 hours after the administration of intrathecal morphine is therefore advisable. Patients with sleep apnea can be especially sensitive to the potent respiratory-depressant effects of opioid medications and although definitive safety data evidence is lacking, the decision to administer neuraxial opioids to these patients is made with considerable caution.[393,394] Older patients also have a higher risk of respiratory depression, and the dose of neuraxial opioids should be reduced in this population (see Chapter 80). Coadministration of systemic sedatives also increases this risk.

INFECTION

Bacterial meningitis and epidural abscess are rare, but potentially catastrophic, infectious complications of all neuraxial techniques. Sources of infection in neuraxial procedures include the equipment, the patient, or the practitioner. Staphylococcal infections arising from the patient's skin are one of the most common epidural-related infections, whereas oral bacteria such as *Streptococcus viridans* are a common cause of infection after spinal anesthesia, underscoring the need for the clinician to wear a facemask when performing neuraxial procedures. Other factors that may increase the likelihood of infection include the presence of a concomitant systemic infection, diabetes, immunocompromised states,[90] and prolonged maintenance of an epidural (or spinal) catheter. Large contemporary studies estimate the rate of serious neuraxial infection to be less than 0.3 per 10,000[341,348,350] for spinal anesthesia, whereas infectious complications after epidural techniques may be at least twice as common.[341,348,350,395,396,397] Obstetric patients are less likely to develop deep infections related to epidural analgesia. The recent United Kingdom NHS audit reported no cases of meningitis and eight cases of epidural abscess after 707,455 neuraxial techniques, five of which occurred among 293,050 epidural techniques, two among 324,950 spinal anesthetics, and one among 47,550 caudal blocks.[323] In 2004, ASRA published practice guidelines regarding the prevention of infectious complications associated with regional anesthesia, specifically addressing (1) the importance and implications of aseptic techniques during regional anesthesia,[229] (2) regional anesthesia in the febrile or infected patient,[90] (3) regional anesthesia in the immunocompromised patient,[398] and (4) infectious risk of chronic pain treatments.[399] These guidelines concluded that chlorhexidine in an alcohol base is the most effective antiseptic for the purposes of neuraxial techniques.[229] Concerns regarding neurotoxicity associated with the routine use of chlorhexidine have not been confirmed.[230,231]

Aseptic meningitis occurred mostly in the early twentieth century, likely secondary to chemical contamination and detergents, which are no longer present in modern preservative-free preparations.

BACKACHE

Back injury is perhaps the most feared complication of neuraxial anesthesia among patients.[400] Nonetheless, approximately 25% of all surgical patients undergoing anesthesia, regardless of anesthetic technique, experience backache, the incidence of which increases to 50% when surgery lasts 4 to 5 hours.[401] There is no association between epidural analgesia and new-onset back pain up to 6 months postpartum.[402,403] Moreover, in a randomized, controlled trial comparing epidural versus systemic analgesia for pain relief during labor, the rates of postpartum back pain were identical between groups, suggesting that the neuraxial techniques do not play a role in the development of back pain after delivery.

NAUSEA AND VOMITING

There are multiple possible mechanisms that contribute to nausea and vomiting in the setting of neuraxial anesthesia, including direct exposure of the chemoreceptive trigger zone in the brain to emetogenic drugs (e.g., opioids), as well as hypotension associated with generalized vasodilation and gastrointestinal hyperperistalsis secondary to unopposed parasympathetic activity (see also Chapter 97).[404] Although regional anesthesia is often recommended as an alternative to general anesthesia for patients at risk for postoperative nausea and vomiting, there are few studies that have primarily investigated the effects of neuraxial anesthesia on postoperative nausea and vomiting with sufficient statistical power. Factors associated with developing nausea or vomiting after spinal anesthesia include the addition of phenylephrine or epinephrine to the local anesthetic, peak block height greater than or equal to T5, baseline heart rate greater than 60 beats/min, use of procaine, history of motion sickness, and the development of hypotension during spinal anesthesia. Among the opioids commonly added to intrathecal or epidural local anesthetics, morphine administration has the most frequent risk of nausea or vomiting, whereas fentanyl and sufentanil carry the least frequent risk.[404] Neuraxial opioid-related nausea and vomiting appears to be dose-dependent. Using less than 0.1 mg morphine reduces the risk of nausea and vomiting, without compromising the analgesic effect.[225]

URINARY RETENTION

Urinary retention can occur in as much as one third of patients after neuraxial anesthesia. Local anesthetic blockade of the S2, S3, and S4 nerve roots inhibits urinary function as the detrusor muscle is weakened. Neuraxial opioids can further complicate urinary function by suppressing detrusor contractility and reducing the sensation of urge.[405] Spontaneous return of normal bladder function is expected once the sensory level decreases to below S2-3.[406] Although male gender and age have been (albeit inconsistently) linked to urinary retention after neuraxial anesthesia, the administration of intrathecal morphine is strongly associated with this complication.[405,407,408]

PRURITUS

Pruritus can be distressing to the patient. It is the most common side effect related to the intrathecal administration of opioids, with rates between 30% and 100%.[225] Pruritus actually occurs more commonly after intrathecal opioid administration than after intravenous opioid administration and is not dependent on the type or dose of opioid administered. Reducing the dose of intrathecal sufentanil from 5 μg to as little as 1.5 μg can reduce the likelihood of pruritus without compromising analgesia when added to hyperbaric bupivacaine for cesarean delivery (see Chapter 77).[409] The mechanism of pruritus is unclear but is likely related to the central opioid receptor activation rather than histamine release because naloxone, naltrexone or the partial agonist nalbuphine can be used for treatment. Ondansetron and propofol are also useful therapies.

SHIVERING

The rate of shivering related to neuraxial anesthesia is as frequent as 55%.[410] The intensity of shivering is likely related more to epidural anesthesia than spinal.[411] Although there are multiple possible explanations for the difference in shivering intensity, this observation may simply be related to the inability to shiver because of the profound motor block associated with spinal anesthesia compared with epidural techniques. Another explanation may be the relatively cold temperature of the epidural injectate, which can affect the thermosensitive basal sinuses.[410] The addition of neuraxial opioids, specifically fentanyl and meperidine, reduces the likelihood of shivering.[410] Recommended strategies to prevent shivering after neuraxial anesthesia include prewarming the patient with a forced air warmer for at least 15 minutes and avoiding the administration of cold epidural and intravenous fluids.

COMPLICATIONS UNIQUE TO EPIDURAL ANESTHESIA

Intravascular Injection

Epidural anesthesia can produce local anesthetic–induced systemic toxicity (see Chapter 36), primarily through the unintentional administration of drug into an epidural vein. The frequency of vascular puncture with the needle or cannulation with the catheter can reportedly approach 10%, with the highest rates seen in the obstetric population, where these vessels are relatively dilated and more vulnerable to entry.[287,412] The rate of seizures related to epidural anesthesia may be as frequent as 1%.[294,344,350] In obstetrics (see also Chapter 77), the likelihood of intravascular injection is decreased by placing the patient in the lateral (as opposed to the sitting) position during needle and catheter insertion, administering fluid through the epidural needle before catheter insertion, using a single-orifice rather than multi-orifice catheter or a wire-embedded polyurethane compared with polyamide epidural catheter, and advancing the catheter less than 6 cm into the epidural space. The paramedian as opposed to the midline needle approach, and the use of a smaller-gauge epidural needle or catheter, does not reduce the risk of epidural vein cannulation.[287]

One of the most controversial issues related to epidural anesthesia has been the use of an epinephrine-containing test dose.[413] Epinephrine (15 μg) in 3 mL of local anesthetic remains the best pharmacologic method of detecting intravascular placement in nonpregnant adult patients.[304] However, controversy surrounds the use of epinephrine in obstetric patients, in whom uterine blood flow may be decreased by the intravascular injection, thereby putting the fetus at risk, and where the cardiovascular changes occurring in active labor may represent a false-positive response to epinephrine. Although epinephrine may place the fetus at risk in theory,[414] no such case has been described. The epidural epinephrine test dose can be unreliable in patients receiving β-adrenergic blockers[415] or if the test dose is administered during general anesthesia.[416] Because there is no fail-safe method of guaranteeing an extravascular location of an epidural local anesthetic, prevention of systemic toxicity should also involve aspiration of the catheter and incremental administration of the local anesthetic. The onset of block, quality of the block, and block height are unaffected by administration of the epidural drug in 5-mL fractions.[417]

Subdural Injection

Blomberg[418] used a fiberoptic technique to demonstrate that the subdural extra-arachnoid space is easily entered in 66% of autopsy attempts in humans. Despite this being an infrequent clinical problem with epidural anesthesia (<1%), it does allow a visual understanding of the subdural complications of epidural anesthesia.[419] This space, unlike the epidural space, also extends intracranially. When an epidural block is performed and a higher-than-expected block develops, but only after a delay of 15 to 30 minutes (unlike a total spinal), subdural placement of local anesthetic must be considered. With a subdural block, the motor block will be modest compared to the extent of the sensory block, and the sympathetic block may be exaggerated. The treatment is symptomatic.

COMPLICATIONS UNIQUE TO COMBINED SPINAL-EPIDURALS

The risk of metal toxicity from abraded spinal needle particles using the needle-through-needle technique has not been confirmed.[420]

OUTCOMES

Although the benefit of properly applied epidural anesthesia and analgesia as an excellent pain relief modality is unquestionable, its effect on postoperative morbidity and mortality is less clear. Several recent meta-analyses showed a relative risk reduction in overall mortality in patients receiving neuraxial blockade, by as much as 30% in patients undergoing all types of surgery[421] to 11% in patients undergoing intermediate- to high-risk noncardiac surgery.[422] For cardiac surgery, recent meta-analyses showed a reduced risk of mortality and myocardial infarction (composite endpoint), a reduced risk for acute renal failure, pulmonary complications, and supraventricular arrhythmia; and reduced duration of postoperative controlled ventilation in patients who received combined intraoperative general anesthesia and thoracic epidural anesthesia.[74,423] For major thoracic and abdominal surgery, thoracic epidural analgesia reduced mortality, respiratory complications, and opioid consumption and improved cough and time to ambulation.[424,425] However, the effect of epidural analgesia on postoperative outcomes is not consistent, and it may be procedure-specific (particularly advantageous for thoracic surgery) and technique-specific (i.e., thoracic epidural is more advantageous than lumbar epidural, and epidural local anesthetic is more advantageous than epidural opioid).

Mortality and morbidity aside, there are other advantages of neuraxial blockade. For bilateral total knee arthroplasty, neuraxial anesthesia decreases the rate of blood transfusion.[426] In patients undergoing major vascular and abdominal surgery, thoracic epidural local anesthetic infusion can reverse postoperative paralytic ileus associated with pain-induced sympathetic overactivity and systemic opioid.[427] Lumbar epidural infusion or thoracic epidural opioid infusion alone does not speed intestinal function recovery. For fast-track laparoscopic colon resection, thoracic epidural analgesia provides superior pain relief but fails to speed intestinal function recovery or hospital discharge time.

What are the potential effects of neuraxial anesthesia on stress response, the immune system, and cancer recurrence?[428-430] Functional cell-mediated immunity is required for monitoring and eradicating cancer cell growth. Lymphocytes, such as the natural killer (NK) cells and the cytotoxic T lymphocytes, can lyse the cancer cell through the perforin and granzyme pathway or through secretion of cytokines (e.g., interferons) to induce cancer cell apoptosis. In addition, the helper T cells control tumor angiogenesis through interferons, inhibit oncogenic signaling, and stimulate tumor destruction by engaging macrophages and granulocytes through interleukin production. There is an inverse relationship between NK cell activity at the time of surgery and the development of metastatic disease. Systemic cancer cell seeding happens during surgical dissection and manipulation. Unfortunately, this happens at a time of significant immunosuppression. Surgically induced stress hormone (e.g., corticosteroids), as well as inhaled volatile anesthetics and systemic opioids (morphine and fentanyl), can diminish NK cell function. Morphine also has proangiogenic properties that may promote dissemination of angiogenesis-dependent tumors. Thoracic epidural anesthesia and analgesia may be beneficial by virtue of its opioid and general anesthetic sparing and surgical stress–alleviating properties. Some encouraging data indicate a reduction of cancer recurrence associated with the use of perioperative epidural anesthesia and analgesia in patients undergoing retropubic prostatectomy,[431,432] rectal cancer,[433] and ovarian cancer resection.[434,435]

RECENT ADVANCES

ULTRASOUND

There is a growing interest in ultrasound imaging to guide neuraxial blockade, because it can accurately identify the intervertebral levels, the midline spinous process, the midline interspinous window, and the paramedian interlaminar window (see also Chapter 58).[233] Bone does not permit ultrasound beam transmission, thus casting a hypoechoic (dark) shadow on the image. Conversely, passage of the ultrasound beam through the interspinous and interlaminar windows allows visualization of the hyperechoic dura (a bright line), the subarachnoid space, and the posterior aspect of the vertebral body.[436] Visualization of the ligamentum flavum and epidural space is often more difficult. Successful transverse or longitudinal scan facilitates identification of the optimal location for proper needle insertion during neuraxial block and an estimation of the skin-to-dura distance. This is particularly useful in patients with difficult surface anatomic landmarks (e.g., obesity), spine pathology (e.g., scoliosis), and previous spine surgery (e.g., laminectomy).[437]

Ultrasound-facilitated neuraxial block involves preprocedure scanning of the spine to determine the best possible intervertebral level and window for needle insertion without actual real-time guidance (a highly challenging technique). Imaging of the lumbar spine is significantly easier than that of the thoracic spine, which has narrow interspinous and interlaminar windows, especially at T5-T8 levels.[438] Ultrasonography in the pediatric population is impressive because the vertebral column with limited ossification not only permits visualization of the spinal canal sonoanatomy, but the inserted needle and catheter tip, dural displacement, and the extent of cranial spread can be visualized during a fluid bolus injection in young infants and children (also see Chapter 93).[439,440] Several outcome studies have confirmed the utility of ultrasonography when neuraxial block is performed by the novice and in patients with difficult anatomic landmarks.[441]

Chapter 57

Peripheral Nerve Blocks

TERESE T. HORLOCKER • SANDRA L. KOPP • DENISE J. WEDEL

Key Points

- Regional anesthesia is only successful when local anesthetic is inserted in close proximity to the targeted nerves. From the inception of regional anesthesia over a century ago, there have been several techniques designed and available to facilitate the correct placement of local anesthetic, including paresthesia-seeking, peripheral nerve stimulator, and most recently ultrasound guidance.
- Continuously administered peripheral nerve block improves outcome and rehabilitation after major surgery to the extremities, including surgery to the knee, hip, and shoulder.
- Total local anesthetic dosage should be determined and kept within acceptable limits. Accumulation may occur with continuous techniques.
- The frequency of neurologic complications after peripheral blockade is less than that associated with neuraxial techniques. Neurotoxicity and direct needle trauma are the major causes of neurologic complications.
- There are no data to support the superiority of one nerve localization technique—paresthesia, nerve stimulation, ultrasound—over another with regard to reducing the risk of nerve injury.
- A lipid infusion improves success of resuscitation from cardiac arrest because of local anesthetic toxicity if given immediately after a local anesthetic overdose (see Chapter 36)

The techniques of peripheral neural blockade were developed early in the history of anesthesia. The American surgeons Halsted and Hall[1,2] described the injection of cocaine into peripheral sites, including the ulnar, musculocutaneous, supratrochlear, and infraorbital nerves, for minor surgical procedures in the 1880s. James Leonard Corning[3] recommended the use of an Esmarch bandage in 1885 to arrest local circulation, prolonging the cocaine-induced block and decreasing the uptake of that local anesthetic from the tissues. This concept was furthered by Heinrich F.W. Braun,[4] who substituted epinephrine, a "chemical tourniquet," in 1903. Braun[5] also introduced the term *conduction anesthesia* in his 1905 textbook on local anesthesia, which described techniques for every region of the body. In 1920, the French surgeon Gaston Labat was invited by Charles Mayo to teach innovative methods of regional anesthesia at the Mayo Clinic. During his appointment there, Labat authored *Regional Anesthesia: Its Technic and Application*.[6] The book was considered the definitive text on regional anesthesia for at least 30 years after its publication. Labat's textbook focused on the intraoperative management of patients undergoing intraabdominal, head, neck, and extremity procedures using infiltration, peripheral, plexus, and splanchnic blockade. Neuraxial techniques were not widely applied at the time.

The use of peripheral nerve blockade has grown in popularity because it decreases pain as assessed by visual analog scale scores postoperatively, decreases the need for postoperative analgesics, decreases the incidence of nausea, shortens postanesthesia care unit time, and increases patient satisfaction.[7] Peripheral nerve blocks can be customized and used for anesthesia, postoperative analgesia, and diagnosis and treatment of chronic pain disorders (see Chapters 64 and 98). The regional technique chosen depends on the surgical site, the anticipated length of the procedure, ambulation requirements, and the desired duration of postoperative pain control. Detailed anatomic knowledge enables the anesthesia provider to choose the appropriate technique for the intended surgical procedure and to salvage inadequate nerve blocks with local anesthetic supplementation. In addition, important side effects and complications of peripheral regional techniques must be understood. With appropriate selection

and sedation, these techniques can be used in all age groups. Skillful application of peripheral neural blockade broadens the anesthesia provider's range of options in providing optimal anesthetic care.

TECHNIQUES FOR LOCALIZING NEURAL STRUCTURES

PARESTHESIA TECHNIQUES

The paresthesia-seeking technique has a long, successful history as a simple technique that requires little specialized equipment. A paresthesia is elicited when a needle makes direct contact with a nerve. Paresthesia-seeking techniques are reliant on patient cooperation and participation to guide the local anesthetic injection accurately; therefore, only small doses of sedation medication are recommended. Paresthesia techniques have been criticized for causing patient discomfort, although clinical studies have not shown a significant increase in neurologic complications with this technique.[8] Caution should be used when initiating the injection of local anesthetic to ensure that the needle is not intraneural. There is controversy in the literature regarding the use of B-bevel (blunt bevel or short bevel) needles versus sharp needles regarding the incidence and severity of nerve injury if the needle inadvertently contacts the nerve. Because B-bevel needles have a blunt tip, which is likely to push the nerve aside, they are much less likely to penetrate the nerve; however, when an injury does occur, it appears to be more severe.[9] In contrast, sharp needles are more likely to penetrate the nerve, but the injury appears to be less destructive.[10] Success with the paresthesia technique is highly dependent on the skill of the practitioner and requires a thorough understanding of anatomy. This technique was slowly replaced by many in the 1980s when peripheral nerve stimulation was introduced. Currently, no single technique has been shown to be superior with respect to success rate or incidence of complications.

PERIPHERAL NERVE STIMULATION

Peripheral nerve stimulators transmit a small electric current to the end of a stimulating needle that will cause depolarization and muscle contraction when the tip of the needle is in close proximity to a neural structure. This technique allows for localization of a specific peripheral nerve without requiring the elicitation of a paresthesia, thus allowing patients to be more heavily sedated during block placement. A thorough understanding of anatomy is a prerequisite to this technique and all techniques of peripheral nerve blockade. It is necessary to attach the cathode (negative terminal) to the stimulating needle and the anode (positive terminal) to the surface of the patient because depolarization occurs as the cathode allows current to flow from the needle to the adjacent nerve. Current flows away from the needle causing hyperpolarization if the terminals are reversed. Most current-stimulating needles are coated with a thin layer of insulation along the needle with the exception of the tip. This allows for a more discrete field of stimulation only at the tip of the needle. Higher current output (>1.5 mA) is more likely to stimulate neural structures through tissue or fascial planes and can be associated with painful, vigorous muscle contractions. After localization of the correct motor response, the current is gradually decreased to a current of 0.5 mA or less. A motor response at a current of approximately 0.5 mA is appropriate when used to facilitate the location of the injection of local anesthetic or catheter placement.

ULTRASOUND-GUIDED REGIONAL ANESTHESIA

Ultrasound-guided regional anesthesia is an exciting and rapidly developing technique used to visualize and localize nerve structures (see Chapter 58). Ultrasound allows visualization of the nerve target, the approaching needle, and the deposition of local anesthetic around the nerve. Superficial nerve structures (e.g., brachial plexus) are easily imaged in most patients and therefore are most suited for ultrasound guidance. Practitioners must become familiar with the fundamentals of ultrasound equipment, as well as sonoanatomy, to become proficient in ultrasound-guided regional anesthesia.[11]

CERVICAL PLEXUS BLOCK

The cervical plexus is derived from the C1, C2, C3, and C4 spinal nerves and supplies branches to the prevertebral muscles, strap muscles of the neck, and phrenic nerve. The deep cervical plexus supplies the musculature of the neck segmentally and the cutaneous sensation of the skin between the trigeminally innervated face and the T2 dermatome of the trunk. Blockade of the superficial cervical plexus results in anesthesia of only the cutaneous nerves.

Clinical Applications

Blocks of the cervical plexus are easy to perform and provide anesthesia for surgical procedures in the distribution of C2 to C4, including lymph node dissections, plastic repairs, and carotid endarterectomy. The ability to monitor the awake patient's neurologic status continuously is an advantage of this anesthetic technique for the latter procedure and has resulted in an upsurge in the popularity of this technique.[12] Bilateral blocks can be used for tracheostomy and thyroidectomy.

Technique

Superficial Cervical Plexus. The superficial cervical plexus is blocked at the midpoint of the posterior border of the sternocleidomastoid muscle. A skin wheal is made at this point, and a 22-gauge, 4-cm needle is advanced, injecting 5 mL of solution along the posterior border and medial surface of the sternocleidomastoid muscle (Fig. 57-1). It is possible to block the accessory nerve with this injection, resulting in temporary ipsilateral trapezius muscle paralysis.

Deep Cervical Plexus. The deep cervical plexus block is a paravertebral block of the C2 to C4 spinal nerves as they emerge from their foramina in the cervical vertebrae (Fig. 57-2). The traditional approach uses three

separate injections at C2, C3, and C4. The patient lies supine with the neck slightly extended and the head turned away from the side to be blocked. A line is drawn connecting the tip of the mastoid process and the Chassaignac tubercle (the transverse process of C6); a second line is drawn 1 cm posterior to this first line. The C2 transverse process lies 1 to 2 cm caudad to the mastoid process, where it can usually be palpated. The C3 and C4 transverse processes lie at 1.5-cm intervals along the second line. After skin wheals are raised over the transverse processes of C2, C3, and C4, three 22-gauge, 5-cm needles are advanced perpendicular to the skin entry site with a slight caudad angulation. The transverse process is contacted at a depth of 1.5 to 3 cm. If a paresthesia is obtained, 3 to 4 mL of solution is injected after careful aspiration for blood and cerebrospinal fluid. If no paresthesia is elicited initially, the needle is walked along the transverse process in the anteroposterior plane until a paresthesia is obtained.

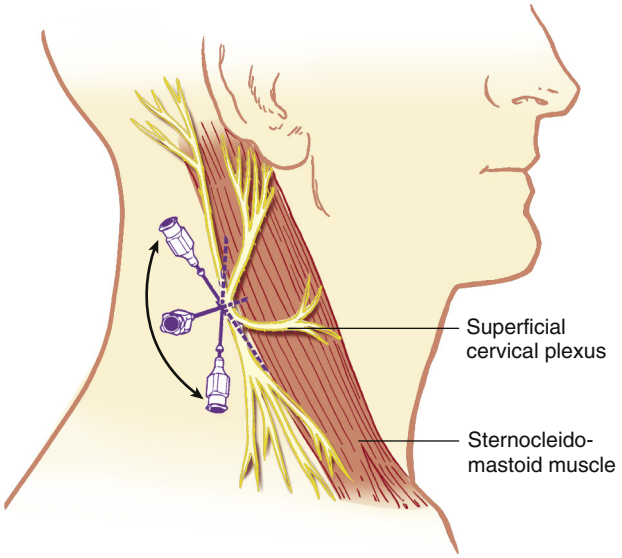

Figure 57-1. Anatomic landmarks and method of needle placement for a superficial cervical plexus block.

This block can also be performed with a single injection of 10 to 12 mL at the C4 transverse process.[13] Cephalad spread of the local anesthetic usually anesthetizes the C2 and C3 nerves. Cervical plexus anesthesia can also be observed after injection at the interscalene level for brachial plexus blockade. Maintenance of distal pressure and a horizontal or slightly head-down position can facilitate the onset of cervical plexus blockade using the interscalene technique.

Side Effects and Complications

Although these blocks are technically straightforward, needle placement for the deep cervical block allows local anesthetic injection in close proximity to a variety of neural and vascular structures. Complications and side effects include intravascular injection, blockade of the phrenic and superior laryngeal nerve, and spread of local anesthetic solution into the epidural and subarachnoid spaces.

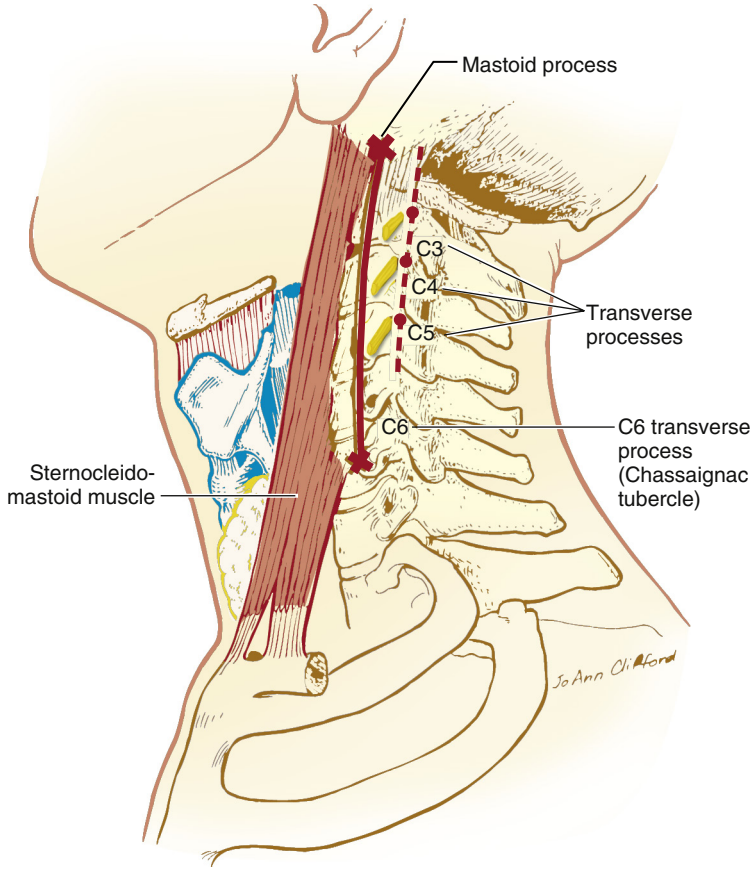

Figure 57-2. Anatomic landmarks and method of needle placement for deep cervical plexus blocks at C2, C3, and C4.

ACCESSORY NERVE BLOCK

The accessory nerve (cranial nerve XI) is occasionally blocked to supplement the interscalene brachial plexus approach for shoulder procedures. A blockade of the accessory nerve results in motor paralysis of the trapezius muscle, ensuring a lack of patient movement during the surgical procedure. The nerve traverses the posterior triangle of the neck (bordered by the posterior border of the sternocleidomastoid muscle, middle third of the clavicle, and anterior border of the trapezius muscle) in a superficial position after emerging from the substance of the sternocleidomastoid muscle at the junction of the superior and middle thirds of that muscle's posterior border. It can be blocked easily at that site by an injection of 6 to 10 mL of local anesthetic. This nerve is often unintentionally anesthetized when a superficial cervical plexus block is performed.

UPPER EXTREMITY BLOCKS

Blockade of the brachial plexus (C5-T1) at several locations from the roots to the terminal branches will allow for surgical anesthesia of the upper extremity and shoulder. Successful regional anesthesia of the upper extremity requires knowledge of brachial plexus anatomy from its origin, where the nerves emerge from the intervertebral foramina, to its termination in the peripheral nerves.

ANATOMY

The brachial plexus is derived from the anterior primary rami of the fifth, sixth, seventh, and eighth cervical nerves and the first thoracic nerve, with variable contributions from the fourth cervical and second thoracic nerves. After leaving their intervertebral foramina, these nerves course anterolaterally and inferiorly to lie between the anterior and middle scalene muscles, which arise from the anterior and posterior tubercles of the cervical vertebra, respectively. The anterior scalene muscle passes caudad and laterally to insert into the scalene tubercle of the first rib; the middle scalene muscle inserts on the first rib posterior to the subclavian artery, which passes between these two scalene muscles along the subclavian groove. The prevertebral fascia invests the anterior and middle scalene muscles, fusing laterally to enclose the brachial plexus in a fascial sheath.

Between the scalene muscles, these nerve roots unite to form three trunks, which emerge from the interscalene space to lie cephaloposterior to the subclavian artery as it courses along the upper surface of the first rib. The superior (C5 and C6), middle (C7), and inferior (C8 and T1) trunks are arranged accordingly and are not in a strict horizontal formation, as often depicted. At the lateral edge of the first rib, each trunk forms anterior and posterior divisions that pass posterior to the midportion of the clavicle to enter the axilla. Within the axilla, these divisions form the lateral, posterior, and medial cords, named for their relationship with the second part of the axillary artery. The superior divisions from the superior and middle trunks form the lateral cord, the inferior divisions from all three trunks form the posterior cord, and the anterior division of the inferior trunk continues as the medial cord.

At the lateral border of the pectoralis minor, the three cords divide into the peripheral nerves of the upper extremity. The lateral cord gives rise to the lateral head of the median nerve and the musculocutaneous nerve; the medial cord gives rise to the medial head of the median nerve, as well as the ulnar, the medial antebrachial, and the medial brachial cutaneous nerves; and the posterior cord divides into the axillary and radial nerves (Fig. 57-3).

Aside from the branches from the cords that form the peripheral nerves as described, several branches arise from the roots of the brachial plexus providing motor innervation to the rhomboid muscles (C5), the subclavian muscles (C5 and C6), and the serratus anterior muscle

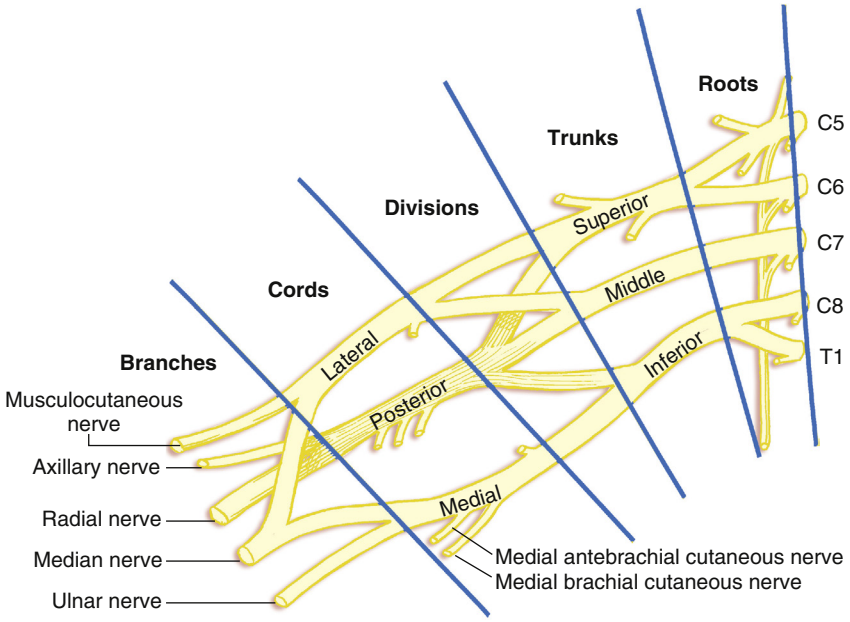

Figure 57-3. Roots, trunks, divisions, cords, and branches of the brachial plexus.

(C5, C6, and C7). The suprascapular nerve arises from C5 and C6, supplies the muscles of the dorsal aspect of the scapula, and makes a significant contribution to the sensory supply of the shoulder joint.

Branches arising from the cervical roots are usually blocked only with the interscalene approach to the brachial plexus. Sensory distributions of the cervical roots and the peripheral nerves are shown in Figure 57-4.

INTERSCALENE BLOCK

Clinical Applications

The principal indication for interscalene block is surgery on the shoulder. Blockade occurs at the level of the superior and middle trunks. Although this approach can be used for forearm and hand surgery, blockade of the inferior trunk (C8 through T1) is often incomplete and requires supplementation of the ulnar nerve for adequate surgical anesthesia in that distribution.[14]

Technique

Peripheral Nerve Stimulation or Paresthesia. The brachial plexus shares a close physical relationship with several structures that serve as important landmarks for the performance of interscalene block. In its course between the anterior and middle scalene muscles, the plexus is superior and posterior to the second and third parts of the subclavian artery. The dome of the pleura lies anteromedial to the inferior trunk.

This technique can be performed with the patient's arm in any position and is technically simple because of easy identification of necessary landmarks.[13] The patient should be in the supine position, with the head turned away from the side to be blocked. The posterior border of the sternocleidomastoid muscle is readily palpated by having the patient briefly lift the head. The interscalene groove can be palpated by rolling the fingers posterolaterally from this border over the belly of the anterior scalene muscle into the groove. A line is extended laterally from the cricoid cartilage to intersect the interscalene groove, indicating the level of the transverse process of C6. Although the external jugular vein often overlies this point of intersection, it is not a constant or reliable landmark.

After injection of a skin wheal, a 22- to 25-gauge, 4-cm needle is inserted perpendicular to the skin with a 45-degree caudad and slightly posterior angle (Fig. 57-5). The needle is then advanced until a paresthesia or nerve stimulator response is elicited. This usually occurs at a superficial level. Paresthesia or motor response of the arm or shoulder is equally efficacious as a distal response.[15] If a blunt needle is used, a "click" may be detected as the needle passes through the prevertebral fascia. If bone is encountered within 2 cm of the skin, it is likely to be a transverse process, and the needle can be "walked" across

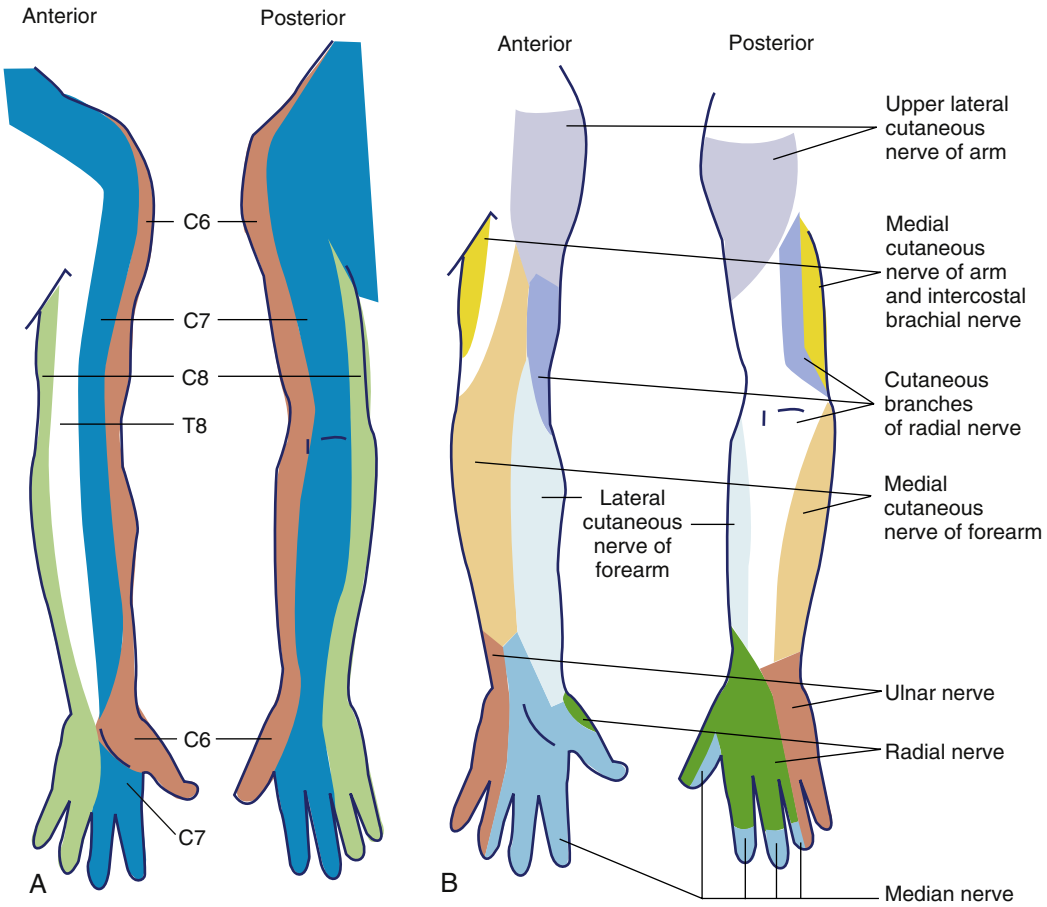

Figure 57-4. A, Cutaneous distribution of the cervical roots. **B,** Cutaneous distribution of the peripheral nerves.

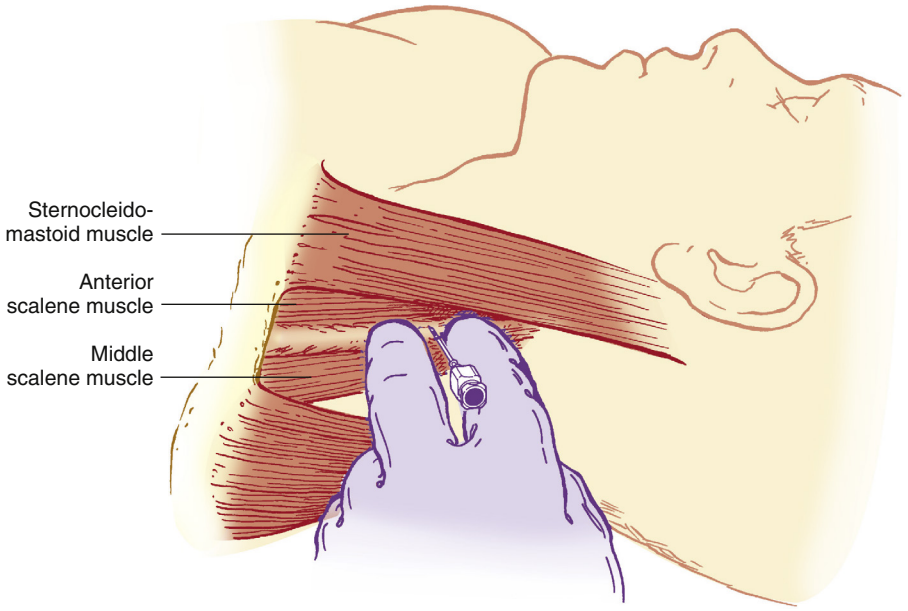

Figure 57-5. Interscalene block. The fingers palpate the interscalene groove, and the needle is inserted with a caudad and slightly posterior angle.

this structure to locate the nerve. Contraction of the diaphragm indicates phrenic nerve stimulation and anterior needle placement; the needle should be redirected posteriorly to locate the brachial plexus.

After the appropriate paresthesia or motor response is obtained, and after negative aspiration, 10 to 30 mL of solution is injected incrementally, depending on the desired extent of blockade. Radiographic studies suggest a volume-to-anesthesia relationship, with 40 mL of solution associated with complete cervical and brachial plexus block.[13] Clinical studies, however, indicate variable blockade of the lower trunk (i.e., ulnar nerve), even with large volumes of solution.[14]

Ultrasound Guided. This block is well suited to the use of ultrasound guidance. It is often easiest to obtain a supraclavicular view of the subclavian artery and brachial plexus and then trace the plexus up the neck with the ultrasound probe until the plexus trunks are visualized as hypoechoic structures between the anterior and medial scalene muscles (Fig. 57-6). The needle can then be advanced in an out-of-plane, or an in-plane approach. After negative aspiration, a small test dose is administered, and local anesthetic spread around the brachial plexus confirms appropriate placement of the needle. Volumes as little as 5 mL may be successful and associated with a decreased frequency of diaphragmatic paresis.[16]

Side Effects and Complications

At the conventional level (C6) of blockade, ipsilateral phrenic nerve block resulting in diaphragmatic paresis occurs in 100% of patients undergoing interscalene blockade,[17] even with dilute solutions of local anesthetics, and is associated with a 25% reduction in pulmonary function.[18,19] This effect probably results from anterior spread of the solution over the anterior scalene muscle and may cause subjective symptoms of dyspnea. Although rare, respiratory compromise can occur in patients with severe respiratory disease. Techniques to decrease blockade of the phrenic nerve include using very small volumes of local anesthetic and localizing the brachial plexus at a lower level in the neck.[20]

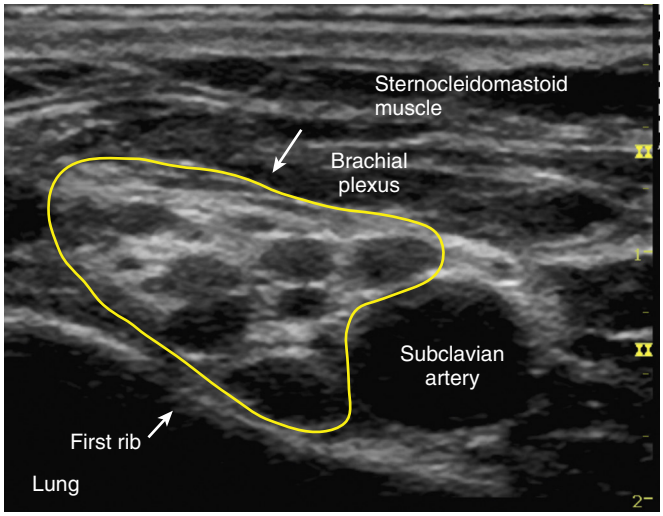

Figure 57-6. Ultrasound image of the brachial plexus at the level of interscalene block.

Involvement of the vagus, recurrent laryngeal, and cervical sympathetic nerves is rarely significant, but the patient experiencing symptoms related to these side effects may require reassurance. The risk of pneumothorax is small when the needle is correctly placed at the C5 or C6 level because of the distance from the dome of the pleura.

Severe hypotension and bradycardia (i.e., Bezold-Jarisch reflex) can occur in awake, sitting patients undergoing shoulder surgery under an interscalene block. The cause is presumed to be stimulation of intracardiac mechanoreceptors by decreased venous return, producing an abrupt withdrawal of sympathetic tone and enhanced parasympathetic output. This effect results in bradycardia, hypotension, and syncope. The frequency is decreased when prophylactic β-adrenergic blockers are administered.[21]

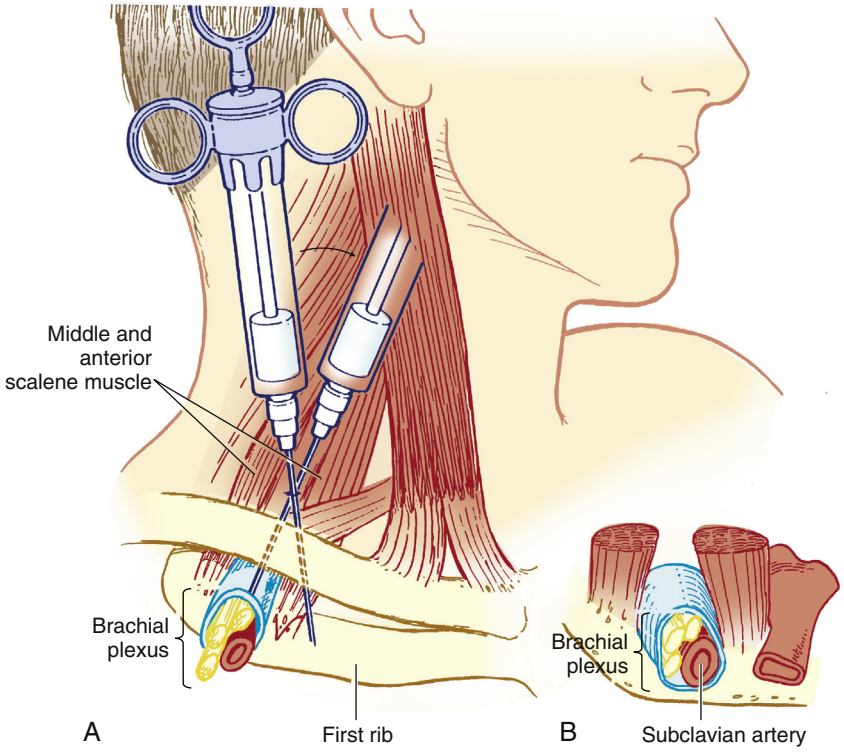

Figure 57-7. A, Supraclavicular block. The needle is systematically walked anteriorly and posteriorly along the rib until the plexus is located. **B,** The three trunks are compactly arranged at the level of the first rib.

Some surgical approaches to the shoulder, such as total shoulder arthroplasty, are associated with neurologic risk to the brachial plexus. In such cases, an interscalene block can be placed postoperatively after the surgical service has ascertained and documented that no neurologic damage has occurred. Epidural and intrathecal injections can occur with this block, a finding emphasizing the importance of inserting the needle in a caudad direction.[22] The proximity of significant neurovascular structures can increase the risk of serious neurologic complications when interscalene block is performed in heavily sedated or anesthetized patients.[23] Accordingly, an interscalene block should be placed with the patient awake or under light sedation.[24]

SUPRACLAVICULAR BLOCK

Clinical Applications

Indications for supraclavicular block are operations on the elbow, forearm, and hand. Blockade occurs at the distal trunk-proximal division level. At this point, the brachial plexus is compact, and a small volume of local anesthetic produces rapid onset of reliable blockade of the brachial plexus. An additional advantage is that the block can also be performed with the patient's arm in any position.

Technique

Peripheral Nerve Stimulation or Paresthesia. Several anatomic points are important in the performance of the supraclavicular approach. The three trunks are clustered vertically over the first rib cephaloposterior to the subclavian artery, which can often be palpated in a slender, relaxed patient. The neurovascular bundle lies inferior to the clavicle at about its midpoint. The first rib acts as a medial barrier to the needle's reaching the pleural dome and is short, broad, and flat, with an anteroposterior orientation at the site of the plexus.

The patient is placed in a supine position, with the head turned away from the side to be blocked. The arm to be anesthetized should be adducted, and the hand should be extended along the side. In the classic technique, the midpoint of the clavicle should be identified and marked. The posterior border of the sternocleidomastoid can be easily palpated when the patient raises the head slightly. The palpating fingers can then roll over the belly of the anterior scalene muscle into the interscalene groove, where a mark should be made approximately 1.5 to 2.0 cm posterior to the midpoint of the clavicle. Palpation of the subclavian artery at this point confirms the landmark.

After injection of a skin wheal, the anesthesiologist stands at the side of the patient facing the patient's head. A 22-gauge, 4-cm needle is directed in a caudad, slightly medial, and posterior direction until a paresthesia or motor response is elicited or the first rib is encountered. If a syringe is attached, this orientation causes the needle shaft and syringe to lie almost parallel to a line joining the skin entry and the patient's ear. If the first rib is encountered without elicitation of a paresthesia, the needle can be systematically walked anteriorly and posteriorly along the rib until the plexus or the subclavian artery is located (Fig. 57-7). Location of the artery provides a useful landmark. The needle can be withdrawn and reinserted in a more posterolateral direction that usually results in a paresthesia or motor response. After localization of the brachial plexus, aspiration for blood should be performed before incremental injections of a total volume of 20 to 30 mL of local anesthetic.

The rib usually is contacted at a needle depth of 3 to 4 cm; however, in an obese patient or in the presence of tissue distortion resulting from hematoma or injection of solution, the depth may exceed the needle length. Nonetheless, before the needle is advanced further, gentle probing in the anterior and posterior directions should be done at the 2- to 3-cm depth if paresthesias are not obtained. Multiple injections can improve the quality or shorten the onset of blockade.

Ultrasound Guided. The use of ultrasound for the supraclavicular block allows the practitioner to see the brachial plexus structures, as well as the subclavian artery and pleura, just below the first rib. The inherent safety of this technique requires continuous visualization of the needle tip during needle advancement (see Chapter 58).

Side Effects and Complications

Although the block is more difficult in obese patients (see Chapter 71), an increased risk of complications has not been documented.[25] The prevalence of pneumothorax after supraclavicular block is 0.5% to 6% and diminishes with increased experience. Importantly, although the use of ultrasound has perhaps decreased the incidence of pneumothorax, the risk has not been eliminated.[26] The onset of symptoms is usually delayed, and it can take up to 24 hours. Thus, routine chest radiography after the block is not justified. The supraclavicular approach is best avoided when the patient is uncooperative or cannot tolerate any degree of respiratory compromise. Other complications include frequent phrenic nerve block (40% to 60%), Horner's syndrome, and neuropathy. The presence of phrenic or cervical sympathetic nerve block usually requires only reassurance. Although nerve damage can occur, it is uncommon and usually is self-limited.

INFRACLAVICULAR BLOCK

Clinical Applications

Infraclavicular block provides anesthesia to the arm and hand. Blockade occurs at the level of the cords and offers the theoretical advantages of avoiding pneumothorax while affording block of the musculocutaneous and axillary nerves. No special arm positioning is required. A nerve stimulator ultrasound visualization is required because there are no palpable vascular landmarks to aid in directing the needle.

Technique

Peripheral Nerve Stimulation or Paresthesia. The needle is inserted 2 cm below the midpoint of the inferior clavicular border and is advanced laterally, using a nerve stimulator to identify the plexus.[27] Marking a line between the C6 tubercle and the axillary artery with the arm abducted is helpful in visualizing the course of the plexus. An incremental injection of 20 to 30 mL of solution is sufficient after the needle is correctly placed. Success rate is improved with a distal motor response.[28] A coracoid technique, with needle insertion site 2 cm medial and 2 cm caudal to the coracoid process, has also been described.[29] However, the more lateral insertion site can result in the absence of blockade of the musculocutaneous nerve, removing the major advantage of this approach over the simpler axillary block.

Ultrasound Guided. Ultrasound guidance is frequently used to visualize the neurovascular bundle and ideally, local anesthetic spread should be visualized around the axillary artery (see Chapter 58).

Side Effects and Complications

Because of the blind approach to the plexus, the risk of intravascular injection may be increased. Exaggerated medial needle direction may result in pneumothorax.

AXILLARY BLOCK

Clinical Applications

The axillary approach to the brachial plexus is popular because of its ease, reliability, and safety.[30] Blockade occurs at the level of the terminal nerves. Although blockade of the musculocutaneous nerve is not always produced with this approach, it can be supplemented at the level of the axilla or at the elbow. Indications for axillary block include surgery to the forearm and hand. Elbow procedures are also performed successfully using the axillary approach.[31] This block is ideally suited for outpatients and is easily adapted to the pediatric population[32] (see Chapter 92). However, axillary block is unsuitable for surgical procedures on the upper arm or shoulder, and the patient must be able to abduct the arm to perform the block.

Anatomic concepts that should be considered before an axillary block include the following:

1. The neurovascular bundle is multicompartmental.[33]
2. The axillary artery is the most important landmark
3. Although anatomic variations exist, typically, the median nerve is found superior to the artery, the ulnar nerve is inferior, and the radial nerve is posterior and somewhat lateral (Fig. 57-8).
4. At this level, the musculocutaneous nerve has already left the sheath and lies with the coracobrachialis muscle.
5. The intercostobrachial nerve, a branch of the T2 intercostal nerve, is usually blocked by the skin wheal overlying the artery; however, adequate anesthesia for the tourniquet can be ensured by extending the wheal 1 to 2 cm caudad and cephalad.

Technique

Peripheral Nerve Stimulation, Paresthesia, or Sheath. The patient should be in the supine position with the arm to be blocked placed at a right angle to the body and the elbow flexed to 90 degrees. The dorsum of the hand rests on the bed or pillow; hyperabduction of the arm with placement of the hand beneath the patient's head is not recommended, because this position frequently obliterates the pulse.

The axillary artery is palpated, and a line is drawn tracing its course from the lower axilla as far proximally as possible. The artery is then fixed against the patient's

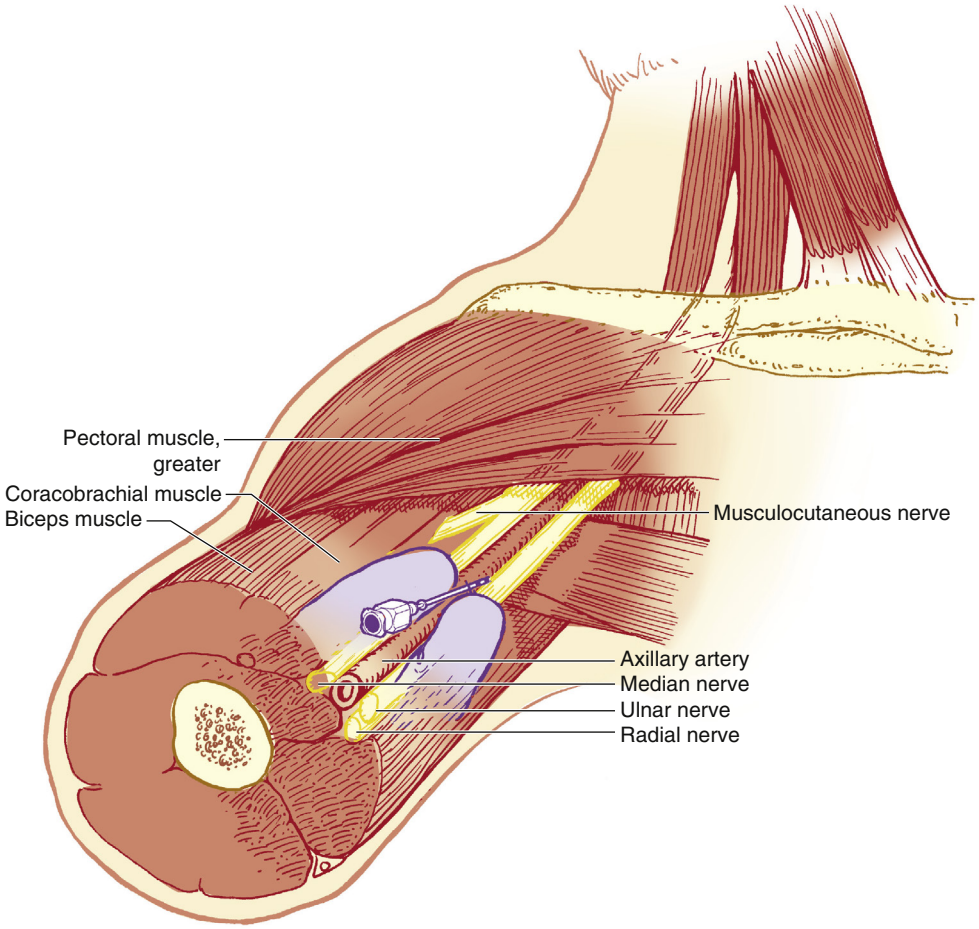

Figure 57-8. Axillary block. The arm is abducted at right angles to the body. Distal digital pressure is maintained during needle placement and injection of the local anesthetic.

humerus by the index and middle fingers of the left hand, and a skin wheal is raised directly over the artery at a point in the axilla approximating the skin crease. Proximal needle placement and maintenance of distal pressure facilitate proximal spread of the solution.

Several methods of identifying the axillary sheath have been described, all with reportedly good results. Overall, paresthesias are unnecessary; however, multiple injections can shorten the onset and improve the reliability of blockade.

1. Paresthesias can be sought with a 25-gauge, 2-cm needle, beginning deeply (i.e., radial nerve) or with the nerves supplying the surgical site. Needles longer than 2 cm are rarely needed to reach the neurovascular bundle. Smaller needles and a short needle bevel may be associated with a less frequent risk of nerve damage.[9] Each paresthesia is injected with 10 mL of local anesthetic.
2. A nerve stimulator can also be used with an insulated needle to locate the nerves. Stimulation with a low current threshold (0.5 mA) decreases onset time, but increases block performance time compared with higher-threshold stimulation (1.0 mA).[34]
3. A short-bevel needle can be advanced until the axillary sheath is entered, as evidenced by a fascial click, whereupon 40 to 50 mL of solution is injected after negative aspiration.
4. A transarterial technique can be used, whereby the needle pierces the artery and 40 to 50 mL of solution is injected posterior to the artery. Alternatively, half of the solution is injected posterior and half is injected anterior to the artery. Great care must be taken to avoid intravascular injection with this technique, particularly because the pressure of injection within the compartments of the axillary sheath may move anatomic structures in relation to the immobile needle.
5. Ultrasound guidance with visualization of local anesthetic spread around the four nerves (with and without motor stimulation) decreases block onset time and can reduce the number of needle redirections; however, the rates of success and complications are similar to other approaches.[35,36] Ultrasound can also help with the success with smaller volumes of local anesthetic, although the overall duration of sensory and motor block will be markedly decreased.[37]

Classically, upon completion of the injection, the arm should be adducted and returned to the patient's side to prevent the humeral head from obstructing proximal flow of the local anesthetic solution. However, maintaining the arm in abduction decreases onset time and prolongs both sensory and motor block.[38] If the musculocutaneous nerve is not blocked by the axillary approach, it can be blocked by injection within the body of the coracobrachialis muscle or at the elbow superficially at the lateral

aspect of the antecubital fossa just above the interepicondylar line.

Success Rate With Axillary Block Techniques

The success rate for an axillary block depends on the definition of a successful block (i.e., surgical anesthesia versus blockade of all four terminal nerves of the upper extremity), the technique used to localize the brachial plexus, and the number of injections. Success rates with single-injection techniques can vary.[39] Thompson and Rorie[33] concluded that the presence of multiple compartments limits diffusion of the local anesthetic (and the success of single injection compared to multiple injection techniques). Although Partridge and coworkers[40] confirmed the presence of these compartments, they concluded that the "septa" dividing them were incomplete based on injections of methylene blue and latex solutions into cadavers. The controversy surrounding single- versus multiple-injection techniques remains unresolved.

Eliciting a paresthesia is as efficacious as peripheral nerve stimulation (with a motor response of 0.5 to 1.0 mA). Most studies suggest that two-injection transarterial techniques are equivalent to single-paresthesia or single-nerve stimulation approaches. In general, the efficacy of paresthesia and peripheral nerve stimulator techniques increases when multiple injections are used. Conversely, success rates with perivascular or fascial click approaches are variously reliable.[41]

Side Effects and Complications

Nerve injury and systemic toxicity are the most significant complications associated with the axillary approach. The assertion that neuropathies are more common with the paresthesia technique is not supported by the available data. Even when paresthesias are not sought, they often occur unintentionally.[8] Injection of large volumes of local anesthetic, particularly with the transarterial approach, increases the risk of intravascular injection and systemic toxicity of local anesthetics. Hematoma and infection are rare complications.

PERIPHERAL BLOCKS AT THE MIDHUMERAL LEVEL, ELBOW, AND WRIST

Clinical Applications

As techniques for brachial plexus blockade have gained popularity, indications for peripheral nerve blockade at the wrist and elbow have diminished. However, these techniques can be useful when limited anesthesia is required, when contraindications to brachial plexus block (e.g., infection, bilateral surgery, coagulation abnormalities, bleeding diathesis, difficult anatomy) exist, or when brachial plexus blockade is incomplete. Only the midhumeral approach provides anesthesia for the use of a tourniquet. Peripheral blocks performed at the level of the elbow and wrist are typically performed as "field" blocks without neural localization. However, ultrasound imaging or peripheral nerve stimulation can be used.

Midhumeral Block

Midhumeral block involves blocking each of the four nerves of the brachial plexus separately in the humeral canal at the level of the proximal one third and distal two thirds of the humerus. At this level, the median and ulnar nerves are located on the lateral and medial aspects of the brachial artery, respectively. The musculocutaneous nerve is identified within the body of the biceps muscle, and the radial nerve lies adjacent to the humerus. A volume of 8 to 10 mL of local anesthetic is injected after localization of each nerve with a nerve stimulator (or ultrasound). Midhumeral block has been reported to have a higher success rate than traditional (defined as stimulation of two nerves) axillary brachial plexus block.[42] In this study, time to complete the block was not different between the two techniques; however, the onset of complete sensory block was shorter in the axillary approach, whereas the success rate of blockade of all four major nerves was higher in the midhumeral group.

Median Nerve Block

Block of the median nerve provides anesthesia of the palmar aspects of the thumb and index finger, the middle finger and radial half of the ring finger, and the nail beds of the same digits. Motor block includes the muscles of the thenar eminence, lumbrical muscles of the first and second digits, and in the case of the block at the elbow, median-innervated wrist flexor muscles of the forearm.

Technique at the Elbow. With the patient's arm placed in the anatomic position (palm up), a line is drawn connecting the medial and lateral epicondyles of the humerus. The major landmark for this technique is the brachial artery, which is found medial to the biceps tendon at the intercondylar line. The median nerve lies medial to the artery (Fig. 57-9) and can be blocked with 3 to 5 mL of solution after eliciting a paresthesia. If no paresthesia is

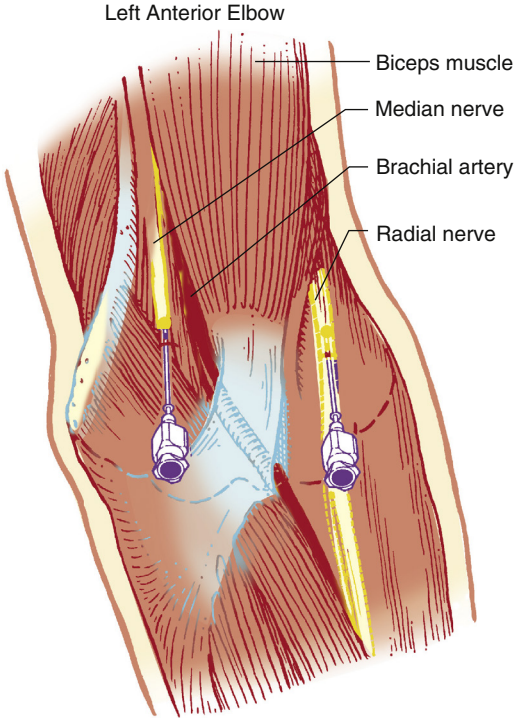

Figure 57-9. Anatomic landmarks for median and radial nerve blocks at the elbow.

obtained, the local anesthetic can be injected in a fanlike pattern medial to the palpated artery.

Technique at the Wrist. The median nerve is located between the flexor carpi radialis and palmaris longus tendons and can be blocked at a point 2 to 3 cm proximal to the wrist crease (Fig. 57-10). (The palmaris longus tendon is congenitally or postsurgically absent from some patients.) A loss of resistance is felt as the needle passes through the flexor retinaculum, at which point 2 to 4 mL of solution should be injected. A superficial palmar branch supplying the skin of the thenar eminence can be blocked by injecting 0.5 to 1 mL of local anesthetic subcutaneously above the retinaculum. Paresthesias should not be sought because of the confinement of this nerve within the carpal tunnel.

Radial Nerve Block

Block of the radial nerve provides anesthesia to the lateral aspect of the dorsum of the hand (i.e., thumb side) and the proximal portion of the thumb, index, middle, and lateral half of the ring fingers.

Technique at the Elbow. The radial nerve can be blocked at the elbow as it passes over the anterior aspect of the lateral epicondyle. The intercondylar line and lateral edge of the biceps tendon are marked. A 22-gauge, 3- to 4-cm needle is inserted at a point 2 cm lateral to the biceps tendon and is advanced until bone is encountered (see Fig. 57-9). A fanlike injection is made using 3 to 5 mL of local anesthetic.

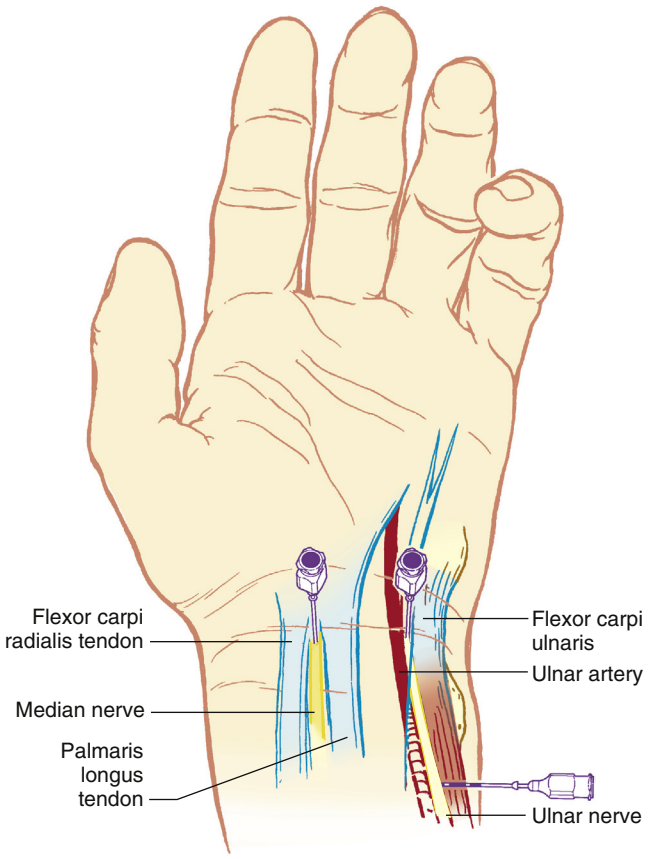

Figure 57-10. Anatomic landmarks for median and ulnar nerve blocks at the wrist. An alternative method for ulnar nerve block, from the ulnar side of the wrist, is shown.

Technique at the Wrist. The radial nerve block at the wrist is a field block of the multiple peripheral branches descending along the dorsum and radial side of the wrist. The extensor pollicis longus tendon can be identified when the patient extends the thumb. The needle insertion is over this tendon at the base of the first metacarpal; the injection is superficial to the tendon. A volume of 2 mL of local anesthetic is injected proximally along the tendon, and an additional 1 mL is injected as the needle passes at a right angle across the anatomic snuffbox (Fig. 57-11).

Ulnar Nerve Block

Blockade of the ulnar nerve provides anesthesia of the ulnar side of the hand, the little finger, and the ring finger and all the small muscles of the hand, except those of the thenar eminence and the first and second lumbrical muscles.

Technique at the Elbow. Although the ulnar nerve is easily accessible at its subcutaneous position posterior to the medial epicondyle, blockade at this site is associated with a high incidence of nerve injury. The nerve is surrounded by fibrous tissue at this point, requiring an intraneural injection for successful blockade. Use of a very fine needle with a small volume of local anesthetic (1 mL) diminishes the risk; however, the nerve can be blocked satisfactorily with 5 to 10 mL of local anesthetic at a site 3 to 5 cm proximal to the elbow. The local anesthetic should be injected in a fanlike fashion without elicitation of a paresthesia.

Technique at the Wrist. At the wrist, the ulnar nerve lies beneath the flexor carpi ulnaris tendon between the ulnar artery and the pisiform bone. At this point, it has already given off its palmar cutaneous and dorsal branches. The nerve can be approached by directing the needle medially from the radial side of the tendon or, alternatively, by directing the needle radially from the ulnar side of the tendon (see Fig. 57-10). After eliciting a paresthesia, 3 to 5 mL of anesthetic solution is injected or spread in a fanlike fashion.

Musculocutaneous Nerve Block

The musculocutaneous nerve terminates as the lateral cutaneous nerve of the forearm. This nerve provides

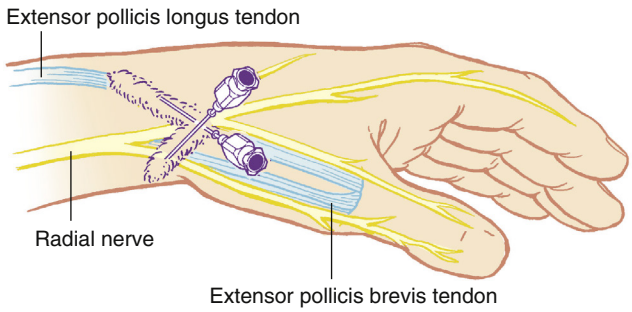

Figure 57-11. Anatomic landmarks and method of needle insertion for a radial nerve block at the wrist.

sensory innervation to the skin on the radial side of the forearm up to the radiocarpal joint. This block is usually performed to supplement the axillary approach to brachial plexus anesthesia.

Technique at the Elbow. The lateral cutaneous nerve of the forearm can be blocked 1 cm proximal to the intercondylar line immediately lateral to the biceps tendon. Fanlike infiltration of 3 to 5 mL of local anesthetic subcutaneously at this site provides excellent anesthesia of this nerve.

Peripheral Blockade at the Elbow Versus the Wrist

The forearm cutaneous nerves arise in the upper arm, and they are not anesthetized by block of the peripheral nerves at the elbow. There is no advantage of a block of the peripheral nerves of the upper extremity when comparing elbow with wrist techniques; both provide sensory anesthesia of the hand.

Side Effects and Complications

In general, distal peripheral blocks have a less frequent risk of complications. However, intravascular injection can occur, and the usual precautions of incremental injection after aspiration are recommended. The risk of nerve injury is more frequent when more distal peripheral blocks are performed, possibly because of superficial nerve placement between bony and ligamentous structures, thereby offering ready access to the probing needle point.

INTRAVENOUS REGIONAL BLOCKS

Intravenous regional blocks were first described by a German surgeon, August Bier, in 1908.[43] Early methods involved two tourniquets and the first synthetic local anesthetic, procaine. The technique lost popularity as reliable methods of blocking the brachial plexus evolved.

Clinical Applications

The Bier block has multiple advantages, including ease of administration, rapidity of recovery, rapid onset, muscular relaxation, and controllable extent of anesthesia. It is an excellent technique for short (<90 minutes) open surgical procedures and for closed reductions of bony fractures.

Technique

An intravenous cannula is placed in the upper extremity to be blocked as distally as possible; the patient should also have an intravenous cannula in the nonoperative upper extremity for administration of fluids and other drugs. Traditionally, a double tourniquet is placed on the operative side; both cuffs should have secure closures and reliable pressure gauges. After exsanguination of the arm, the proximal cuff is inflated to approximately 150 mm Hg greater than the systolic pressure, and absence of a radial pulse confirms adequate tourniquet pressure. The total dose of local anesthetic is based on the patient's weight, and it is injected slowly (3 mg/kg of 0.5% prilocaine or lidocaine, without epinephrine). The use of bupivacaine for intravenous regional anesthesia has been associated with local anesthetic toxicity and death[44] and is not recommended (see Chapter 36). However, dilute solutions (0.125% levobupivacaine) of long-acting amides and the addition of adjuvants (tramadol, ketorolac, clonidine) have been used to prolong sensory block and analgesia after tourniquet deflation.[45]

The onset of anesthesia is usually within 5 minutes. When the patient complains of tourniquet pain, the distal tourniquet, which overlies anesthetized skin, is inflated, and the proximal tourniquet is released. Use of a single, wide cuff allows use of smaller inflation pressures during intravenous regional anesthesia. The postulated advantage is that the smaller pressures will decrease the incidence of neurologic complications related to high inflation pressures with the narrow double cuffs.[46] The tourniquet can be released safely after 25 minutes, but the patient should be closely observed for local anesthetic toxicity for several minutes after the tourniquet release. Slow injection of local anesthetic solutions at a distal site decreases the risk of toxicity.[47]

Side Effects and Complications

Technical problems with this block include tourniquet discomfort, rapidity of recovery leading to postoperative pain, difficulty in providing a bloodless field, and the necessity of exsanguination in the case of a painful injury. Accidental or early deflation of the tourniquet or use of excessive doses of local anesthetics can result in toxic reactions. Injection of the drug as distally as possible at a slow rate decreases blood levels and theoretically may increase safety.[47] Cyclic deflation of the tourniquet at 10-second intervals increases the time to peak arterial lidocaine levels that can decrease potential toxicity.[48] Other rare complications associated with this technique include phlebitis (with 2-chloroprocaine), development of compartment syndrome, and loss of a limb.

BLOCKS OF THE THORAX AND ABDOMEN

PARAVERTEBRAL BLOCK

Anatomic landmarks of the wedge-shaped paravertebral space include the parietal pleura anteriorly; the vertebral body, intervertebral disk, and foramen medially; and the posterior intercostal membrane laterally and the superior costotransverse ligament posteriorly. The neural structures within the paravertebral space include the intercostal nerve, the dorsal rami and communications, and the sympathetic chain. The intercostal nerve itself is fragmented within the paravertebral space and is blocked easily with local anesthetics. Awareness of the spinous processes, transverse processes, ribs, and costotransverse ligaments are essential while performing the block.

Clinical Applications

The paravertebral block can be used to provide anesthesia or analgesia to patients undergoing intrathoracic, abdominal, or pelvic procedures or surgery to the breast.[49,50] Bilateral and continuous applications have been described.[51,52] In patients undergoing thoracotomy,

thoracic paravertebral block provides analgesia comparable to epidural techniques, but with fewer side effects and complications.[53,54] Paravertebral block can be useful in the diagnosis and treatment of certain chronic pain disorders, including postthoracotomy and postmastectomy pain.

Technique

Thoracic Paravertebral Block. Thoracic paravertebral blockade occurs as the spinal nerves emerge from the vertebral foramina. This results in somatic and sympathetic block of multiple contiguous thoracic dermatomes above and below the injection site.

Neural Localization. Peripheral nerve stimulation has been used to signify entry into the paravertebral space and guard against pleural puncture. The peripheral nerve stimulator will elicit a motor response on the intercostal muscles before the needle enters the pleura. Caution needs to be taken during a multilevel block, because local anesthetic injected at one level can spread to the contiguous levels and either modify or abolish the intercostal motor response. Ultrasound measurements of the depth from skin to the transverse process and from skin to the parietal pleura have been found to correlate closely to the actual needle depth. Theoretically, knowing the maximal insertion depth could minimize the risk of pneumothorax.

Thoracic paravertebral block can be performed with the patient in the sitting, lateral, or prone position; the sitting position allows easy identification of landmarks. Typically, the thoracic spinous processes are identified, and the needle is inserted 2.5 to 3 cm lateral to the most cephalad aspect of the spinous process and advanced perpendicular to the skin in all planes to contact the transverse process of the vertebra below, typically at a depth of 2 to 4 cm. After the transverse process is identified, traditionally, the needle is redirected cephalad and gradually advanced until a loss of resistance is felt 1 to 1.5 cm past the superior edge. However, walking the needle caudad can decrease the risk of pneumothorax.[51] The safety of this procedure relies on the proceduralist not advancing the needle farther than 1 to 1.5 cm past the skin-transverse process distance.

Although spread of local anesthetic is variable, a single injection of 15 mL produces unilateral somatic blockade over four or five dermatomes; there is a tendency for caudal (compared with cephalad) spread.[51] To achieve greater spread, 3 to 4 mL of a local anesthetic may be injected at each segment.[55]

Lumbar Paravertebral Block. Lumbar nerves exit the vertebral foramina inferior to the caudad edge of the transverse process. Each nerve divides into anterior and posterior branches; the anterior branches of L1 through L4 (with a contribution from T12) form the lumbar plexus.

The patient is placed in the prone position as described for intercostal blockade. Lines are drawn across the cephalad edges of the lumbar vertebral spinous processes. These lines lie opposite the caudad edges of the homologous transverse processes (Fig. 57-12, *A*). A skin wheal is raised 3 cm lateral to the midline, and a 20-gauge, 10-cm needle is advanced perpendicularly until it contacts the transverse process at a depth of 3 to 5 cm. The needle is then redirected to walk off the caudad edge of the transverse process. At 1 to 2 cm (the thickness of the transverse process) beyond this point, 6 to 10 mL of local anesthetic is injected (see Fig. 57-12, *B*). Elicitation of a paresthesia or use of a nerve stimulator is helpful in confirming correct needle placement.

Side Effects and Complications

Because of the proximity of the neuraxis, epidural or subarachnoid injection of local anesthetic is a risk.[49] Intravascular injection through the lumbar vessels, vena cava, or aorta is possible. Pleural puncture and pneumothorax have occurred with frequencies of 1.1% and 0.5%, respectively.[51]

INTERCOSTAL NERVE BLOCK AND INTERPLEURAL CATHETER PLACEMENT

The intercostal nerves are the primary rami of T1 through T11. T12 is technically a subcostal nerve, and it supplies branches to the ilioinguinal and iliohypogastric nerves. Fibers from T1 contribute to the brachial plexus; T2 and T3 provide a few fibers to the formation of the intercostobrachial nerve, which supplies the skin of the medial aspect of the upper arm. Each intercostal nerve has four branches: the gray ramus communicans, which passes anteriorly to the sympathetic ganglion; the posterior cutaneous branch, supplying skin and muscle in the para vertebral area; the lateral cutaneous branch, arising just anterior to the midaxillary line and sending subcutaneous branches anteriorly and posteriorly; and the anterior cutaneous branch, which is the termination of the nerve.

Medial to the posterior angles of the ribs, the intercostal nerves lie between the pleura and the internal intercostal fascia. At the posterior angle of the rib, the nerve lies in the costal groove accompanied by the intercostal vein and artery.

Clinical Applications

Few surgical procedures can be performed with an intercostal block alone, and the application of these blocks in combination with other techniques has largely been supplanted by epidural blockade. However, in patients with contraindications to neuraxial blockade, these techniques can be used alone or combined with celiac plexus blocks and light general anesthesia to provide excellent surgical conditions for intraabdominal procedures. In a similar fashion, intrathoracic surgery can be accomplished using intercostal and stellate ganglion blocks with endotracheal sedation. Although surgical applications are possible, the majority of indications are for postoperative analgesia.

Interpleural catheter placement for management of postoperative pain was first described by Reiestad and Stromskag in 1986.[56] Because the mechanism of action is poorly understood, and reports of efficacy have varied, the use of this technique has varied in frequency over time. Overall, the results with cholecystectomy have been most favorable. The advantages of interpleural analgesia are more difficult to prove in patients undergoing thoracotomy, perhaps because of technical problems relating to blood in the pleural space and chest tube drainage. Recent applications include analgesia after minimally invasive cardiopulmonary bypass surgery.[57]

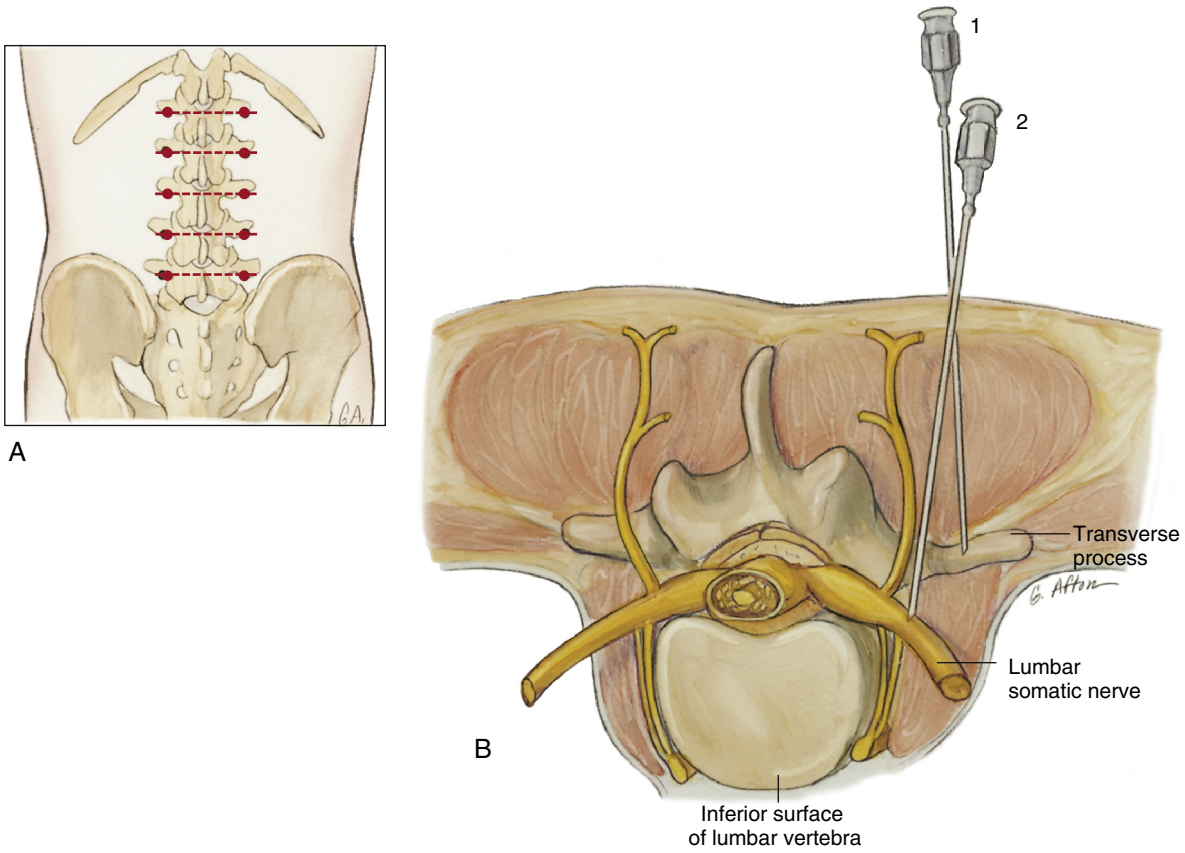

Figure 57-12. A, Patient positioning and surface landmarks for a lumbar paravertebral nerve block. **B,** For a paravertebral nerve block, the needle is advanced perpendicularly until it contacts the transverse process. It is redirected to walk off the caudad edge of the transverse process and advanced 1 to 2 cm.

Technique

Intercostal Block. The intercostal nerve can be readily blocked at the angle of the rib just lateral to the sacrospinalis muscle group. The patient is placed in the prone position with a pillow placed under the abdomen to reduce the lumbar curve (Fig. 57-13, *A*). A line is drawn along the posterior vertebral spines. Nearly parallel lines are drawn along the posterior angles of the rib, which can be palpated 6 to 8 cm from the midline. These lines angle medially at the upper levels to prevent overlying of the scapula. The inferior edge of each rib is palpated and is marked on the line intersecting the posterior angle of the rib. After appropriate skin preparation, skin wheals are injected at each of these points. A 22-gauge, short-bevel, 4-cm needle is attached to a 10-mL syringe. Beginning at the lowest rib, the index finger of the left hand displaces the skin up over the patient's rib. The needle is inserted at the tip of the finger until it rests on the rib. The fingers of the left hand are shifted to grasp the needle hub firmly. The left hand then walks the needle 3 to 5 mm off the lower rib edge, where 3 to 5 mL of local anesthetic are injected (see Fig. 57-13, *B, C*). This process is repeated at each rib. Appropriate intravenous sedation providing analgesia and some degree of amnesia is desirable for the patient's comfort. Ultrasound imaging of the intercostal nerves has been reported, but the visibility is highly variable.

Alternatively, intercostal block can be performed in the supine patient at the midaxillary line. Theoretically, the lateral cutaneous branch of the nerve can be missed, but computed tomography studies show that injected solutions spread several centimeters along the costal groove. Further injection of 1 to 2 mL of local anesthetic as the needle is withdrawn blocks the subcutaneous branches.

Interpleural Catheter. The technique for interpleural catheter placement is simple and can be performed with the patient in a lateral (and slightly oblique) or sitting position. The sixth or seventh intercostal space is identified. Needle insertion is performed approximately 10 cm lateral from the posterior midline, and an epidural needle tip is advanced until it rests on the cephalad edge of the rib below the intercostal space to be entered. A glass syringe filled with saline or air is then attached to the needle, and the unit is advanced slowly over the superior edge of the rib. When the tip of the needle enters the parietal pleura, the solution in the syringe is drawn into the chest cavity because of the negative intrathoracic pressure. This effect can be observed in mechanically and spontaneously ventilating patients, but it is accentuated in the latter group.

The catheter is then inserted approximately 5 to 8 cm into the interpleural space and is secured on the chest

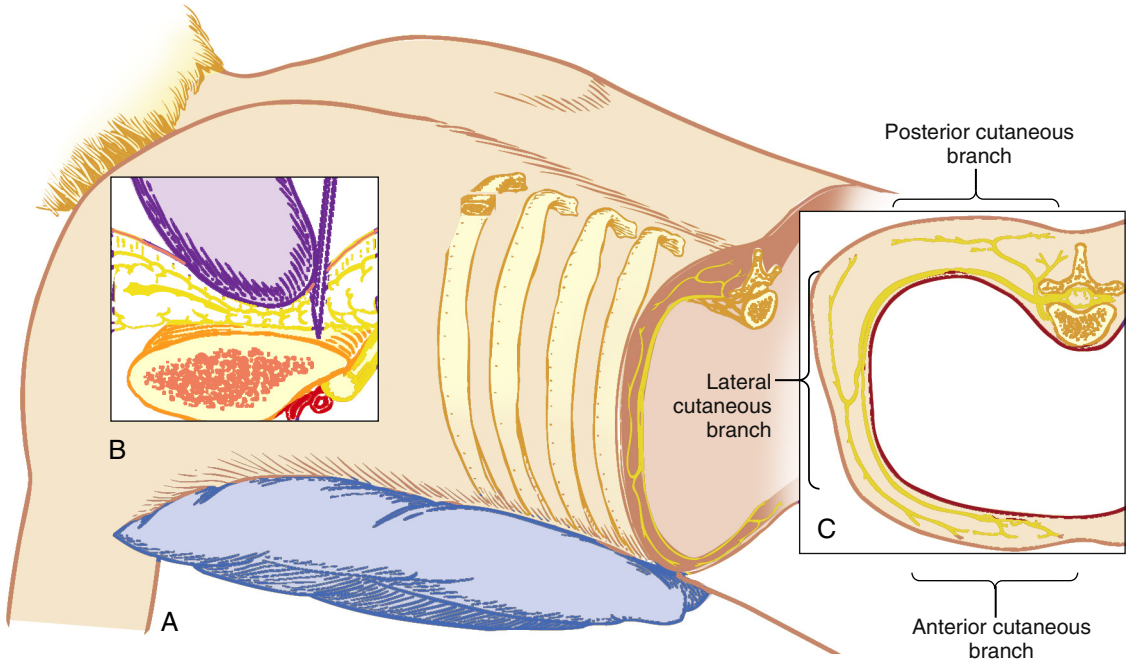

Figure 57-13. A, Patient positioning for an intercostal nerve block. **B,** The index finger displaces the skin up over the rib. The needle is inserted at the tip of the finger and rests on the rib. The needle is walked off the lower rib edge and inserted 3 to 5 mm. **C,** An intercostal nerve and its branches.

wall. During needle positioning and catheter placement, care must be taken to minimize entrainment of air through the needle. Lung parenchymal damage can occur with loss-of-resistance techniques or insertion of excessive lengths of catheter.

Side Effects and Complications

The major complication feared with intercostal blockade is pneumothorax. The actual incidence, however, was as low as 0.07% in a large series performed by anesthesiologists at all levels of training. Routine postoperative chest radiographs showed an incidence of nonsymptomatic pneumothorax of 0.42%.[58] If this unusual complication occurs, treatment is usually limited to observation, administration of oxygen, or needle aspiration. Rarely, chest tube drainage is required when these treatments are unsuccessful.

The risk of systemic local anesthetic toxicity is present with multiple intercostal blocks because of the large volumes and rapid absorption of the solutions. Use of epinephrine has been shown to decrease blood levels. Patients should be monitored and observed carefully during the block and for at least 20 to 30 minutes afterward. Interpleural block should not be performed in patients with pleural fibrosis or inflammation, pleural effusion, lung parenchymal disease associated with pleural disease, or bleeding diathesis. Pleural disease can result in poor spread of local anesthetic solutions or rapid uptake in the case of inflammation. Patients with severe pulmonary disease who rely on their intercostal muscles can exhibit respiratory decompensation after bilateral intercostal blockade.

TRANSVERSUS ABDOMINUS PLANE BLOCK

The lateral abdominal wall consists of subcutaneous tissue, the external oblique muscle, the internal oblique muscle, and the transversus abdominis muscle progressing from superficial to deep. The fascial sheath that lies deep to the internal oblique muscle and superficial to the transversus abdominis muscle is the target for the transversus abdominus plane (TAP) block. The nerves that exit the thoracolumbar spinal column pass laterally through the fascial layer to innervate the abdominal wall.

The landmarks for the TAP block are referred to as the *triangle of Petit*, and they consist of the iliac crest, the latissimus dorsi muscle, and the external oblique muscle. The triangle of Petit is located along the midaxillary line inferior to the lower costal margin and superior to the iliac crest.

Indications

TAP blocks are indicated for any lower abdominal surgery, including hernia repair, appendectomy, caesarian delivery, abdominal hysterectomy, laparoscopic surgery, renal transplantation, and prostatectomy.[59-61] Bilateral blocks can be used for midline incisions or laparoscopic procedures. It is reasonable to expect analgesia between T10 and L1 with a single injection.

Technique

Loss of Resistance (Blind Injection). The point of entry for the blind TAP block is the lumbar triangle of petit. This is situated between the lower costal margin and iliac crest. It is bound anteriorly by the external oblique muscle and posteriorly by the latissimus dorsi. This technique relies on feeling double "pops" as the needle traverses the external oblique and internal oblique muscles. A blunt needle will make the loss of resistance more significant.

Ultrasound-Guided. The patient is positioned supine. Using sterile technique the ultrasound probe is placed

firmly several centimeters superior and parallel to the iliac crest. A 21-gauge, 10-cm insulted needle is inserted several centimeters medial to the probe using an in-plane approach. Bowel peristalsis can often be seen just deep to the transversus abdominis muscle layer. After negative aspiration, 15 to 20 mL of local anesthetic is incrementally injected under ultrasound visualization (see Chapter 58).

Side Effects and Complications

Peritoneal puncture is possible (even with ultrasound guidance),[62] and there has been one reported case of a liver hematoma following a blind TAP block technique.[63]

ILIOINGUINAL AND ILIOHYPOGASTRIC BLOCKS

The ilioinguinal and iliohypogastric nerves arise from the first lumbar spinal root. They pierce the transversus abdominus cephalad and medial to the anterior superior iliac spine and lie between the transversus abdominus and internal oblique muscles. After traveling a short distance caudal and medially, their ventral rami pierce the internal oblique muscle before giving off branches, which then pierce the external oblique and provide sensory fibers to the skin. The ilioinguinal nerve courses anterior and inferiorly to the inguinal ring, where it exits to supply the skin on the proximal, medial portion of the thigh. The iliohypogastric nerve supplies the skin in the inguinal region.

Indications

Ilioinguinal and iliohypogastric blocks are used for analgesia following inguinal hernia repair and for lower abdominal procedures utilizing a Pfannenstiel incision. These blocks have been shown to reduce pain associated with herniorrhaphy significantly, although they do not provide visceral analgesia, and they cannot be used as the sole anesthetic during surgery. Despite the relatively simple technique, a failure rate as frequent as 10% to 25% has been reported.

The ilioinguinal and iliohypogastric nerves arise from the first lumbar spinal root. They pierce the transversus abdominus cephalad and medial to the anterior superior iliac spine and lie between the transversus abdominus and internal oblique muscles. After traveling a short distance caudal and medially, their ventral rami pierce the internal oblique muscle before giving off branches, which then pierce the external oblique and provide sensory fibers to the skin. The ilioinguinal nerve courses anterior and inferiorly to the inguinal ring, where it exits to supply the skin on the proximal, medial portion of the thigh. The iliohypogastric nerve supplies the skin in the inguinal region.

Technique

Landmark Technique. These blocks are performed using a loss-of-resistance technique. The local anesthetic should be inserted between the transversus abdominus and the internal oblique and between the internal and external oblique muscles.

The anterior superior iliac spine is located and a mark is made 2 cm cephalad and 2 cm medial. A blunt needle is inserted perpendicular to the skin through a small puncture site. Increased resistance is noted as the needle passes into the external oblique muscle. A loss of resistance is then observed as the needle passes through the external oblique muscle to lie between it and the internal oblique muscle. After negative aspiration, 2 mL of local anesthetic is injected. The needle is then inserted farther until another loss of resistance is noted as the needle passes out of the internal oblique to lie between it and the transversus abdominus muscle where another 2 mL of local anesthetic is injected. The needle is withdrawn, and the same procedure is repeated two more times in a fanlike distribution between the internal and external oblique and then the internal oblique and the transversus abdominus muscle. A total of approximately 12 mL of local anesthetic is used.

It is often difficult to appreciate the loss of resistance. Given the potential complications of advancing the needle too far, ultrasound guidance is often used for these blocks (see Chapter 58).

Side Effects and Complications

Blind injection can result in inadvertent injury to the intestine or blood vessels. Perforation of the large and small bowel and pelvic hematoma have been reported. Lower extremity weakness owing to local anesthetic spread and subsequent femoral nerve blockade can occur.

LOWER EXTREMITY BLOCKS

Knowledge of the anatomy of the lumbosacral plexus and peripheral nerves of the lower extremity enables anesthesiologists to provide comprehensive anesthetic care. These blocks are safe and have certain advantages, such as postoperative pain relief and lack of complete sympathectomy, which make them ideal for selected patients.

Historically, lower extremity blocks were less popular than blocks used routinely for surgical procedures of the upper extremity, in part because of the widespread acceptance and safety of spinal and epidural anesthesia. Unlike the brachial plexus, the nerves supplying the lower extremity are not anatomically clustered where they can be blocked easily with a relatively superficial injection of local anesthetic. Because of the anatomic considerations, lower extremity blocks are technically more difficult and require more training and practice before expertise is acquired. Many of these blocks were classically performed using paresthesia, loss of resistance, or field block technique, and success rates varied. Advances in needles, catheters, nerve stimulator technology, and ultrasound imaging have facilitated localization of neural structures and improved success rate.[64] Recent applications have focused on postoperative analgesia (rather than intraoperative anesthesia) to improve patient comfort and to assist in rehabilitation and hospital dismissal.

ANATOMY

The nerve supply to the lower extremity is derived from the lumbar and sacral plexuses. The lumbar plexus

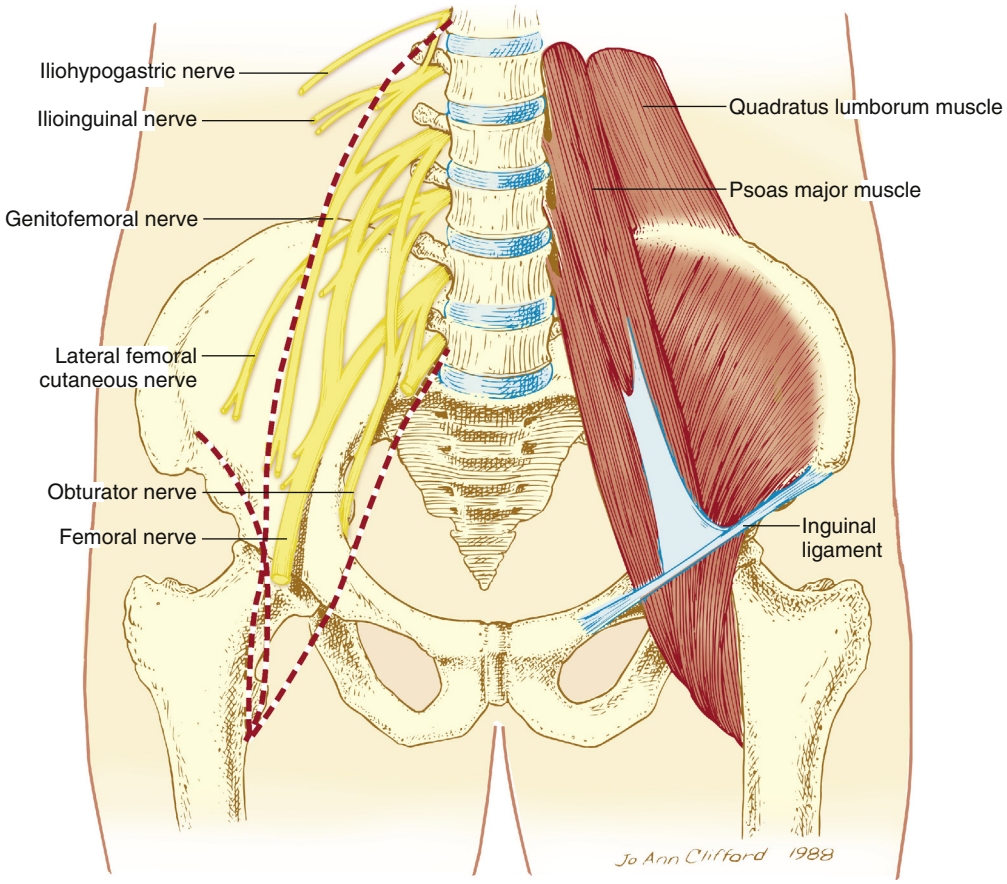

Figure 57-14. The lumbar plexus lies in the psoas compartment between the psoas major and quadratus lumborum muscles.

is formed by the anterior rami of the first four lumbar nerves, frequently including a branch from T12 and occasionally from L5 (Fig. 57-14). The plexus lies between the psoas major and quadratus lumborum muscles in the so-called psoas compartment. The lower components of the plexus, L2, L3, and L4, primarily innervate the anterior and medial thigh. The anterior divisions of L2, L3, and L4 form the obturator nerve; the posterior divisions of the same components form the femoral nerve; and the lateral femoral cutaneous nerve is formed from posterior divisions of L2 and L3.

The sacral plexus gives off two nerves that are important for lower extremity surgery: the posterior cutaneous nerve of the thigh and the sciatic nerve. The posterior cutaneous nerve of the thigh and the sciatic nerve are derived from the first, second, and third sacral nerves plus branches from the anterior rami of L4 and L5, respectively. These nerves pass through the pelvis together, and the greater sciatic foramen and are blocked by the same technique. The sciatic nerve is a combination of two major nerve trunks, the tibial (i.e., ventral branches of the anterior rami of L4, L5, S1, S2, and S3) and the common peroneal (i.e., dorsal branches of the anterior rami of L4, L5, S1, S2, and S3), which form the sciatic nerve. The trunks separate at or above the popliteal fossa, with the tibial nerve passing medially and the common peroneal laterally. The cutaneous distributions of the lumbosacral and peripheral nerves are shown in Figure 57-15.

PSOAS COMPARTMENT BLOCK (POSTERIOR APPROACH TO THE LUMBAR PLEXUS)

The psoas compartment block uses a technique in which a needle is placed into the space between the psoas major and quadratus lumborum muscles. The block was initially performed using a loss-of-resistance technique and a large volume of injected solution to provide anesthesia to the hip and anterolateral thigh.[65]

Clinical Applications

The psoas compartment block provides blockade of the three main components of the lumbar plexus with a single injection.[66] The technique must be combined with a sciatic block for anesthesia of the entire lower extremity. Psoas compartment block is often used to provide postoperative analgesia for patients undergoing major knee and hip surgery.[67,68]

Technique

Although loss-of-resistance or paresthesia techniques are feasible,[69] most practitioners use nerve stimulation to confirm the location of the lumbar plexus.[64] With the classic technique, the patient is placed in the lateral position, with hips flexed and operative extremity uppermost. A line is drawn to connect the iliac crests (i.e., intercristal line), identifying the fourth lumbar spine. A skin wheal is raised 3 cm caudad and 5 cm lateral to

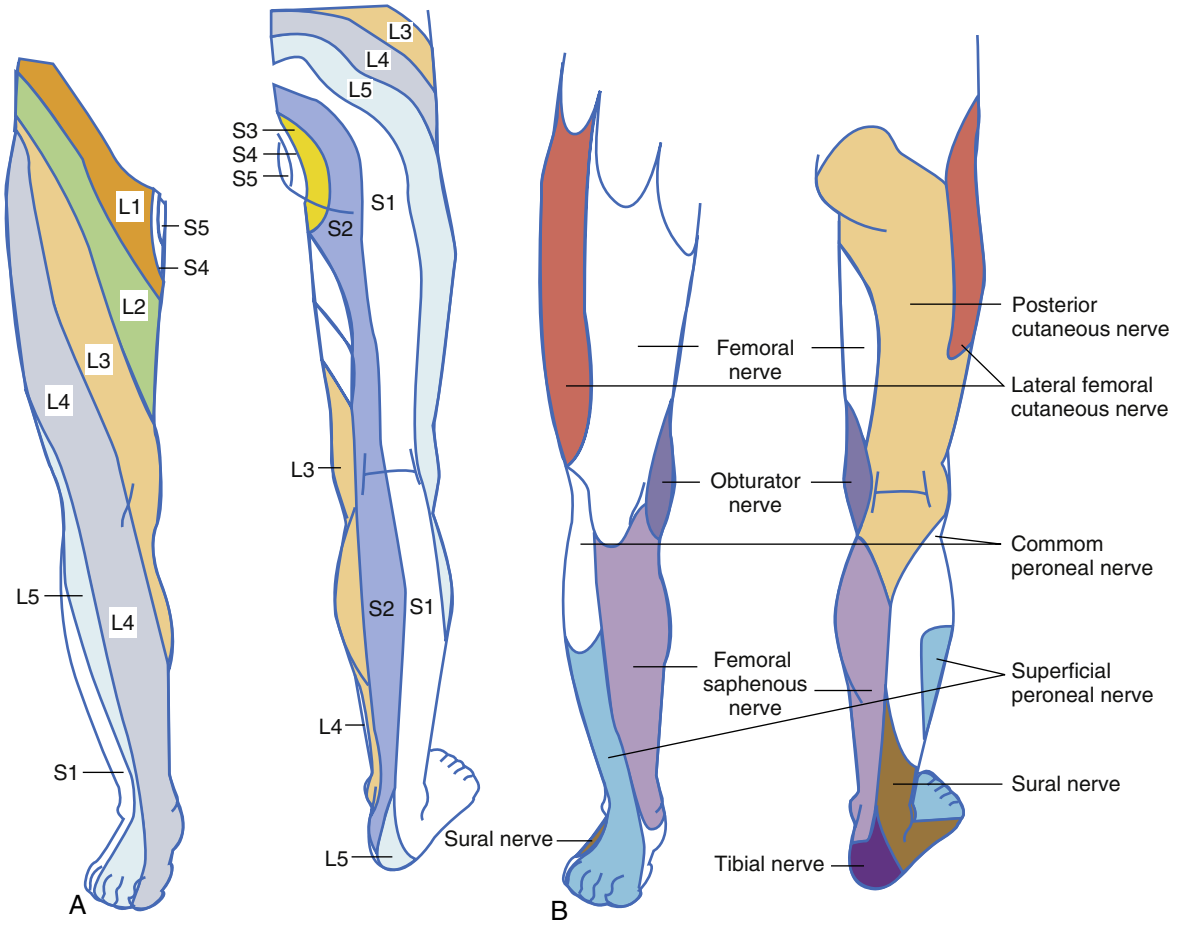

Figure 57-15. A, Cutaneous distribution of the lumbosacral nerves. **B,** Cutaneous distribution of the peripheral nerves of the lower extremity.

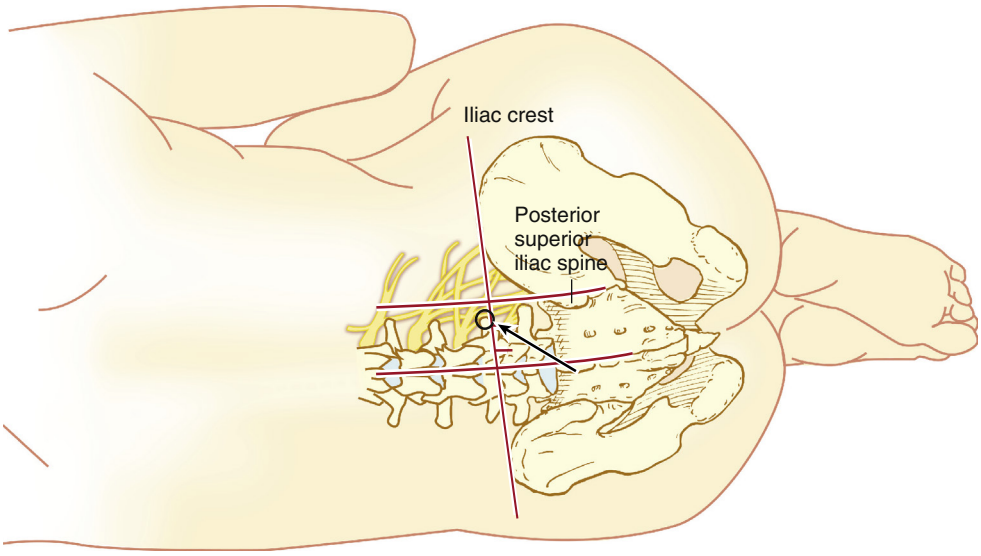

Figure 57-16. Psoas compartment block**.** Needle entry is marked 1 cm cephalad to the intercristal line, two thirds the distance from the midline to the posterior superior iliac spine line. The lumbar plexus is identified between the transverse processes of L4 and L5. Dural sleeves extend 3 to 5 cm laterally. The cross is the site of needle insertion.

the midline on the side to be blocked. A 21-gauge, 10-cm stimulating needle is then advanced perpendicular to the skin entry site until it contacts the fifth lumbar transverse process. The needle is redirected cephalad until it slides off the transverse process. The lumbar plexus is identified by elicitation of a quadriceps motor response, and after negative aspiration, 30 mL of local anesthetic is incrementally injected.

Based on anatomic imaging studies, Capdevila and colleagues[70] modified the classic psoas technique (Fig. 57-16). Needle insertion site is the junction of the lateral third and medial two thirds of a line between the spinous

process of L4 and a line parallel to the spinal column passing through the posterior superior iliac spine. (The spinous process of L4 was estimated to be approximately 1 cm cephalad to the upper edge of the iliac crests.) The needle is advanced perpendicularly to the skin until contact with the transverse process of L4 is obtained and is then advanced under the transverse process until quadriceps femoris muscle twitches are elicited. Despite a difference between men and women in the depth of the lumbar plexus, the distance from the L4 transverse process to the lumbar plexus was comparable (median value, 2 cm) in both sexes (see Fig. 57-12). It is crucial to achieve contact with the L4 transverse process to establish appropriate needle depth and position. A more recent study using ultrasound imaging demonstrated that the intersection of the middle and lateral thirds of the intercrestal line between the midline, and a parallel line through the posterosuperior iliac spine was too lateral to permit needle–transverse process contact in 50% of patients.[71]

Ultrasound-Guided Psoas Compartment Block

Despite the recent popularity of ultrasound guidance in regional anesthesia, there has been limited interest in using ultrasound for lumbar plexus blockade (see Chapter 58). This is likely due to the deep nature of the block; the increasing number of obese patients (also see Chapter 71); and the need for specialized curved-array, low-frequency transducers. Although images of the lumbar plexus have been obtained in volunteers and cadavers, the actual clinical experience for using ultrasound guidance to facilitate the placement of lumbar plexus blocks has not been well described.

Side Effects and Complications

Unlike the relatively minor complications associated with other lower extremity nerve blocks, the risks associated with a posterior lumbar plexus block can be quite severe.[72] Because of the proximity of the neuraxis, intrathecal or epidural local anesthetic or catheter placement is a potential complication. Epidural spread of local anesthetic is the most common complication with an incidence ranging from 1.8% to 16%.[64,66,67,70] Factors that contribute to epidural spread are a medially directed needle, large volumes of local anesthetic, and the presence of a spinal deformity (scoliosis). Less commonly, intrathecal or subarachnoid injection or catheter placement can lead to risk of widespread spinal anesthesia.

Because the psoas compartment block results in injection of local anesthetic into large, richly vascularized muscles (e.g., psoas, quadratus lumborum), the early plasma concentrations are significantly higher than levels obtained during a femoral block. Patients must be monitored for signs of local anesthetic toxicity when given large boluses of local anesthetics. Because of the same rich vascular supply, severe retroperitoneal or renal capsular hematomas have occurred in patients who have undergone a psoas compartment block while anticoagulated, or who received anticoagulation medication shortly after block placement or in the presence of a continuous psoas catheter. Although larger studies are needed, the American Society of Regional Anesthesia conservatively recommends that patients having a lumbar plexus block be managed in much the same way as those undergoing neuraxial blockade when thromboprophylaxis is ordered.[73]

PERIVASCULAR THREE-IN-ONE (FEMORAL) NERVE BLOCK

The femoral nerve is formed within the psoas major muscle by posterior divisions of the second, third, and fourth lumbar nerves. It emerges from the lateral border of the psoas muscle to descend in the groove between the psoas and iliacus muscles and enters the thigh by passing beneath the inguinal ligament lateral to the femoral artery. At this point, the nerve divides into multiple terminal branches, which have been classified as anterior and posterior. The anterior branches are primarily cutaneous, and the deep branches are chiefly motor.The femoral nerve supplies the anterior compartment muscles of the thigh (i.e., quadriceps, sartorius) and the skin of the anterior thigh from the inguinal ligament to the knee. Its terminal branch is the *saphenous nerve*, which supplies an area of skin along the medial side of the leg from the knee to the big toe.

Clinical Applications

The perivascular approach (i.e., three-in-one block) to the lumbar plexus is based on the premise that injection of a large volume of local anesthetic within the femoral canal while maintaining distal pressure will result in proximal spread of the solution into the psoas compartment and subsequent lumbar plexus block.[74] However, imaging studies suggest that blockade occurs through lateral (lateral femoral cutaneous nerve) and medial (obturator nerve) spread of injected local anesthetic.[75]

Indications for femoral nerve block include anesthesia for knee arthroscopy in combination with intraarticular local anesthesia and analgesia for femoral shaft fractures, anterior cruciate ligament reconstruction, and total knee arthroplasty as a part of multimodal regimens. Their use in complex knee operations is associated with smaller pain scores and fewer hospital admissions following same-day surgery.[64,67]

Technique

Femoral Block

Peripheral Nerve Stimulation or Paresthesia. The patient is placed in the supine position. A line is drawn between the anterior superior iliac spine and the pubic tubercle, identifying the inguinal ligament. The femoral artery is marked. A 22-gauge, 4-cm needle is advanced lateral to this line (Fig. 57-17, *A*). Elicitation of a motor response (or paresthesia) verifies correct needle position. Commonly, the anterior branch of the femoral nerve is identified first. Stimulation of this branch leads to contraction of the sartorius muscle and should not be accepted. The needle should be redirected slightly laterally and with a deeper direction to encounter the posterior branch of the femoral nerve. Stimulation of this branch is identified by patellar ascension as the quadriceps contract. A total of 20 to 40 mL of local anesthetic is injected incrementally after negative aspiration. Reliable anesthesia of the femoral and lateral

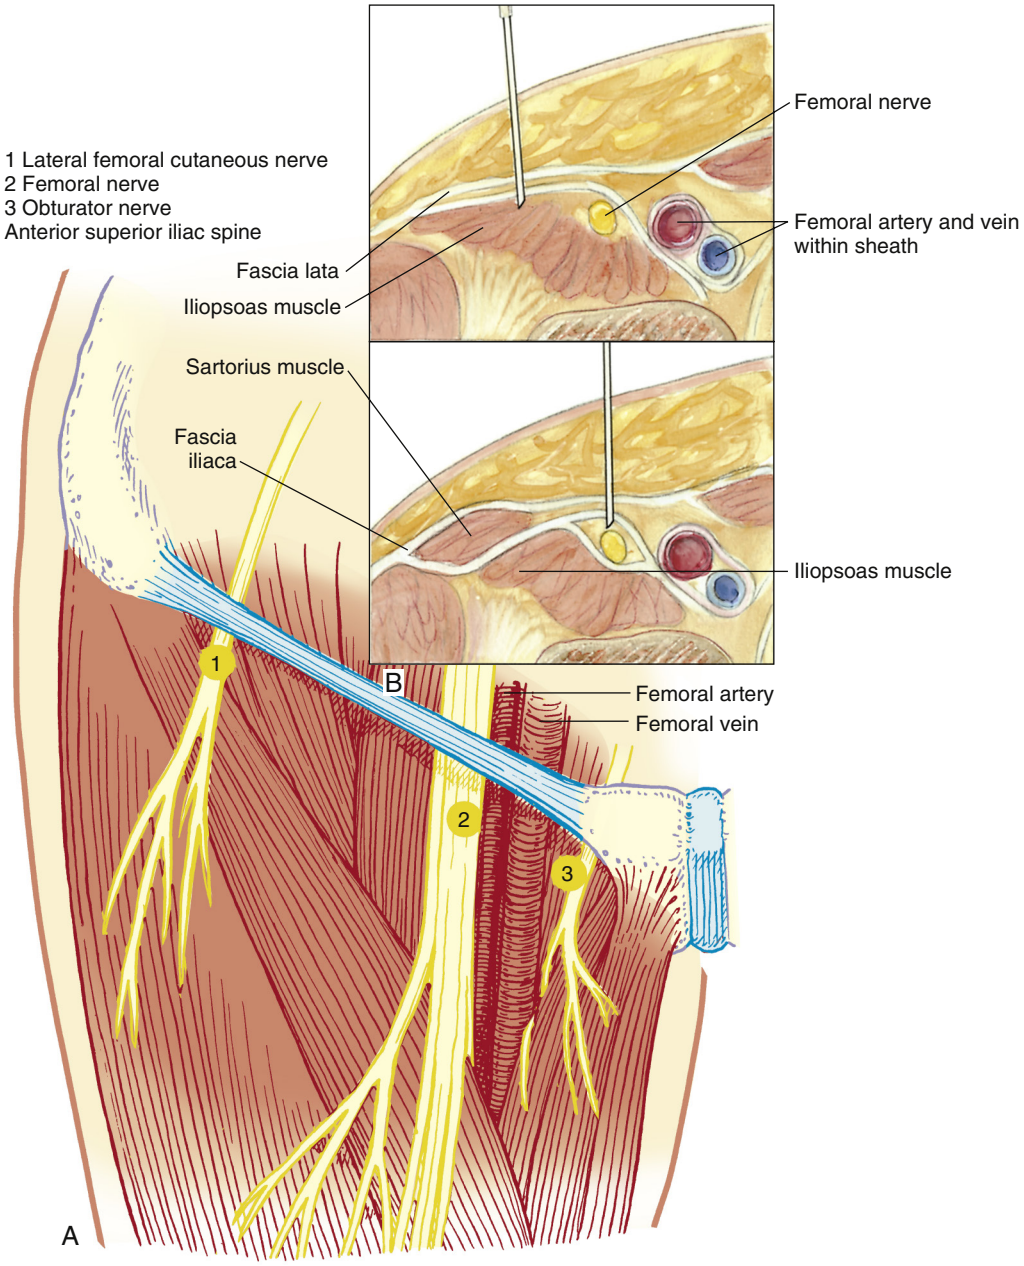

Figure 57-17. A, Anatomic landmarks for lateral femoral cutaneous, femoral, and obturator nerve blocks. **B,** For an obturator nerve block, the needle is walked off the inferior pubic ramus in a medial and cephalad direction until it passes into the obturator canal.

femoral cutaneous nerves can be predicted with 20 mL; however, obturator nerve block might not occur even with volumes greater than 30 mL.

Ultrasound Guided. The use of ultrasound can be useful in patients in whom it is difficult to palpate a femoral pulse, because of weight, anatomic variability, or changes to the needle insertion site (before radiation or surgery). The femoral nerve can be identified lateral to the artery as a triangular shaped structure.

Technique

Fascia Iliaca Nerve (Modified Femoral) Block. The fascia iliaca block was originally described in children (see Chapter 92). The clinical applications for its use are the same as those for femoral nerve block.[64,76] The simplicity of the double pop technique has been emphasized. The *double pop* refers to the sensation felt as the needle traverses the fascia lata then the fascia iliaca. Penetration of both layers of fascia is important for successful fascia iliaca blockade (see Fig. 57-17). To facilitate the appreciation of the "clicks" or "pops," the use of a short bevel or bullet-tipped needle has been advocated to provide more tactile feedback than cutting needles. The needle entry site for the fascia iliaca block is determined by drawing a line between the pubic tubercle and the anterior superior iliac crest and dividing this line into thirds. The needle entry point is one centimeter caudal to the intersection of the medial

two thirds and lateral one third along this line. This site is well away from the femoral artery, which is useful for patients in whom femoral artery puncture is contraindicated. Ultrasound can also be used to visualize the two fascial layers and spread of local anesthetic behind the fascia iliaca.

Side Effects and Complications

Intravascular injection and hematoma are possible because of the proximity of the femoral artery. Anatomically, the nerve and artery are located in separate sheaths approximately 1 cm apart. In most patients with normal anatomy, the femoral artery can be easily palpated, allowing correct, safe needle positioning lateral to the pulsation. The presence of femoral vascular grafts is a relative contraindication to these techniques. Nerve damage is rare.

LATERAL FEMORAL CUTANEOUS NERVE BLOCK

The lateral femoral cutaneous nerve (L2 and L3) emerges at the lateral border of the psoas muscle immediately caudad to the ilioinguinal nerve. It descends under the iliac fascia to enter the thigh deep to the inguinal ligament 1 to 2 cm medial to the anterior superior iliac spine. The nerve emerges from the fascia lata 7 to 10 cm below the spine and divides into anterior and posterior branches. The skin of the lateral portion of the thigh from the hip to midthigh is supplied by the posterior branch; the anterior branch supplies the anterolateral thigh to the knee.

Clinical Applications

The lateral femoral cutaneous nerve block is useful for skin graft harvesting and can be used in concert with other peripheral nerve blocks for complete anesthesia of the lower extremity.

Technique

A point is marked 2 cm medial and 2 cm caudad to the anterior superior iliac spine. A 22-gauge, 4-cm needle is advanced perpendicular to the skin entry site until a sudden release indicates passage through the fascia lata. As the needle is moved in a fanlike pattern laterally and medially, 10 to 15 mL of solution is injected, depositing local anesthetic above and below the fascia (see Fig. 57-17, *A*). Although a sensory nerve, the lateral femoral cutaneous nerve can be localized using a nerve stimulator technique by seeking pulsatile tingling in the distribution of the nerve.[77]

Side Effects and Complications

There is an infrequent risk of associated complications because there are no large blood vessels near this nerve. In addition, the likelihood of rapid uptake or intravascular injection is low.

SAPHENOUS NERVE BLOCK

Indications

The saphenous nerve provides innervation to the medial aspect of the lower extremity from the knee to the medial malleolus. Saphenous nerve blocks are commonly combined with popliteal and ankle blockade. Several approaches to the saphenous nerve block have been described using both a transsartorial (above the knee) and paravenous (below the knee) approach.[78] Ultrasound guidance can be used for both techniques. The saphenous nerve can also be blocked at the level of the ankle and will be described as part of the ankle block.

Anatomy

The saphenous nerve is a cutaneous sensory branch off the posterior division of the femoral nerve. It runs in the adductor canal along the posterior border of the sartorius muscle. The nerve emerges and divides at the level of the knee before continuing distally along the medial border of the tibia, posterior to the great saphenous vein. The saphenous nerve is located approximately 1 cm medial and 1 cm posterior to the saphenous vein at the level of the tibial tuberosity.

Technique

The saphenous nerve is purely sensory; therefore, a field block technique is most common. Ultrasound guidance can also be used to identify the neural and vascular structures.

Paravenous Approach. At the level of the tibial tuberosity, approximately 5 to 10 mL of local anesthetic is infiltrated deep to the great saphenous vein.

Localized Field Block. Approximately 5 to 10 mL of local anesthetic may be infiltrated from the medial condyle of the tibia anteriorly to the tibial tuberosity and posteriorly to the medial head of the gastrocnemius muscle. Success rates for this technique range from 33% to 65%.

Transsartorial Approach. The sartorius muscle is palpated on the medial side of the leg, just cephalad to the patella. At the upper pole of the patella, a 22-gauge, 5-cm needle is advanced 45 degrees from the coronal plane, through the muscle belly of the sartorius until a fascial pop is noted. Approximately 5 to 10 mL of local anesthetic is injected. Success rates for this technique range from 70% to 80%.

Ultrasound Guided. Ultrasound-guided saphenous nerve block can be performed either above or below the knee. For the transsartorial technique, the nerve can be found lying medial to the vastus medialis muscle within the fascia.

Side Effects and Complications

The risks of complications with this block are low, although the same theoretical risks all regional anesthetic techniques apply to this block. Given that the great saphenous vein is used as a landmark for the field block technique, minor hematoma formation is not uncommon.

OBTURATOR NERVE BLOCK

The obturator nerve is derived primarily from the third and fourth lumbar nerves, with an occasional minor

contribution from L2. The nerve lies deep in the obturator canal, having descended from the medial border of the psoas muscle. As the nerve leaves the obturator canal, it divides into anterior and posterior branches. The anterior branch supplies an articular branch to the hip and the anterior adductor muscles and a variable cutaneous branch to the lower medial thigh. The posterior branch innervates the deep adductor muscles and may send an articular branch to the knee.

Clinical Applications

The obturator nerve usually is blocked as part of regional anesthesia for knee surgery.[67] Because it is primarily a motor nerve, it is rarely blocked on its own; however, obturator nerve block can be useful in treating or diagnosing the extent of adductor spasm in patients with cerebral palsy and other muscle or neurologic diseases affecting the lower extremities before surgical intervention (e.g., adductor tenotomy).

Technique

The patient is placed in the supine position, and a mark is made 1 to 2 cm lateral and 1 to 2 cm caudad to the pubic tubercle. A skin wheal is raised, and a 22-gauge, 8- to 10-cm needle is advanced perpendicular to the skin entry site with a slight medial direction. The inferior pubic ramus is encountered at a depth of 2 to 4 cm, and the needle is walked in a lateral and caudad direction until it passes into the obturator canal. The obturator nerve is located 2 to 3 cm past the initial point of contact with the pubic ramus (see Fig. 57-17, *B*). After negative aspiration, 10 to 15 mL of local anesthetic is injected. A nerve stimulator is helpful in locating the obturator nerve, and correct needle position is evidenced by contraction of the adductor muscles of the medial thigh.

The classic approach to obturator nerve block involves painful periosteal contact and multiple needle redirections. An alternate interadductor approach was described by Wasseff.[79] In this technique, the needle is inserted behind the adductor tendon, near its pubic insertion, and is directed laterally toward a mark on the skin 1 to 2 cm medial to the femoral artery and immediately below the inguinal ligament representing the obturator canal. The nerve is identified by a motor response to peripheral nerve stimulation in the adductor muscle. An inguinal approach, with needle insertion in the inguinal crease at the midpoint of a line drawn between the inner border of the adductor longus tendon and the femoral arterial pulse has been recently described.[80]

Side Effects and Complications

Complications are rare, but this block is technically more difficult than other lower extremity blocks. The obturator canal contains vascular and neural structures, and there is a theoretical risk of intravascular injection, hematoma, and nerve damage.

PARASACRAL BLOCK

Parasacral block will consistently block both components of the sciatic nerve and the posterior cutaneous nerve of the thigh. Spread of local anesthetic may also anesthetize other branches of the sacral plexus including the superior and inferior gluteal and pudendal nerves. The pelvic splanchnic nerves (S2-S4), the terminal portion of the sympathetic trunk, the inferior hypogastric plexus, and the obturator nerve all lie in close proximity to the elements of the sacral plexus and can all be anesthetized with this approach.[81]

Clinical Applications

For procedures about the knee, the parasacral block can provide an advantage over more distal approaches to the sciatic nerve because of the block of both the sciatic and posterior cutaneous nerves, particularly if a tourniquet is used. For procedures below the knee, the adductor weakness from the obturator and superior gluteal nerve block may actually be disadvantageous for mobilization of the patient. This technique is also useful when immediate access to the individual nerves of the sacral plexus is not possible, such as owing to trauma or infection.

Technique

This approach is based on the bony relationship of the posterior superior iliac spine and the ischial tuberosity. The patient is positioned laterally with the side to be blocked uppermost. The most prominent aspects of the posterior superior iliac spine and the ischial tuberosity are identified, and a line is drawn joining these two points. Along the line, a mark is made at 6 cm inferior to the posterior superior iliac spine, defining the needle insertion site (Fig. 57-18). A 21-gauge, 10-cm, insulated needle is advanced in a sagittal plane until an evoked motor response is elicited, typically at a depth of 5 to 7 cm from the skin. Once the needle is placed properly, 20 to 30 mL of local anesthetic is injected slowly and incrementally. Plantar flexion of the foot (tibial nerve component) or dorsiflexion (common peroneal nerve) is an acceptable motor response. Because of the proximal nature of the block, a hamstring motor response also is acceptable.

Complications

Because the sacral nerves represent the parasympathetic portion of the autonomic nervous system, sympathetic blockade and its potential for hypotension are not seen with transsacral block unless excessive volumes of solution spread proximally to the lumbar sympathetic fibers. Loss of parasympathetic function to bowel, bladder, and sphincters can occur.[82] Injection of local anesthetic through misdirected needles into the subarachnoid or vascular compartments is a remote risk. Classically, the dural sac terminates at the lower border of S2; however, there are clinical reports of subarachnoid puncture with a 6- to 7-cm caudal needle to suggest individual variations below this "classic" location. Finally, an appreciation of the pelvic contents, especially colon, rectum, and bladder, is important. Should a deeply inserted needle enter the colon or rectum and not be noticed, it can result in contamination of the sacral canal.

SCIATIC NERVE BLOCK

The sciatic nerve (L4 and L5, S1 through S3) is the largest of the four peripheral nerves of the lower extremity,

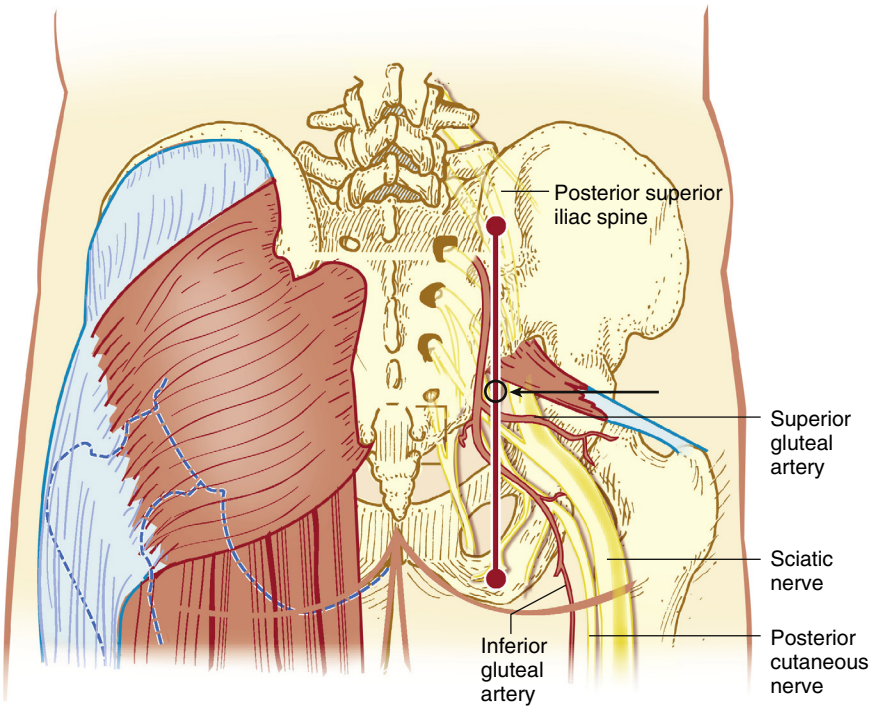

Figure 57-18. Parasacral block. This is the most proximal approach to the sciatic nerve, and it results in block of the posterior femoral cutaneous nerve. The most prominent aspects of the posterior superior iliac spine and the ischial tuberosity are identified, and a line is drawn joining these two points. Needle insertion site is along the line, 6 cm inferior to the posterior superior iliac spine.

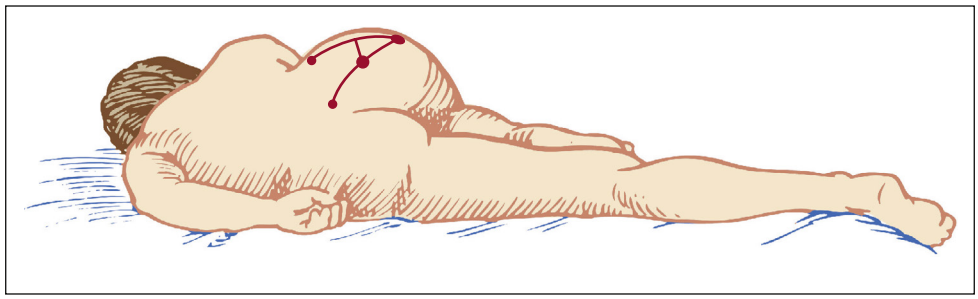

Figure 57-19. Patient positioning for the posterior approach to the sciatic nerve.

with a width of 2 cm as it leaves the pelvis with the posterior cutaneous nerve of the thigh. The sciatic nerve is composed of two nerves bound by a common sheath of connective tissue; the tibial component is medial and anterior, and the common peroneal component is lateral and slightly posterior. After passing through the sacrosciatic foramen beneath the piriformis muscle, it lies between the greater trochanter of the femur and the ischial tuberosity. The nerve becomes superficial at the lower border of the gluteus maximus muscle, where it begins its descent down the posterior aspect of the thigh to the popliteal fossa. The nerve supplies cutaneous innervation to the posterior aspect of the thigh and the entire leg and foot below the knee, except a thin medial strip supplied by the saphenous nerve.

Clinical Applications

Because of its wide sensory distribution, the sciatic nerve block can be used, together with a saphenous or femoral nerve block, for any surgical procedure below the knee that does not require a thigh tourniquet. It can also be combined with other peripheral nerve blocks to provide anesthesia for surgical procedures involving the thigh and knee. This form of anesthesia avoids the sympathectomy associated with neuraxial blocks and therefore may be advantageous when any shift in hemodynamics could be deleterious, such as in patients with severe aortic stenosis.

Technique

Classic (Posterior) Approach of Labat. For the classic (posterior) approach of Labat, the patient is positioned laterally, with the leg to be blocked rolled forward onto the flexed knee as the heel rests on the knee of the dependent nonoperative leg (modified Sims position; Fig. 57-19).[6] A line is drawn to connect the posterior superior iliac spine to the greater trochanter of the femur. A perpendicular line is drawn bisecting the first line and extending 5 cm caudad. A second line is drawn from the greater trochanter to the sacral hiatus. The intersection of this line with the perpendicular line indicates the point of needle entry and falls 3 to 5 cm along the line. A 22-gauge, 10- to 12-cm needle is advanced until a motor response (or paresthesia) is elicited or bone is contacted (Fig. 57-20). Stimulation

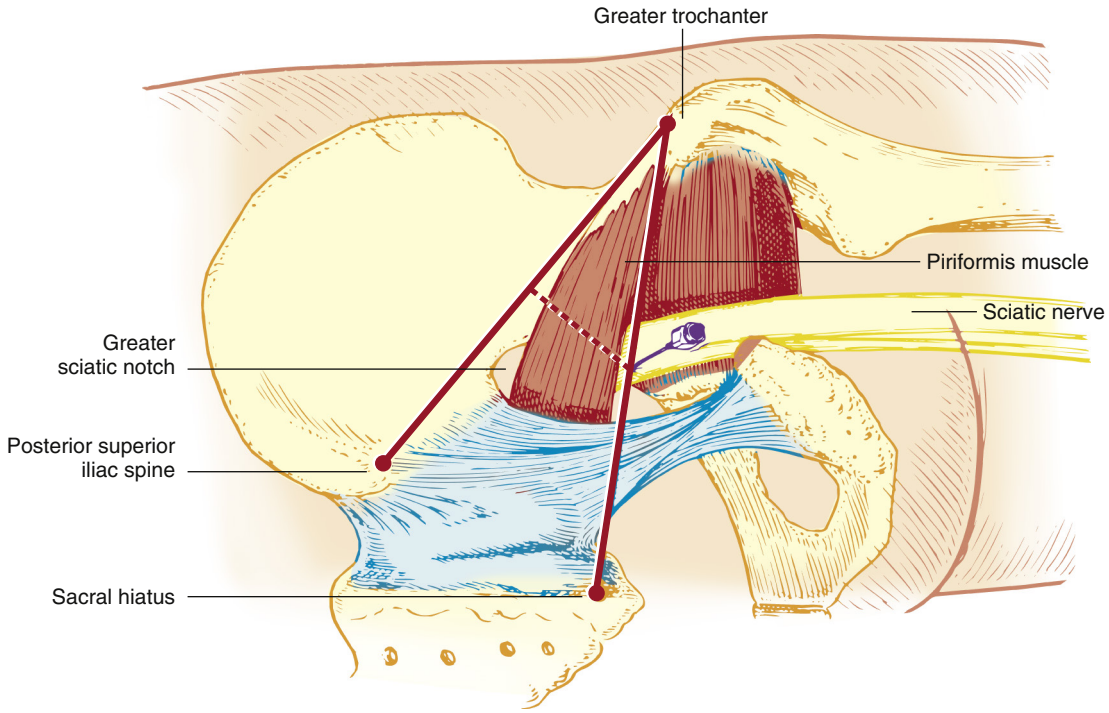

Figure 57-20. Anatomic landmarks for the classic posterior approach of Labat for sciatic nerve block.

of the tibial nerve component produces plantar flexion and inversion of the foot, and common peroneal nerve stimulation produces dorsiflexion and eversion. If bone is encountered, the needle is redirected medially; if blood is apirated (superior gluteal artery), the needle is redirected laterally. After the needle is placed properly, a total of 20 to 30 mL of local anesthetic is injected.

Subgluteal Approach. With this approach, the patient is positioned laterally in a modified Sims position; the leg to be blocked is rolled forward onto the flexed knee as the heel rests on the knee of the dependent (nonoperative) leg. This approach is based on the bony relationship to the greater trochanter and the ischial tuberosity. The most prominent aspects of the greater trochanter and the ischial tuberosity are identified by palpation, and a line is drawn joining these two points. A perpendicular line is drawn bisecting this line and extending 4 to 6 cm caudad. The second line approximates the location of the sciatic nerve. The site of the needle insertion can be at the intersection of the two lines or as far as 6 cm distally along the second line. A 21-gauge, 10- to 12-cm needle is inserted perpendicularly and advanced until a tibial or peroneal motor response (or paresthesia) in the ankle or foot is elicited, and 20 to 30 mL of local anesthetic is injected incrementally (Fig. 57-21). If no response is elicited, the needle can be redirected 1 to 2 cm medially or laterally to the original direction of the needle. It may be helpful to palpate or visualize the groove on the posterior aspect of the thigh. If bony contact is made, the needle is withdrawn and redirected medially.

Ultrasound Guided. A curvilinear probe is placed just distal to the gluteal cleft and scanned lateral to medial. The sciatic nerve can be identified as a flat hyperechoic structure medial to the greater trochanter and lateral to the hyperechoic border of the ischial tuberosity. The needle is advanced in an out-of-plane approach towards the sciatic nerve (see also Chapter 58).

Anterior Approach. The anterior approach is useful when the patient cannot be positioned for the classic posterior approach because of pain.[83] With the patient in the supine position, a line drawn along the inguinal ligament from the anterior superior iliac crest to the pubic tubercle is trisected. A second line parallel to the inguinal ligament is drawn, beginning at the tuberosity of the greater trochanter. The intersection of this second line with the more medial of the perpendicular lines represents the point of needle entry. A 22-gauge, 10.5- to 12-cm needle is inserted perpendicularly with a slightly lateral angulation at the point where the line representing the juncture of the middle and medial thirds crosses the second line. The needle is advanced until it contacts bone, the lesser trochanter of the femur (Fig. 57-22). The needle is redirected medially past the femur, and a paresthesia or nerve stimulator response is sought at a depth of about 5 cm past the bone. A total of 20 to 25 mL of solution is injected incrementally after careful aspiration.

Other Approaches. The sciatic nerve can also be blocked with the patient in the lateral[84] and lithotomy positions,[85] although these are rarely used clinically.

Side Effects and Complications

Serious complications of sciatic nerve block are rare; however, theoretical concerns regarding muscle trauma and puncture of a variety of vascular structures, must be considered. Sciatic nerve block is primarily a somatic nerve block. It does carry some sympathetic fibers to the extremity,

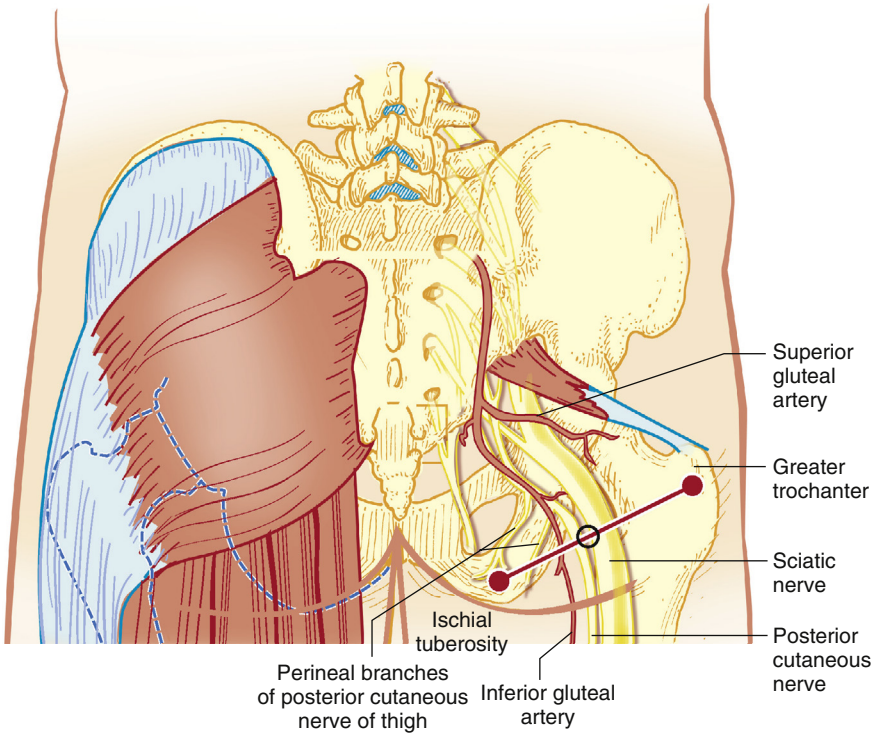

Figure 57-21. Sciatic nerve block (subgluteal approach). The sciatic nerve is relatively superficial at this level. Needle insertion is near the gluteal crease, between the hamstring muscles.

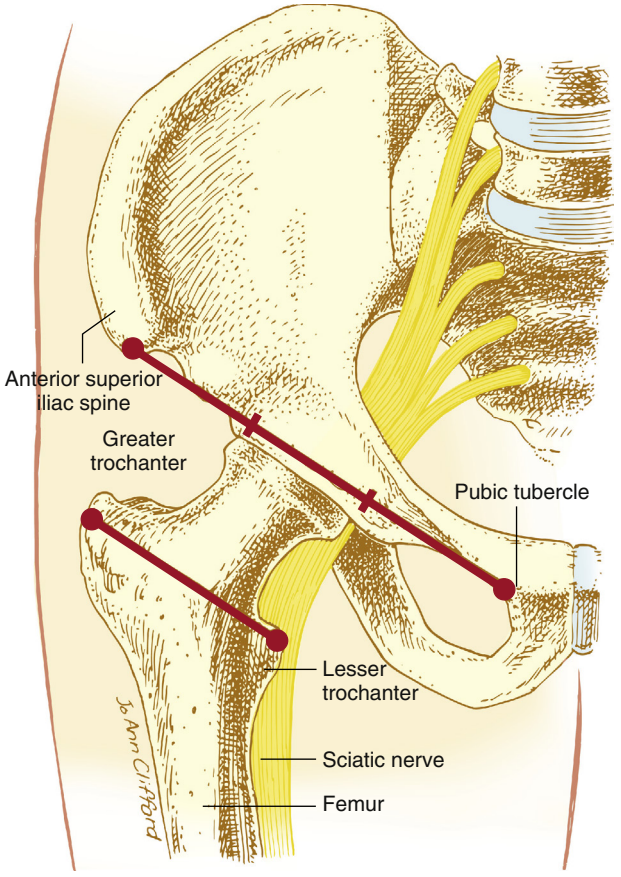

Figure 57-22. Anatomic landmarks for the anterior approach to a sciatic nerve block.

however, and may therefore allow pooling of small quantities of blood that is usually insufficient to cause significant hypotension. On some occasions, such as limb reimplantations and sympathetically mediated pain conditions, this sympathetic block may be advantageous. Residual dysesthesias for periods of 1 to 3 days are not uncommon, but usually resolve within several months.[72,86] Importantly, many orthopedic surgical procedures (including total hip and knee replacement) are associated with neuropraxia to one or both components of the sciatic nerve. Thus, thoughtful application of this technique is required to optimize neurologic outcome for patients considered to be at high risk of perioperative nerve injury from surgery or preexisting neurologic dysfunction.

POPLITEAL FOSSA BLOCK

The posterior muscles of the thigh are the biceps femoris, the semimembranosus, semitendinosus, and the posterior portion of the adductor magnus. As these muscles are traced distally from their origin on the ischial tuberosity, they separate into medial (semimembranosus, semitendinosus) and lateral (biceps) musculature, and they form the upper border of the popliteal fossa. The lower border of the popliteal fossa is defined by the two heads of the gastrocnemius. In the upper part of the popliteal fossa, the sciatic nerve lies posterolateral to the popliteal vessels. The popliteal vein is medial to the nerve, and the popliteal artery is most anterior, lying on the popliteal surface of the femur. Near the upper border of the popliteal fossa, the two components of the sciatic nerve separate. The peroneal nerve diverges laterally, and the larger tibial branch descends almost straight down through the fossa. The tibial nerve and popliteal vessels then disappear deep to the converging heads of the gastrocnemius muscle.

Clinical Applications

This block is chiefly used for foot and ankle surgery. Popliteal fossa block is preferable to ankle block for surgical procedures requiring the use of a calf tourniquet. The components of the sciatic nerve may be blocked at the level of the popliteal fossa through posterior or lateral approaches. Supplemental block of the saphenous nerve is required for surgical procedures to the medial aspect of the leg or when a calf tourniquet or Esmarch bandage are used.

Technique

Posterior Approach: Peripheral Nerve Stimulation or Paresthesia. The classic approach to the popliteal fossa is posteriorly, with the patient positioned prone. However, access can also occur with the patient in the lateral position (operative side nondependent) or supine position (with leg flexed at the hip and knee).

The borders of the popliteal fossa are identified by flexing the knee joint. A triangle is constructed, with the base consisting of the skin crease behind the knee, and the two sides composed of the semimembranosus (medially) and the biceps (laterally). A bisecting line is drawn from the apex to the base of the triangle, and a 5-cm needle is inserted at a site 5 to 10 cm above the skin fold and 0.5 to 1 cm lateral to the bisecting line (Fig. 57-23, *A*). Classically, the 5-cm distance was described; however, in an attempt to block the sciatic nerve before its division, a 7- to 10-cm distance has been recommended.[87] The needle is advanced at a 45-degree angle until a motor response (or paresthesia) is elicited. With a nerve stimulator technique, inversion is the motor response that best predicts complete neural block of the foot.[88] Injection of approximately 30 mL of local anesthetic solution is sufficient.

The success rate is typically 90% to 95%.[88] No formal comparison between paresthesia and nerve stimulator techniques has been performed to assess efficacy and complications. It is believed that incomplete block is the result of poor diffusion (because of the size of the sciatic nerve), the separate fascial coverings of the tibial and peroneal nerves, or blockade of only a single component of the sciatic nerve. Identification of the tibial and peroneal components decreases onset time and improves the success rate.[89]

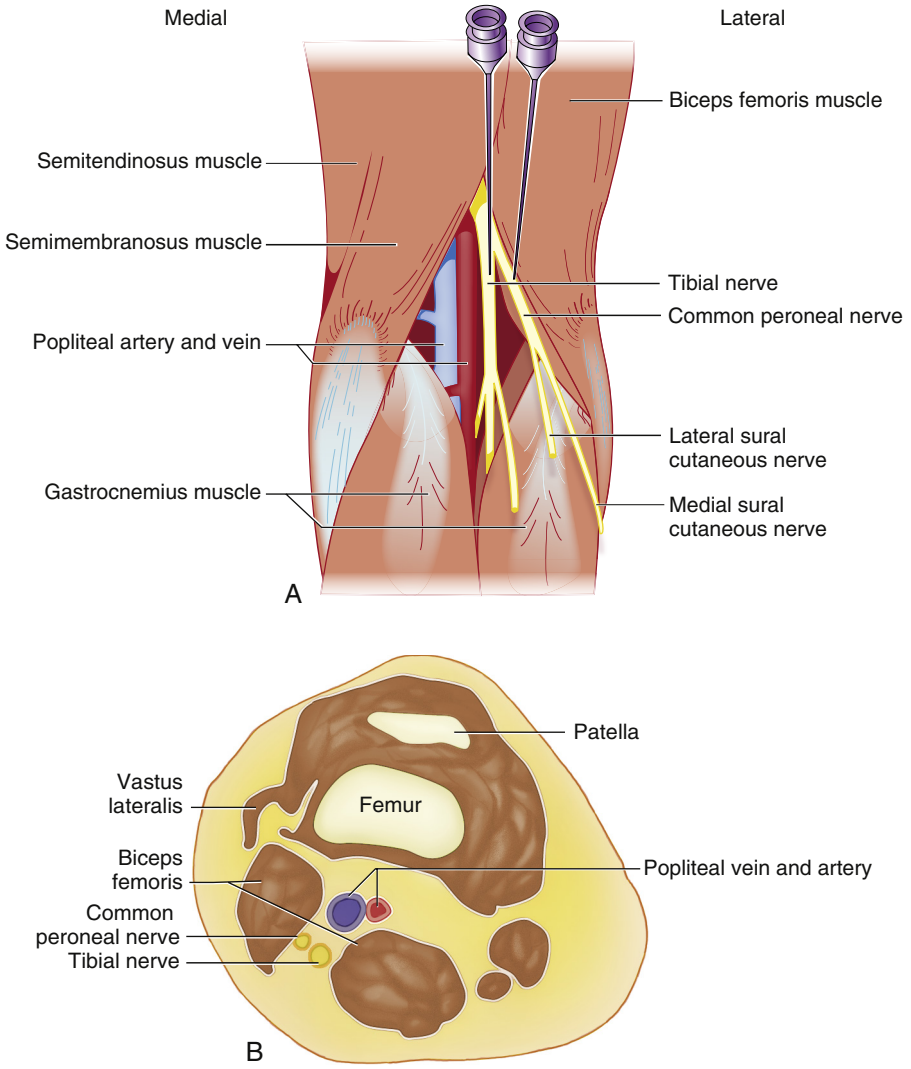

Figure 57-23. A, Anatomic landmarks for the posterior approach to the sciatic nerve in the popliteal fossa. **B,** Anatomic landmarks for the lateral approach to the sciatic nerve in the popliteal fossa.

Ultrasound Guided. The use of ultrasound can help identify the point of divergence of the sciatic nerve into the peroneal and tibial branches. Blockade at this level allows for a single (rather than a double) injection with comparable success[90] (see Figs. 57-23 and 57-24)

Lateral Approach. A lateral approach to blockade of the sciatic nerve in the popliteal fossa has been described.[91] Although block time is somewhat longer, onset and quality of block are similar to the posterior approach.[92] The lateral approach allows the patient to be positioned supine and eliminates the need for repositioning. The patient's leg is extended, with the long axis of the foot at a 90-degree angle to the table. The site of insertion is the intersection of the vertical line drawn from the upper edge of the patella and the groove between the lateral border of the biceps femoris and vastus lateralis. A 10-cm needle is advanced at a 30-degree angle posterior to the horizontal plane (see Fig. 57-23, *B*). Because the common peroneal nerve is located lateral to the tibial nerve, the stimulating needle often encounters the common peroneal nerve first with the lateral approach. As with the classic posterior approach, a tibial response is sought.[93] If a response associated with common peroneal nerve stimulation (e.g., eversion) is elicited, the needle is redirected more posteriorly.

Side Effects and Complications

Intravascular injection can occur because of the presence of vascular structures within the popliteal fossa. Performance of popliteal fossa block in patients with previous total knee arthroplasty or vascular bypass (femoral-popliteal) obviously should be performed extremely carefully. However, there have been no cases of graft disruption or joint infections related to needle placement in these patients.

NERVE BLOCKS AT THE ANKLE

Four of the five individual nerves that can be blocked at the ankle to provide anesthesia of the foot are terminal branches of the sciatic nerve: the posterior tibial, sural, superficial peroneal, and deep peroneal branches. The sciatic nerve divides at or above the apex of the popliteal fossa to form the common peroneal and tibial nerves. The common peroneal nerve descends laterally around the head of the fibula, where it divides into the superficial and deep peroneal nerves.

The tibial nerve divides into the posterior tibial and sural nerves in the lower leg. The posterior tibial nerve becomes superficial at the medial border of the Achilles tendon near the artery of the same name, and the sural nerve emerges laterally to the Achilles tendon.

Clinical Applications

Ankle blocks are simple to perform and offer adequate anesthesia for surgical procedures of the foot not requiring a tourniquet above the ankle.

Technique

Posterior Tibial Nerve. The posterior tibial nerve can be blocked with the patient in either the prone or the supine positions. The posterior tibial artery is palpated, and a 25-gauge, 3-cm needle is inserted posterolateral to the artery at the level of the medial malleolus (see Fig. 57-24, *A, B*). A paresthesia is often elicited; however, it is not necessary for a successful block. If a paresthesia is obtained,

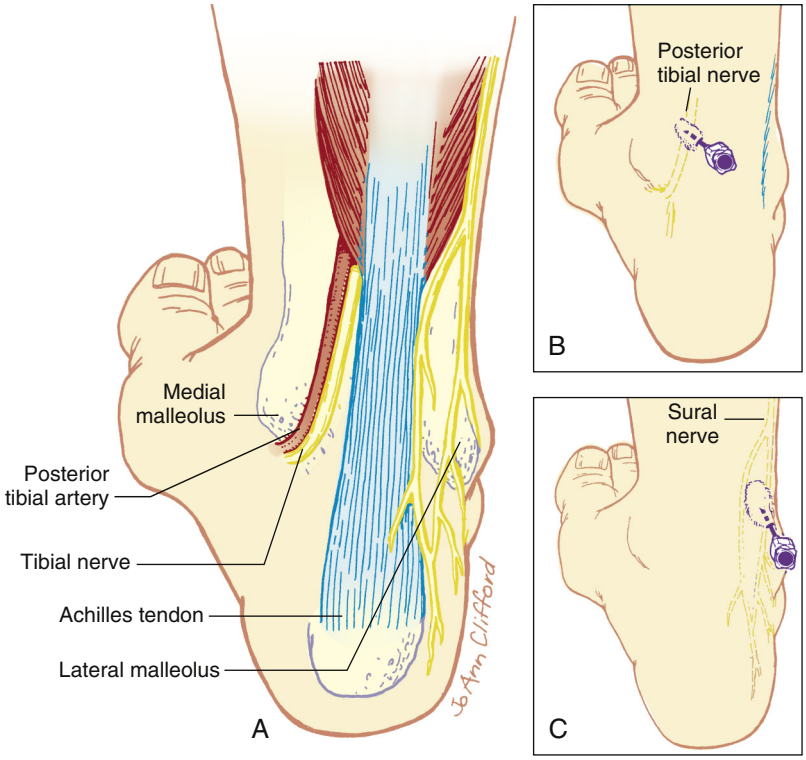

Figure 57-24. A, Anatomic landmarks for a block of the posterior tibial and sural nerves at the ankle. **B,** Posterior tibial nerve and method of needle placement for a block at the ankle. **C,** Sural nerve and method of needle placement for a block at the ankle.

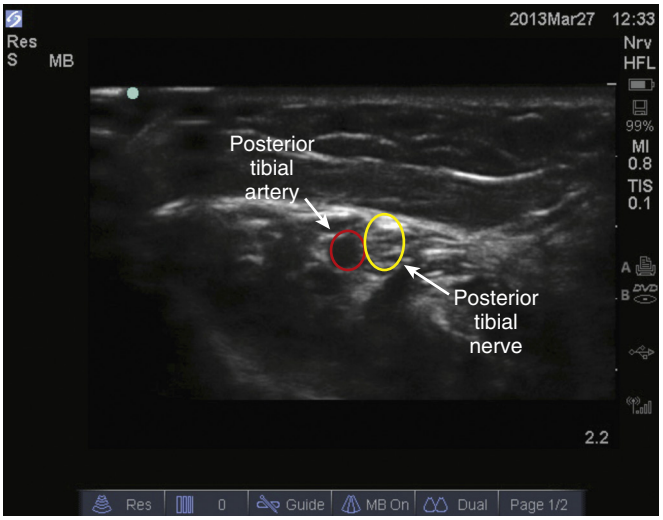

Figure 57-25. Ultrasound image of the medial aspect of the ankle showing the posterior tibial artery *(red)* and the posterior tibial nerve *(yellow)*.

3 to 5 mL of local anesthetic should be injected. Otherwise, 7 to 10 mL of local anesthetic should be injected as the needle is slowly withdrawn back from the posterior aspect of the tibia. Blockade of the posterior tibial nerve provides anesthesia of the heel, plantar portion of the toes, and the sole of the foot, as well as some motor branches in the same area. Ultrasound imaging of the posterior tibial nerve can shorten onset time[94] (Fig. 57-25).

Sural Nerve. The sural nerve is located superficially between the lateral malleolus and the Achilles tendon. A 25-gauge, 3-cm needle is inserted lateral to the tendon and is directed toward the malleolus as 5 to 10 mL of solution is injected subcutaneously (Fig. 57-26, *A, C*). This block provides anesthesia of the lateral foot and the lateral aspects of the proximal sole of the foot.

Deep Peroneal, Superficial Peroneal, and Saphenous Nerves. The deep peroneal, superficial peroneal, and saphenous nerves can be blocked through a single needle entry site (see Fig. 57-26). A line is drawn across the dorsum of the foot connecting the malleoli. The extensor hallucis longus tendon is identified by having the patient dorsiflex the big toe. The anterior tibial artery lies between this structure and the tendon of the extensor digitorum longus muscle and is palpable at this level. A skin wheal is raised just lateral to the pulsation between the two tendons on the intermalleolar line. A 25-gauge, 3-cm needle is advanced perpendicular to skin entry site, and 3 to 5 mL of local anesthetic is injected deep to the extensor retinaculum to block the deep peroneal nerve. This technique anesthetizes the skin between the first and second toes and the short extensors of the toes.

The needle is directed laterally through the same skin wheal while injecting 3 to 5 mL of local anesthetic subcutaneously, blocking the superficial peroneal nerve and resulting in anesthesia of the dorsum of the foot, excluding the first interdigital cleft. The same maneuver can be performed in the medial direction, thereby anesthetizing the saphenous nerve, a terminal branch of the femoral

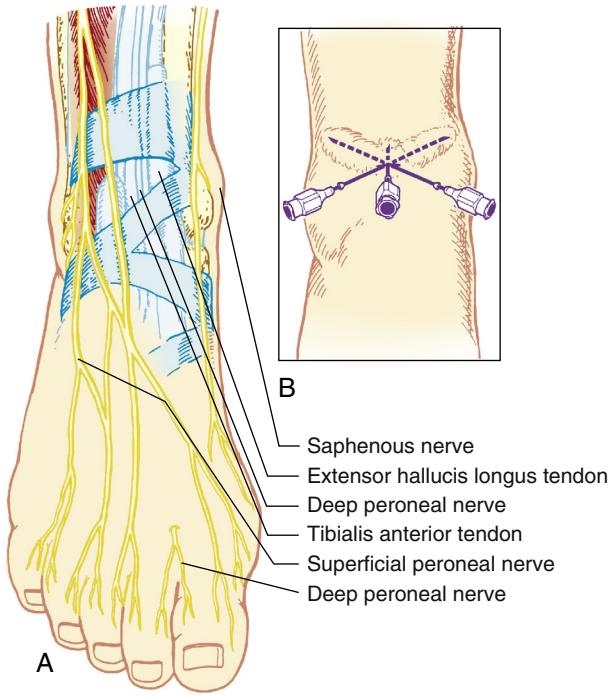

Figure 57-26. A, Anatomic landmarks for a block of the deep peroneal, superficial peroneal, and saphenous nerves at the ankle. **B,** Method of needle placement for a block of the deep peroneal, superficial peroneal, and saphenous nerves through a single needle entry site.

nerve that supplies a strip along the medial aspect of the foot.

Side Effects and Complications

Multiple injections are required for some techniques, resulting in discomfort for the patient. Persisting paresthesias can occur, but they are self-limited. The presence of edema or induration in the area of the ankle block can make palpation of landmarks difficult. Intravascular injection is possible but unlikely if aspiration for blood is negative. The volume of local anesthetic used is small, thereby decreasing the risk of local anesthetic toxicity.

CONTINUOUS CATHETER TECHNIQUES

The advantages cited for continuous nerve blockade include prolongation of surgical anesthesia, decreased risk of toxicity because of lower incremental doses, and postoperative pain relief and sympathectomy. Catheter placement using over-needle and through-needle methods have been described. Advances in equipment technology, including the development of stimulating needles and catheters and portable pumps allowing local anesthetic infusion after hospital dismissal, have increased the success rate and popularity of continuous peripheral blockade (Fig. 57-27).[95] Although concern regarding accurate catheter placement and maintenance still exists, the use of stimulating catheters and radiographic confirmation may further improve the functionality.[96] Overall, continuous peripheral nerve block provides superior analgesia compared with conventional opioid therapy. Minor technical problems such as catheter kinking, displacement

or leakage, and bacterial colonization are frequent, with no adverse clinical consequences in the large majority of cases. However, major neurologic and infectious adverse events are rare.[97]

Methods of providing continuous brachial plexus anesthesia have been described since at least the 1940s. These methods frequently offer ingenious solutions for the placing and securing of the needle or catheter. This technique is especially applicable to patients with upper extremity or digit replantation, total shoulder or elbow arthroplasty, or reflex sympathetic dystrophies, for which prolonged pain relief and sympathectomy are advantageous.[95]

Continuous lower extremity techniques were also described decades ago, but remained underused compared with continuous upper extremity and neuraxial approaches until recently. Reliable, improved success rates and the risk of spinal hematoma after neuraxial techniques led clinicians to reconsider continuous lower extremity blocks. Contemporary applications for continuous psoas compartment, sciatic, femoral, and popliteal fossa blockade have been reported. Compared with conventional systemic and neuraxial analgesic methods, continuous lower extremity blocks provide superior analgesia with fewer side effects, improve perioperative outcomes, and accelerate hospital dismissal after major joint replacement.[95,98]

CHOICE OF LOCAL ANESTHETIC

The choice of local anesthetic for a peripheral nerve block obviously depends to some degree on the duration of the surgical procedure, although other factors are also important (see Chapter 36). Prolonged blockade for up to 24 hours often occurs with long-acting local anesthetics such as bupivacaine or ropivacaine. Although this feature results in superb postoperative pain relief for the inpatient, it may be undesirable for the ambulatory patient because of the possible risk of nerve or tissue injury in a partially blocked limb. A short- or medium-acting local anesthetic, such as lidocaine or mepivacaine, may be more appropriate in the outpatient setting (see Chapter 89). Whatever drug is chosen, the total dosage should be calculated for each patient and should be kept within safe limits (see Chapter 36 for details).

The highest concentrations of local anesthetic drugs are not appropriate for peripheral neural blockade; therefore, 0.75% bupivacaine or ropivacaine, 2% lidocaine, 2% mepivacaine, and 3% 2-chloroprocaine *are not recommended*. The lowest concentrations of the same local anesthetics (i.e., 0.25% bupivacaine or ropivacaine and 0.5% mepivacaine or lidocaine) might not provide complete motor blockade.

Vasoconstrictors, usually epinephrine, can be added to the chosen local anesthetic to improve onset of action, to decrease drug uptake, and to prolong action. A concentration of 1:200,000 epinephrine is usually recommended. Ideally, the epinephrine should be added to the local anesthetic at the time the block is to be performed. Commercially prepared solutions with epinephrine have a lower pH than those in which it is freshly added, resulting in a higher percentage of ionized drug molecules. These ionized molecules do not readily cross the neural membrane, delaying the onset of drug action after injection. Epinephrine should not be added to the local anesthetic for blocks of the digits or penis because tissue ischemia can result. Various other additives, including clonidine, opioids, and ketamine, have been reported to enhance or prolong local anesthetic peripheral nerve blockade.[41,64]

COMPLICATIONS

Nerve injury is a recognized complication of peripheral regional techniques (Box 57-1). In a combined series involving more than 250,000 regional anesthetics, the frequency of neurologic complications after peripheral blockade was less than that associated with neuraxial techniques and was associated with pain on needle placement or injection of local anesthetic.[72,99] Risk factors contributing to neurologic deficit after regional anesthesia include neural ischemia, traumatic injury to the nerves during needle or catheter placement, infection, and choice of local anesthetic solution. However, postoperative neurologic injury due to pressure from improper patient positioning, tightly applied casts or surgical dressings, and surgical trauma is often attributed to the regional anesthetic. Patient factors such as body habitus or a preexisting neurologic dysfunction can also contribute.

Although needle gauge, type (i.e., short versus long bevel), and bevel configuration can influence the degree of nerve injury after peripheral nerve block, the findings are conflicting, and there are no confirmatory human studies. Theoretically, localization of neural structures with a nerve stimulator or ultasound imaging would allow a high success rate without increasing the risk of neurologic complications, but this has not been established.[11]

BOX 57-1 ***Recommendations for Limiting Peripheral Nerve Injury***

- The superiority of one nerve localization technique—paresthesia, nerve stimulation, ultrasound—over another concerning reducing the likelihood of nerve injury is not clear.
- Animal data have linked high injection pressures to subsequent fascicular injury, but the effectiveness of injection pressure monitoring for limiting nerve injury has not been confirmed in humans.
- The superiority of one local anesthetic or additive over another concerning reducing the likelihood of neurotoxicity has not been confirmed in humans.
- Patients with diseased or previously injured nerves (e.g., diabetes mellitus, severe peripheral vascular disease, or chemotherapy) may theoretically be at increased risk for block-related nerve injury. Although isolated case reports have described new or progressive neurologic deficits after regional anesthetic techniques in patients with multiple sclerosis or previous exposure to chemotherapy, clinical experience can neither refute nor confirm these concerns. Based on limited animal data, consideration may be given to avoiding potent local anesthetics, reducing local anesthetic doses or concentration, and avoiding or limiting vasoconstrictive additives in these patients.
- If damage to protective tissue barriers, such as the perineurium, is suspected from an abnormally painful paresthesia or pain on injection of local anesthetic, further injection should be terminated immediately, and the needle repositioned. Consideration may be given to aborting the block procedure to avoid further deposition of local anesthetic and vasoconstrictive additives.

From Neal JM, Bernards CM, Hadzic A, Hebl JR, et al: Asra practice advisory on neurologic complications in regional anesthesia and pain medicine, Reg Anesth Pain Med *33:404, 2008.*

Likewise, prolonged exposure, high dose, or high concentrations of local anesthetic solutions can also result in permanent neurologic deficits. In laboratory models, the addition of epinephrine increases the neurotoxicity of local anesthetic solutions and decreases nerve blood flow; however, the clinical relevance of these findings in humans remains unclear. Nerve damage caused by traumatic needle placement, local anesthetic neurotoxicity, and neural ischemia during the performance of a regional anesthetic can worsen neurologic outcome in the presence of an additional patient factor or surgical injury.[100]

Hemorrhagic complications have been described with nearly every peripheral technique and range from localized bruising and tenderness to severe hematomas or hemorrhagic complications. Patients who are receiving hemostasis-altering medications (e.g., low-molecular-weight heparin, warfarin, antiplatelet or antithrombotic medications) are at the highest risk. The risk of hematoma in anticoagulated patients undergoing peripheral nerve blockade is less clear than the risk of spinal hematoma in anticoagulated patients undergoing neuraxial blockade. The placement of peripheral nerve blocks in patients with a coagulopathy should be performed with caution, especially in a deep, noncompressible site where an expanding hematoma could go unnoticed (lumbar plexus) or in a location where a hematoma could compress the airway (interscalene).[73]

Infectious complications can be caused by exogenous (contaminated medication or equipment) or endogenous sources.[101] Infection at the site of needle placement is an absolute contraindication to peripheral nerve blockade, although caution should be used in patients with nearby cellulitis or systemic blood infections (bacteremia or sepsis). Although bacterial colonization of peripheral nerve catheters is not uncommon, cellulitis, abscess, or bacteremia are extremely rare.[97]

Prevention of neurologic complications begins during the preoperative visit with a careful evaluation of the patient's medical history and appropriate preoperative discussion of the risks and benefits of the available anesthetic techniques. It is imperative that all preoperative neurologic deficits are documented to allow early diagnosis of new or worsening neurologic dysfunction postoperatively. Postoperative sensory or motor deficits must also be distinguished from residual (prolonged) local anesthetic effect. Imaging techniques, such as computed tomography and magnetic resonance imaging, are useful in identifying infectious processes and expanding hematomas. Although most neurologic complications resolve completely within several days or weeks, significant neural injuries necessitate neurologic consultation to document the degree of involvement and coordinate further workup. Neurophysiologic testing, such as nerve conduction studies, evoked potentials, and electromyography, are often useful in establishing a diagnosis and prognosis.

Several large studies have established that severe systemic toxicity (seizures with or without cardiac arrest) occur on the order of 1:1000 for peripheral nerve blocks, depending on the type of block.[99] Therefore, practitioners of regional anesthesia must be familiar with the immediate detection and treatment of systemic local anesthetic toxicity. Systemic local anesthetic toxicity can occur immediately from an intravascular injection or it may be delayed because of rapid or excessive systemic absorption of local anesthetic. In addition to frequent aspiration during injection of local anesthetic, the addition of epinephrine will help alert the practitioner to potential intravascular injection. Attaching intravenous tubing to the needle allows immobility of the needle during injection. Typically, an assistant will aspirate with the syringe after each 5 mL injection of local anesthetic. Recent studies indicate that a lipid infusion improves success of resuscitation from cardiac arrest due to local anesthetic toxicity if given immediately after a local anesthetic overdose.[102]

SUMMARY

It is possible to perform all surgical procedures while the patient is under general anesthesia, but the addition of peripheral nerve block techniques adds flexibility and skills that benefit the patient intraoperatively and postoperatively. Successfully mastering these techniques and applying them to the appropriate clinical situations add valuable options to the anesthetic care. Knowledge of regional anesthesia is also essential for the diagnosis and treatment of acute and chronic pain syndromes (see Chapters 64 and 98).

Chapter 58

Ultrasound Guidance for Regional Anesthesia

JENS KESSLER • ANDREW T. GRAY

Key Points

- Ultrasound is a highly useful tool for discovery, particularly enlightening and revealing to those who practiced regional anesthesia before the advent of direct nerve imaging. Ultrasound imaging can elucidate the structure of peripheral nerves and adjacent anatomic structures for regional block. Anatomic variation in nerve position and course, which is a potential source of block failure, can be directly visualized.
- Peripheral nerves have a characteristic *honeycomb* echotexture formed by their connective tissue and nerve fibers.
- Ultrasound provides real-time imaging for needle tip placement and drug injection. Successful local anesthetic injections clarify the border of the nerve and track along the nerve path and its branches.
- Ultrasound guidance results in more consistent procedure times for peripheral nerve blocks[1] and can be applied to many regional anesthesia procedures.[2]

INTRODUCTION

The last decade of clinical practice has witnessed a revolution in how regional anesthesia is performed. Ultrasound imaging allows direct visualization of peripheral nerves, the block needle tip, and local anesthetic distribution.[3] This imaging modality has proven highly useful for guiding targeted drug injections and catheter placement. This chapter describes the general principles of ultrasound imaging for regional blocks and gives specific examples of peripheral nerve block procedures.

FUNDAMENTAL ASSUMPTIONS AND ARTIFACTS IN ULTRASOUND IMAGING

Ultrasound is sound with a frequency above the audible range (greater than 20,000 cycles per second). The frequencies used in clinical imaging are within the range of 1 to 20 megahertz (MHz). High-frequency ultrasound beams are well collimated and therefore can provide high resolution. For most regional blocks, the highest frequency is selected that adequately penetrates the depth of field. Sound waves reflected at the interface of two tissues with different acoustic impedances generate echoes. Ambient lighting has a large effect on visual discrimination; therefore, dim lighting without glare is especially useful for imaging low-contrast targets such as peripheral nerves.

Ultrasound imaging is predicated on several common assumptions.[4] First, the speed of sound through soft tissue is 1540 m/sec, meaning 13 microseconds elapse for each centimeter of soft tissue traversed back and forth for the total fly-back time of received echoes. This assumption allows interconversion of time and distance for echo-ranging. Local heterogeneities in soft tissue can cause artifactual bending of the block needle on ultrasound scans, the so-called *bayonet artifact*[5,6] (Fig. 58-1). Bayonet artifacts are commonly observed during the lateral in-plane approach to popliteal block (see "Sciatic Nerve Blocks in the Popliteal Fossa") because more adipose tissue is present over the nerves near the posterior midline of the leg. (Adipose tissue has a slower speed of sound than the adjacent muscle.) The speed of sound artifacts relate both to time-of-flight considerations and to refraction that occurs at the interface of tissues with different speeds of sound.

Second, ultrasound waves are assumed to take a straight path to and from tissue. When this does not occur, reverberation artifacts are displayed deep to the reflector. Reverberation artifacts are commonly observed from the block needle shaft at shallow angles of insertion because sound waves bounce back and forth between the walls of the needle before returning to the transducer (Fig. 58-2). Comet tail artifact is another type of reverberation artifact and helps identify strong reflectors such as the pleura during supraclavicular and intercostal blocks. At low receiver gain, the comet tail is seen as a tapering series of discrete echo bands just deep to a strongly reflecting structure. The spacing between the bands represents the distance between the anterior and posterior walls of the object.[7] Internal reverberations (arising from within the object) cause the comet tail artifact, most intensely observed when the anatomic object is perpendicular to the beam. Comet-tail artifact

from the pleura relates to lung water content, because small collections of lung water lined by the strongly reflecting pleura can allow the sound beam to enter and then return at varying times to the transducer (Fig. 58-3).

Third, all reflectors are assumed to be on the central ray of the transducer beam. When this assumption is not true, out-of-plane artifacts are observed (slice thickness artifacts). Definitive proof of out-of-plane artifacts requires multiple views, which are recommended when such ambiguities arise.

Unlike adjacent soft tissue, most biologic fluids do not significantly attenuate the sound beam and therefore cause acoustic enhancement (sometimes referred to as *posterior acoustic enhancement* or *increased through-transmission*). Acoustic enhancement artifacts deep to blood vessels can be erroneously interpreted as peripheral nerves (Fig. 58-4). For example, acoustic enhancement deep to the second part of the axillary artery in the axilla can be mistaken for the radial nerve.

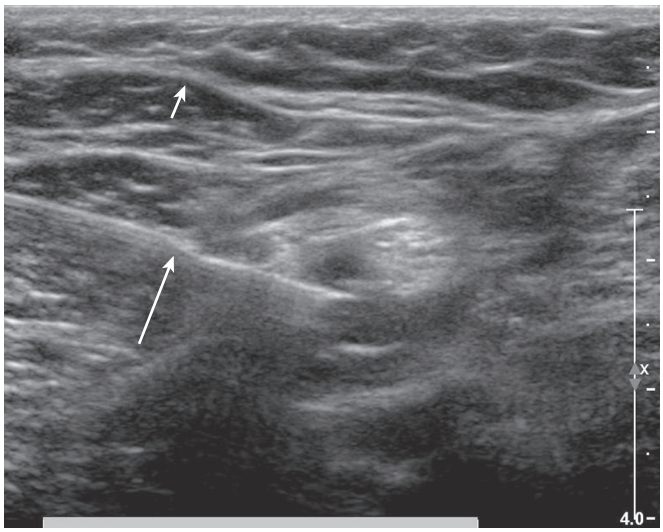

Figure 58-1. Bayonet artifact is observed during popliteal block of the sciatic nerve. In this sonogram, the block needle appears to bend as it approaches the sciatic nerve in the popliteal fossa *(long arrow)*. The slower speed of sound in the overlying adipose tissue, compared with the adjacent muscle *(short arrow)*, produces this artifact.

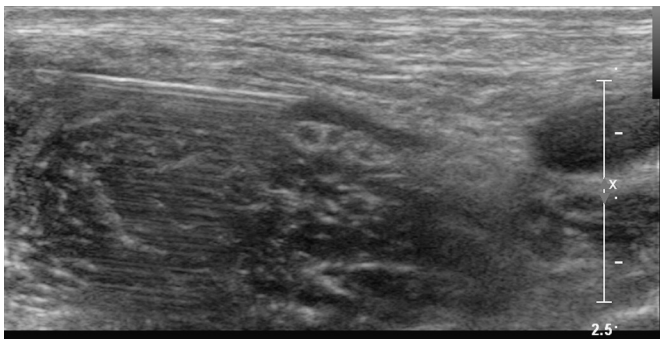

Figure 58-2. Reverberation artifact is observed during femoral nerve block. Sound waves reverberate back and forth between the walls of the needle and then return later to the transducer. Because the sound waves return at a later time, they are displayed deep within the field of imaging. No reverberation artifact is observed from the needle tip because the bevel opening does not have opposing walls.

In the infraclavicular region, acoustic enhancement deep to the axillary artery can be mistaken for the posterior cord of the brachial plexus (similarly, for the femoral artery and the femoral nerve in the inguinal region).

Acoustic shadowing occurs deep to strong reflecting structures, such as the cortical surface of mature bone (Fig. 58-5). Acoustic shadows from refraction (refractile shadowing or lateral edge shadowing) are often observed deep to the edges of blood vessels when the vessels are imaged in the short-axis view. Refractive edge shadows can be seen from the carotid artery during stellate ganglion block or from the second part of the axillary artery during infraclavicular block. Refraction artifacts (e.g., refractile shadowing) are less apparent when spatial compound imaging (refer to the discussion later in this chapter) is used to reduce angle-dependent artifacts.

TRANSDUCER SELECTION, MANIPULATION, AND MODES OF IMAGING

Ultrasound transducers consist of piezoelectric crystals that emit and receive high-frequency sound waves by interconverting electrical and mechanical energy. Transducer selection is important to the success of ultrasound-guided

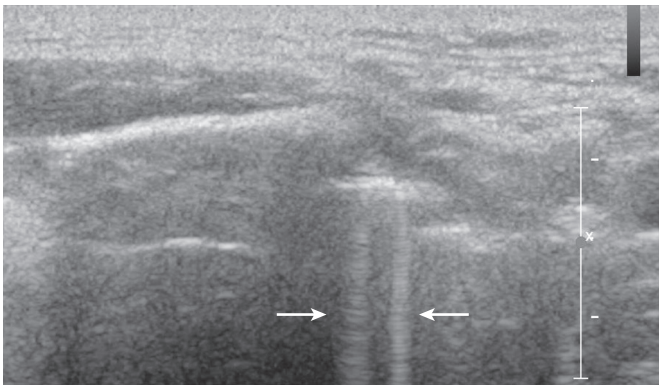

Figure 58-3. Comet-tail artifact is observed during the scanning of the upper airway *(arrows)*. Small collections of water near the air interface, which also are seen during scanning of the pleura, generate this artifact.

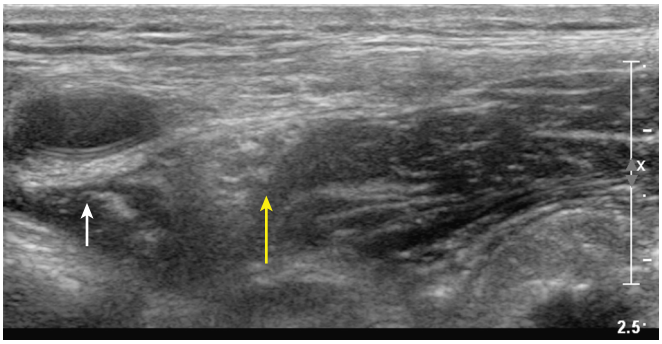

Figure 58-4. Posterior acoustic enhancement artifact is observed during femoral nerve block. The echoes deep to the femoral artery are enhanced *(white arrow)* and may be incorrectly identified as the femoral nerve *(yellow arrow)*.

regional anesthesia procedures. High-frequency sound waves provide the best resolution but will not penetrate far into tissue. The frequency range is therefore chosen to be the highest that will allow adequate insonation of the entire depth of field. A low-frequency transducer can be used to image large nerves that lie deep, such as the cords of the brachial plexus that surround the second part of the axillary artery or the proximal sciatic nerve in the gluteal region.

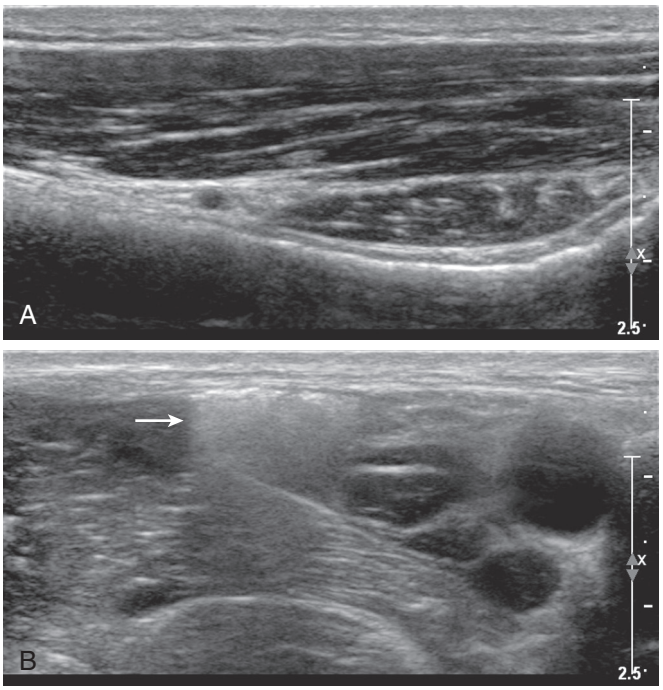

Figure 58-5. Acoustic shadowing occurs during regional blocks. **A,** During block of the axillary nerve in the proximal arm, the cortical surface of the humerus reflects and absorbs sound waves, thereby producing acoustic shadowing deep to the bone surface. **B,** During femoral nerve block, air inadvertently injected into the field layers to produce strong reflection and acoustic shadowing *(arrow)*.

The footprint size (i.e., the length of the active face transducer that contacts the skin) is chosen to provide a broad enough view of the structures of interest. As a general rule, the footprint should be at least as large as the anticipated depth of field. A square or landscape view is better than a keyhole view (depth greater than footprint) for guidance. For in-plane technique (see "Approaches to Regional Block With Ultrasound"), the millimeter of the footprint is approximately the millimeter of guidance.

Linear-array transducers generally have a higher scan line density than curved arrays and therefore produce the best image quality. Images from linear arrays are usually displayed in a rectangular format. When a linear transducer is needed but space at the site of block is limited by anatomic structures such as adjacent bone, a compact linear (*hockey stick*) transducer that has a smaller footprint can be very useful. Curved arrays provide a broad field of view for a given footprint size and are generally used when space is limited (e.g., infraclavicular region). Curved probes are easier to rock (see "Infraclavicular Blocks") and produce images in sector format.

Universal precautions should be used when handling dirty equipment. External surface probes require disinfection between every use and after extended periods of nonuse, per instructions of the manufacturer. Do NOT drop any ultrasound transducer, because the active face of the transducer is especially sensitive to contact with hard surfaces.

One of the essential skills to acquire for regional block with ultrasound is transducer manipulation (Fig. 58-6). Standardized nomenclature has been established[8]:

- Sliding (moving contact) the transducer along the known course of the nerve using a short-axis view often helps with nerve identification.

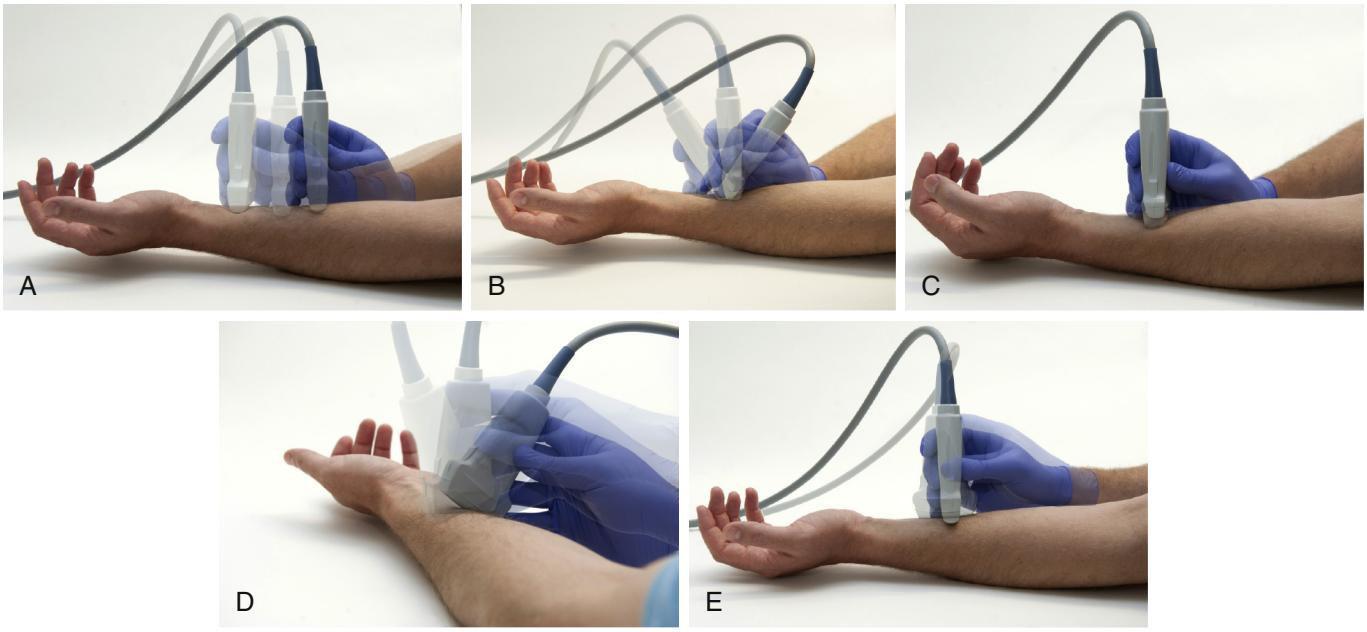

Figure 58-6. Transducer manipulation. Sliding (**A**), tilting (**B**), compression (**C**), rocking (**D**), and rotation (**E**) of the transducer are shown.

- Tilting (cross-plane, side-to-side) will vary the echobrightness of peripheral nerves. Optimizing this angle is critical to promote nerve visibility.
- Compression is often used to confirm venous structures. To improve imaging, compression not only provides better contact, but it also brings the structures closer to the surface of the transducer. Soft tissue is subject to compression; therefore, estimates of tissue distances will vary.
- Rocking (in-plane, toward or away from the indicator) is often necessary to improve visibility of the needle and anatomic structures when the working room is limited.
- Rotation of the probe will produce true short-axis views rather than oblique or long-axis views.

Anisotropy is the change in echogenicity with inclination of the transducer. In general, when objects are obliquely imaged, they appear less echogenic (Fig. 58-7). This relationship is most pronounced for tendons but also occurs for muscle and nerves.[9] Although the term *anisotropy* was first used to describe changes in received echoes when rocking the transducer with structures viewed in long axis, it has also been used for short-axis views when tilting the transducer. With experience, operators learn to rock and tilt the transducer naturally to fill in the received echoes from peripheral nerves. Sliding and rotating the transducer achieves needle tip localization after optimizing peripheral nerve echoes by tilting.

Spatial compound imaging steers ultrasound beams in different, predetermined angles, typically within approximately 20 degrees from the perpendicular (Fig. 58-8). These multiple lines of insonation are then combined to produce a single composite image. Spatial compound imaging appears to reduce angle-dependent artifacts, anisotropic effects, and acoustic shadows. Another advantage for regional block is that the definition of tissue planes and the detection of nerve borders can be improved. In the systems that have been tested, spatial compound imaging improves needle tip visibility over a limited range of needle insertion angles (less than 30 degrees). The stray lines of sight (i.e., those that travel off the field underneath the transducer) can be used to form a wider field of view in a trapezoidal format.

A Doppler shift occurs when a wave source and receiver are moving relative to each other, which produces a change in frequency such that the frequencies of the transmitted and reflected sound waves are not the same. When a wave source and receiver are moving toward each other, the observed frequency is greater than the source frequency; and when moving away from each other, the observed frequency is lower. The change in frequency is related to the velocity of moving reflectors and the angle of insonation. Red blood cells are the primary reflectors that produce Doppler shifts in clinical medicine.

Doppler ultrasound imaging has different modes (Fig. 58-9). Traditional color Doppler encodes mean-frequency shifts to provide directional velocity information; that is, conventional blue color indicates flow away from the transducer, whereas red color indicates flow toward the transducer. More recently, a more sensitive Doppler technology has been developed that encodes color based on the integration of the Doppler power spectrum.[10] Power Doppler is less angle dependent and not subject to aliasing. The disadvantages are that no directional information is provided and motion sensitivity (flash artifact) is high. Power Doppler is especially useful for detecting small arteries that accompany nerves (Box 58-1 and Table 58-1). Power Doppler can detect these small arteries and better delineate the course of tortuous vessels that have unfavorable angles to the ultrasound beam.

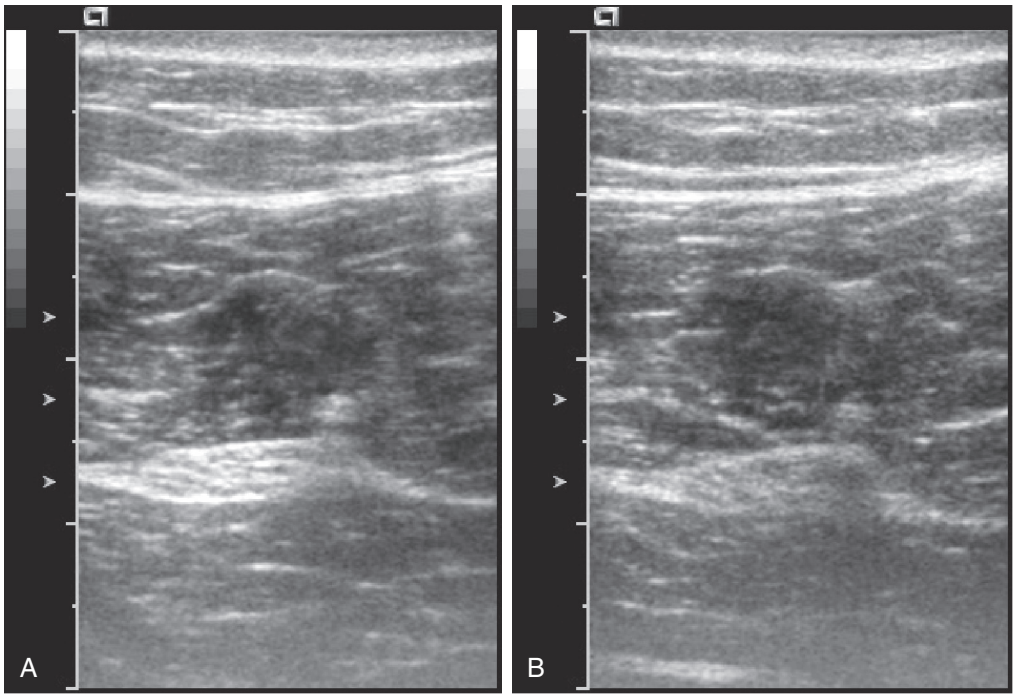

Figure 58-7. A, Sciatic nerve imaging in the subgluteal region. **B,** The amplitude of the received echoes diminishes when the angle of insonation is changed away from perpendicular to the nerve path, thereby demonstrating anisotropy.

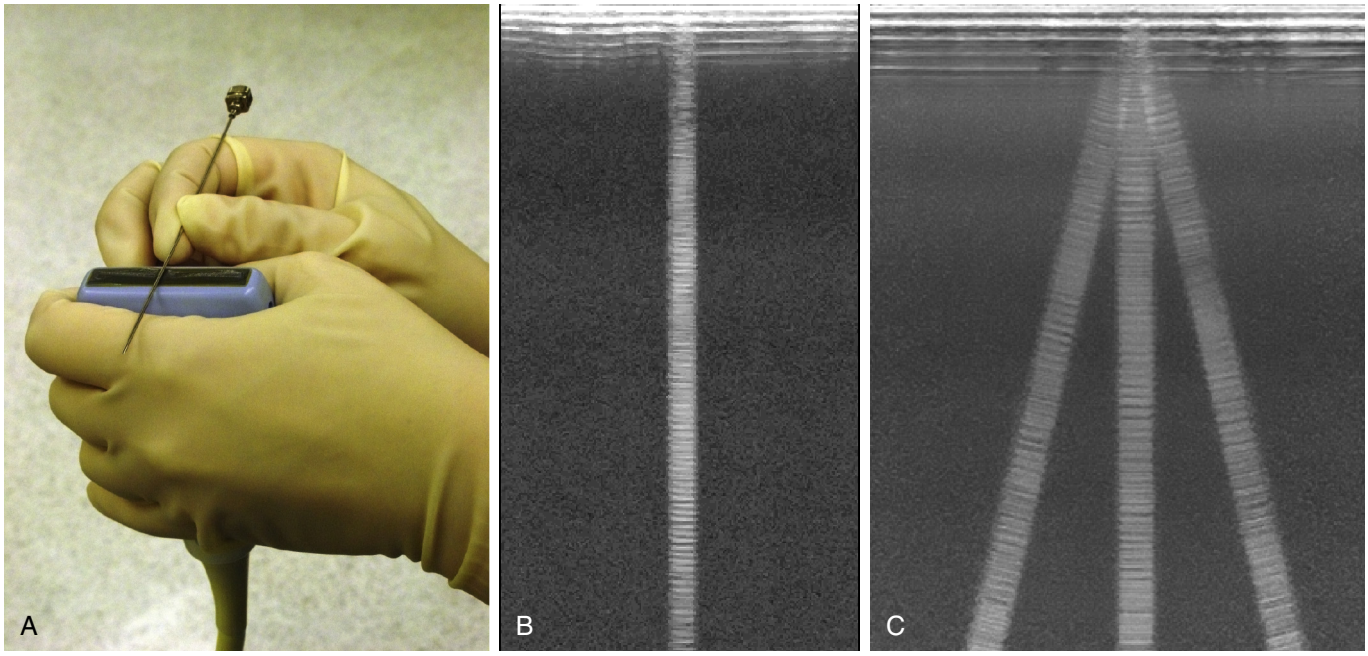

Figure 58-8. Spatial compound imaging. Some forms of ultrasound imaging use multiple lines of sight by electronically steering the beam to different angles. These sonograms were obtained by placing a linear array test tool (the solid metal stylet of a 17-gauge epidural needle) over the active face of the transducer to isolate a single element. **A,** External photograph demonstrates the linear array test tool applied to the active face of the ultrasound transducer. **B,** Single-beam imaging is demonstrated. **C,** Three lines of sight are used to form a compound image. The test tool images do not display the beam itself, but rather the transmit and receive apertures.

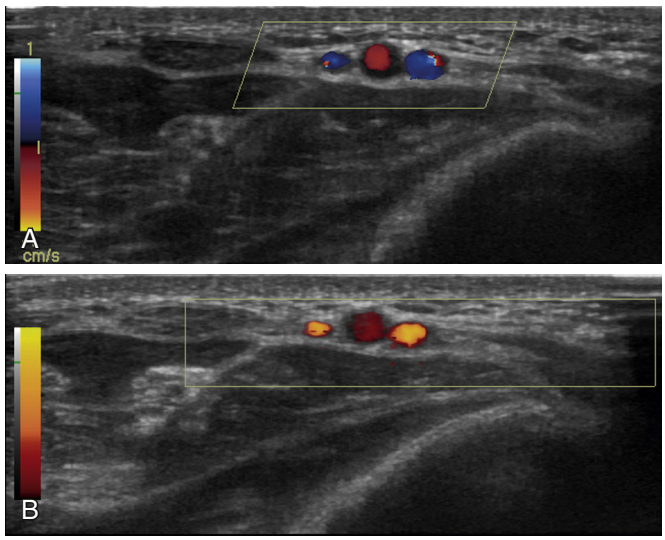

Figure 58-9. Duplex sonograms illustrate the Doppler shift. **A,** In color Doppler, color encoding is based on the mean frequency shift. **B,** In power Doppler, color encoding is based on the power spectrum.

NEEDLE TIP VISIBILITY

A large number of factors influence needle tip visibility in clinical practice. Metal needles are hyperechoic and can cause reverberation artifact. Needle tip visibility is best when the needle path is parallel to the active face of the transducer. Under this condition, the needle is perpendicular to the sound beam; therefore, strong specular reflections will be produced; that is, mirror-like reflections will be produced from a smooth surface.

BOX 58-1 *Respective Advantages of Color and Power Doppler Imaging Modalities*

Color Doppler

- Directional information
- Velocity estimates
- Less motion artifact (flash artifact)

Power Doppler

- More sensitive to detect the presence of flow (by a factor of 3 to 5 in some cases)
- Less angle dependent
- No aliasing

TABLE 58-1 **EXAMPLES OF ACCOMPANYING ARTERIES FREQUENTLY IMAGED DURING REGIONAL BLOCKS***

Regional Block	Adjacent Artery
Mandibular nerve	Maxillary artery
Cervical root	Radicular artery
Stellate ganglion	Vertebral artery
	Inferior thyroid artery
Suprascapular nerve	Suprascapular artery
Intercostal nerve	Intercostal artery
Transversus abdominis plane	Subcostal artery
Ilioinguinal nerve	Deep circumflex iliac artery
Rectus sheath	Epigastric artery
Proximal fascia iliaca	Deep circumflex iliac artery
Obturator nerve	Obturator artery
Parasacral sciatic nerve	Superior gluteal artery

*These small arteries can be used as sonographic landmarks to help identify adjacent peripheral nerves.

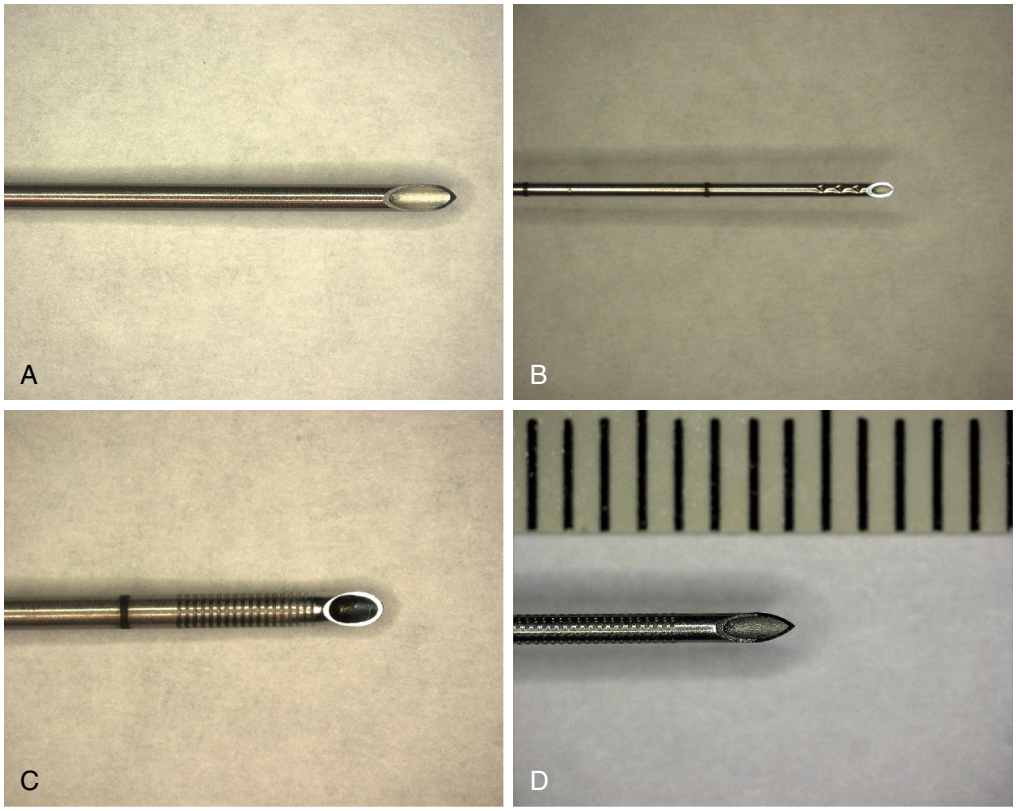

Figure 58-10. Photomicrographs of needles are used for regional block. A plain conventional needle (**A**) and echogenic designs (**B, C, D**) are shown. A smooth needle may not generate a recordable echo because its rounded shaft reflects most incident sound away from the source. A variety of textured surfaces are manufactured and marketed to improve needle tip detection on acquired sonograms. *(Modified from Gray AT:* Atlas of ultrasound-guided regional anesthesia*, ed 2. Philadelphia, 2012, Saunders.)*

As the angle of incidence is increased, the mean brightness will decrease.[11] In this same study, the bevel angles were ground from 10 to 70 degrees but were found to have no effect on the needle tip echo. However, bevel orientation does influence the needle tip echo; visibility is best with the bevel either directly facing or averting the transducer.[12] Because needle diameters are smaller than the scan plane thickness, larger needles are more echogenic than finer ones.

Visualization of needles in echogenic tissue is difficult, particularly in bright adipose tissue. A number of strategies have been proposed to improve needle tip visibility.[13,14] A low-receiver gain can improve the detection of the needle tip echo. Spatial compound imaging can help identify the needle tip when the needle path is at an angle with respect to the transducer. However, one limitation of this strategy is that only a small triangular section of the field of imaging receives all the lines of sight and is therefore fully compounded. In addition, the range of angles for spatial compound imaging is limited and is usually exceeded by the desired needle insertion path. Rocking back the transducer can improve the angle between the ultrasound beam and needle during in-plane technique (see "Approaches to Regional Block with Ultrasound"). Most practitioners orient the needle so that the needle bevel faces the transducer.

Among needles originally developed for use in regional anesthesia, Hustead bevels tended to be more visible than side port needles that lack cutting bevels. Needles with echogenic modifications are now commercially marketed for peripheral nerve blocks. One engineering strategy has been to texture the needle surface so that echoes return to the transducer source, regardless of the angle of insonation (Fig. 58-10). One potential limitation of these needle designs is the finite size of the needle texturing. Low-frequency transducers produce longer wavelengths that may be too large to reflect strongly back from the textured surface of the needle.

APPROACHES TO REGIONAL BLOCK WITH ULTRASOUND

Peripheral nerves can be directly detected with high-resolution ultrasound imaging.[15] The fascicular echotexture is the most distinguishing feature of nerves (*honeycomb* architecture) (Fig. 58-11). More central nerves, such as the cervical ventral rami, have fewer fascicles and can appear monofascicular on ultrasound scans. Ultrasound frequencies of 10 MHz or higher are required to distinguish tendons from nerves based on echotexture alone. One of the most powerful techniques to identify nerve fascicles is to slide a broad linear transducer over the known course of a peripheral nerve with the nerve viewed in short axis (transverse cross section).

Nerves can be round, oval, or triangular. Although nerve shape can change along the nerve path, the cross-sectional nerve area is relatively constant in the absence of major branching[16] (Fig. 58-12). Peripheral nerves are pathologically enlarged either by entrapment or in certain neuromuscular disorders, such as Charcot-Marie-Tooth, type 1A, disorder (Fig. 58-13). Some evidence suggests that patients with diabetic neuropathy also have enlarged peripheral nerves.

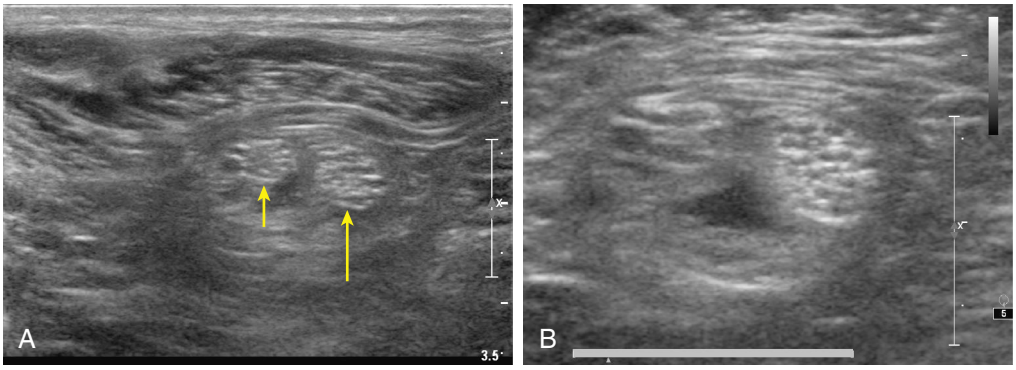

Figure 58-11. Nerve echotexture. **A,** Fascicles of the common peroneal *(short yellow arrow)* and tibial *(long yellow arrow)* nerves are visualized in the popliteal fossa. In this sonogram the *honeycomb* appearance of a polyfascicular peripheral nerve is observed. **B,** Close-up view shows detailed echotexture of the two nerves.

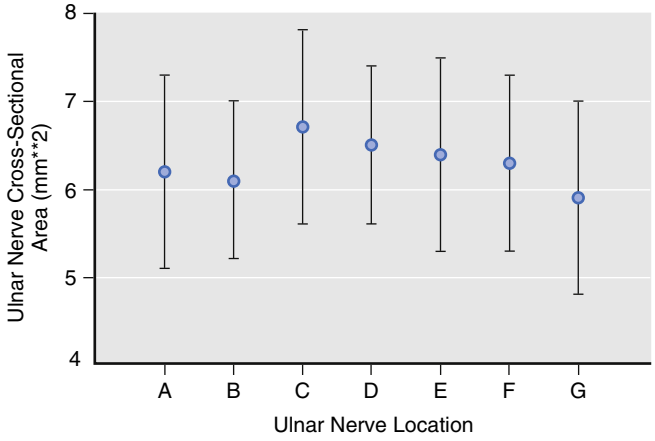

Figure 58-12. Cross-sectional area of a peripheral nerve as a function of nerve path length. In this figure the cross-sectional area of the ulnar nerve is shown at various points in the upper extremity. Axilla *(A)*; midhumerus *(B)*; 2 cm proximal to medial epicondyle *(C)*; medial epicondyle *(D)*; 2 cm distal to medial epicondyle *(E)*; arterial split *(F)*; and wrist crease *(G)*. Data are shown as mean values with standard deviations. Despite changes in shape that can occur, the cross-sectional area of nerves is relatively constant along the nerve path in the absence of major branching. *(Modified from Cartwright MS, Shin HW, Passmore LV, Walker FO: Ultrasonographic findings of the normal ulnar nerve in adults,* Arch Phys Med Rehabil *288(3): 394-396, 2007.)*

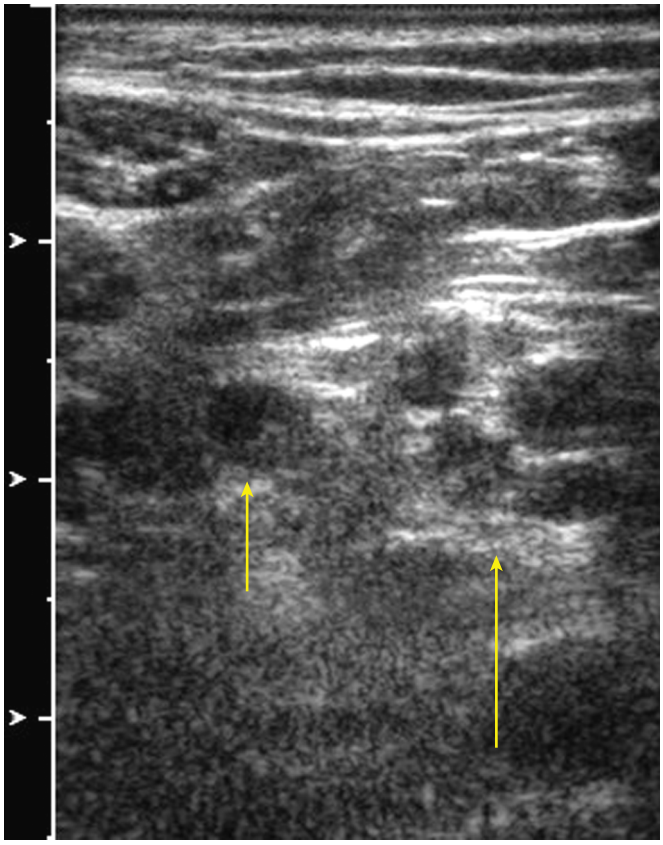

Figure 58-13. Sonogram demonstrates the popliteal fossa of a patient with Charcot-Marie-Tooth, type 1A, disorder. The peripheral nerves are significantly enlarged because of the large fascicles *(yellow arrows)*. Nerves of the symptomatic and asymptomatic sides can appear similar in these patients. Large tick marks are 10 mm apart.

Although direct nerve imaging has led to a phenomenal increase in ultrasound-guided regional anesthesia, the identification of other nearby anatomic structures, such as the fascia and other connective tissue), is also critical in this endeavor. These layers permit favorable distribution of local anesthetic, making nerve contact with the block needle unnecessary.

Many approaches to regional blocks with ultrasound are available (Table 58-2). Peripheral nerves are usually viewed in short axis rather than long axis. The needle can approach within the plane of imaging (in-plane technique) or cross the plane of imaging as an echogenic dot (out-of-plane technique). For some regional blocks, offline markings (skin markings before needle insertion) are used instead of online imaging (i.e., imaging during needle insertion and injection). Most studies have suggested that adequate visualization and correct identification of the relevant structures (e.g., peripheral nerve, needle tip, local anesthetic, adjacent anatomic structures) is more important than the approach, per se, for outcomes after regional blocks. Nevertheless, consistent practice patterns are developing among institutions and illustrate the underlying principles.

Successful injection for peripheral nerve block has several characteristics (Fig. 58-14). Injections should distribute around the nerve (clarifying the nerve border), travel along the nerve path and branches, and separate the nerve from common anatomic structures such as adjacent arteries that are wrapped together

in common fascia and connective tissue. Because anechoic fluid is typically injected, echoes received from the peripheral nerve will also be enhanced by increased through transmission (but not necessarily a sign of block success).

TABLE 58-2 **EXAMPLES OF APPROACHES TO REGIONAL BLOCKS WITH ULTRASOUND GUIDANCE**

Approach	Examples of Regional Block
Short axis view, in-plane	Almost any peripheral nerve block Almost any peripheral catheter placement
Short axis view, out-of-plane	Shallow blocks Interscalene catheter Lateral femoral cutaneous nerve block Femoral nerve catheter placement
Long axis view, in-plane	Proximal fascia iliaca block Proximal obturator block Anterior sciatic block
Long axis view, out-of-plane	Epidural placement (longitudinal paramedian view during midline approach) Transtracheal anesthesia

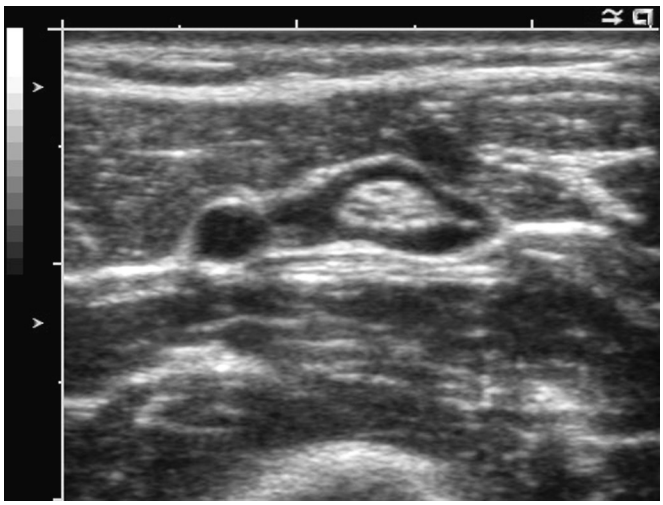

Figure 58-14. Local anesthetic injection for successful peripheral nerve block. The ulnar nerve and ulnar artery are viewed in short axis in the forearm in this sonogram. The nerve is surrounded with anechoic local anesthetic.

EXAMPLES OF COMMON REGIONAL BLOCKS

SUPRACLAVICULAR BLOCKS

Ultrasound-guided blocks were first described in the supraclavicular region.[17] The advantages of the supraclavicular block are that the brachial plexus is compact, the nerve visibility is extremely good, and the structures are shallow (20- to 30-mm field). In the supraclavicular region, sonography will image the divisions of the brachial plexus. Excellent block characteristics have been reported from ultrasound-guided supraclavicular blocks. The principal concerns are the risk of vascular puncture in an area that is difficult to compress and the risk of pneumothorax.

An in-plane approach from medial to lateral to ensure that the needle will pass over the subclavian artery can be used to reach the brachial plexus (Fig. 58-15). One current technique is to place the patient in a semi-sitting position with the head turned to the opposite side and the arms flush with the body. The operator either stands at the head of the bed or at the patient's side, depending on the side of the block and the handedness of the operator. Proximity to the phrenic nerve occurs if the block location is too cephalad. A compact linear transducer (20- to 30- mm footprint) is used for the procedure[18] to provide working room and to allow rocking of the transducer. Some authors have also recommended a specialized compact linear *hockey stick* transducer for supraclavicular blocks. The C5 ventral ramus (and other contributions to the brachial plexus) can pass over or through the anterior scalene muscle rather than between the scalene muscles. When this condition is identified, the block is usually performed at a more caudal position in the neck to avoid incomplete brachial plexus anesthesia.[19] The medial-to-lateral and the lateral-to-medial in-plane approaches to supraclavicular block both have excellent efficacy and safety profiles.

INFRACLAVICULAR BLOCKS

The advantages of the infraclavicular block are that it usually results in complete brachial plexus anesthesia,

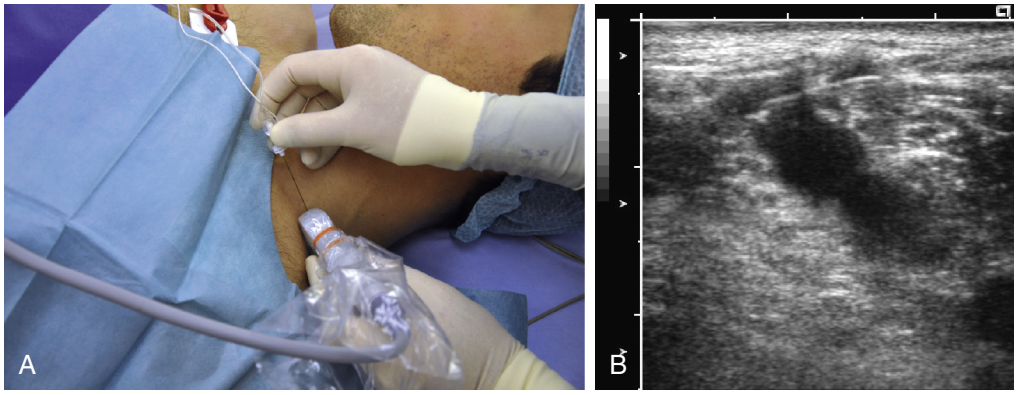

Figure 58-15. Supraclavicular block with ultrasound imaging. **A**, In this external photograph of ultrasound-guided supraclavicular block, the needle approaches the brachial plexus from medial to lateral. **B,** Sonogram of supraclavicular block with ultrasound guidance. The block needle approaches from medial to lateral within the plane of imaging for this procedure. Local anesthetic is observed to distribute around the compact brachial plexus.

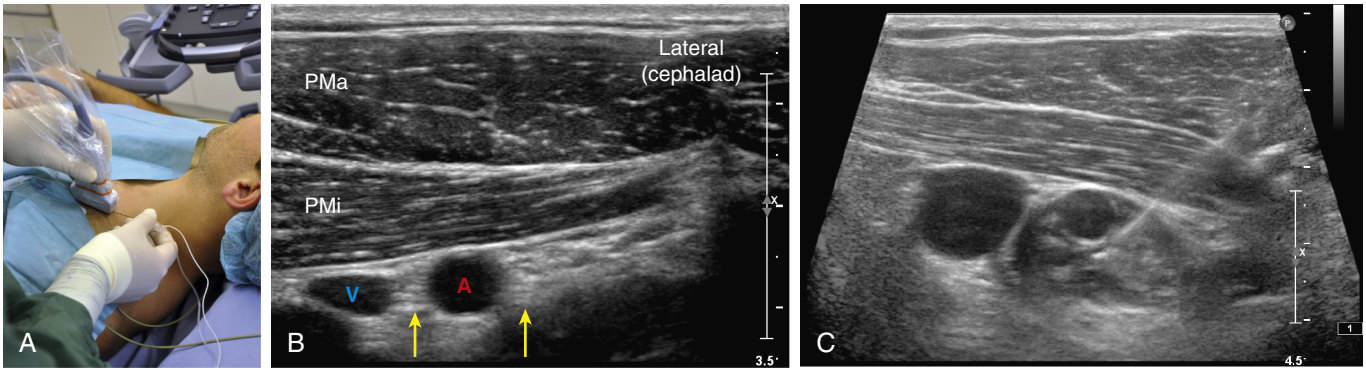

Figure 58-16. Infraclavicular block with ultrasound imaging. **A,** External photograph of the setup for infraclavicular block shows the arm has been abducted in this case. **B,** Sonogram of the cords of the brachial plexus *(yellow arrows)* are adjacent to the axillary artery *(A)* and vein *(V)*. The neurovascular bundle lies deep to the pectoralis major *(PMa)* and pectoralis minor *(PMi)* muscles in this anatomic region. **C,** Needle tip is in position for infraclavicular block and the resulting local anesthetic distribution.

TABLE 58-3 EXAMPLES OF SONOGRAPHIC LANDMARKS FOR INFRACLAVICULAR BLOCK*

Proximal	Optimal Location	Distal
Cephalic vein	Pectoralis minor muscle (midportion)	Subscapular artery
Thoracoacromial artery	Brachial plexus cords surround axillary artery	Coracobrachialis muscle
Chest wall and pleura	Posterior (or medial) cord underneath axillary artery	Anterior circumflex artery Posterior circumflex artery

* Infraclavicular block is usually performed at the level of the second part of the axillary artery (deep to the pectoralis minor muscle). Proximal and distal landmarks along the course of the axillary artery are listed.

BOX 58-2 ***Sonographic Signs Indicating Infraclavicular Block Success***

- U-shaped distribution underneath the axillary artery
- Separation of cords from axillary artery
- *White wall* appearance to the axillary artery
- Reduction in axillary artery diameter
- *Dark streak* underneath the axillary artery in the long axis view

Several studies of clinical block characteristics have validated the high predictive value of local anesthetic distribution underneath the axillary artery for three-cord anesthesia.

TABLE 58-4 COMPARISON OF THE INFRACLAVICULAR AND AXILLARY APPROACHES TO BRACHIAL PLEXUS BLOCK

	Infraclavicular Block	Axillary Block
Depth	Deep (two muscles)	Shallow
Onset	Slower	Faster
Tourniquet tolerance	Better	Good
Catheter success	High	Low

it is a stable place for a catheter, and no manipulation of the arm is necessary. The disadvantages are that the infraclavicular block is a deeper block; therefore, needle or probe manipulations are necessary, along with steep angles of needle insertion that result in needle tip visibility issues. Although the arm can remain at the side of the patient, the block is easier when the arm is abducted to straighten the neurovascular bundle. The three arterial wall-hugging cords are named with respect to the second part of the axillary artery; therefore, the expected positions are medial, lateral, and posterior. The artery is visualized in short-axis view deep to the pectoralis major and minor muscles (Fig. 58-16). Most practitioners use an in-plane approach from the head of the table or side of the table. The ideal place for local anesthetic distribution to achieve complete infraclavicular block of the brachial plexus is posterior to the axillary artery for single-shot or catheter placement. Substantial evidence suggests that local anesthetic distribution posterior to the axillary artery produces complete brachial plexus block in the infraclavicular region (Table 58-3 and Box 58-2). The cords of the brachial plexus do not need to be directly visualized for successful block. Duplication of the axillary vein is one of the few anatomic variations in the infraclavicular region. The clinical problem is that the accessory vein lies adjacent to the lateral cord of the brachial plexus and near the usual desired position of the needle tip.

AXILLARY BLOCKS

The axillary block is a versatile block for upper extremity anesthesia. Although relatively safe and effective with classical approaches, the cardinal weakness has been the failure to block the musculocutaneous nerve. With the advent of ultrasound imaging, this limitation can be overcome by directly visualizing the musculocutaneous nerve.

The axillary block provides surgical anesthesia of the elbow and more distal upper extremity. The shallow depth of the neurovascular bundle (a 20-mm field is typical) and the large amount of working room make this block relatively easy with ultrasound guidance (Table 58-4). Usually, three arterial wall-hugging branches (median, ulnar, and radial) and one branch with a characteristic medial-to-lateral course in the axilla (musculocutaneous) are

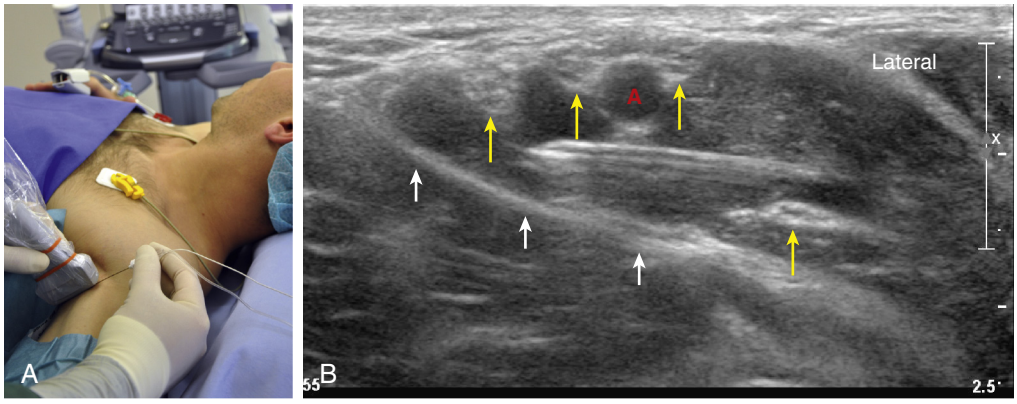

Figure 58-17. Axillary block with ultrasound guidance. **A,** External photograph demonstrates the in-plane approach. **B,** Sonogram of the neurovascular bundle in the short axis view shows the needle tip in-plane after injection of the local anesthetic. The probe compression is just sufficient to coapt the walls of the satellite veins. The block is performed at the level of the conjoint tendon of the latissimus dorsi and teres major *(white arrows)*, which lies under the neurovascular structures. The third part of the axillary artery *(A)* and nerves of the brachial plexus—radial, ulnar, median, and musculocutaneous—in order from medial to lateral *(yellow arrows)* are shown.

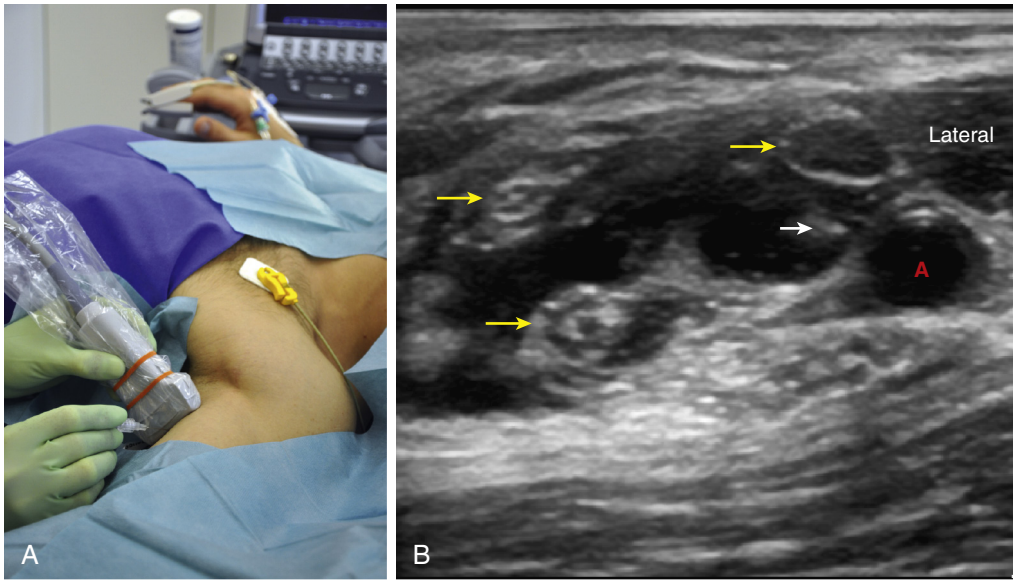

Figure 58-18. Axillary block with ultrasound guidance. **A,** External photograph demonstrates the out-of-plane approach. **B,** Sonogram of the neurovascular bundle in the short axis view shows the needle tip *(white arrow)* crossing the plane of imaging. The probe compression is just sufficient to coapt the walls of the satellite veins. The third part of the axillary artery *(A)* and nerves of the brachial plexus *(yellow arrows)* are shown.

visualized. In addition, the musculocutaneous nerve has a characteristic change in shape as it moves from adjacent to the artery (round) to within the coracobrachialis muscle (flat) and then exiting the muscle (triangular).

Both in-plane (with needle approaching from the lateral side of the arm) and out-of-plane (with needle approaching from distal to proximal) techniques can be used (Figs. 58-17 and 58-18). The block is performed in the proximal axilla, with the transducer gently pressed against the chest wall to visualize the conjoint tendon of the latissimus dorsi and teres major. A high-frequency linear probe with a small footprint (25 to 50 mm) with sterile cover can be used for axillary block. The ideal location for local anesthetic injection is between the nerves and the artery so that separation between the two structures occurs to ensure distribution within the neurovascular bundle. These injections result in excellent clinical blocks. The musculocutaneous nerve is usually blocked within the coracobrachialis, where its flat shape gives a large amount of surface area for rapid block. Duplication of the axillary artery and musculocutaneous-median nerve fusion (low-lying lateral cord) are common anatomic variations in the axilla.

TRANSVERSUS ABDOMINIS PLANE AND ILIOINGUINAL NERVE BLOCKS

Four peripheral nerves, the subcostal, ilioinguinal, iliohypogastric, and genitofemoral, primarily innervate the lower abdominal wall.[20] The extended course of the first three nerves through the abdominal wall within the layer between the transversus abdominis and the internal oblique muscles makes this the desired anatomic location for regional block. For ultrasound-guided transversus abdominis plane (TAP) block, the patient is usually in the supine position (Fig. 58-19). The transducer is placed between the iliac crest and costal margin in the midaxillary line. In this location, the muscle layers of the lateral abdominal wall (external oblique, internal oblique, and transversus abdominis) are well defined.

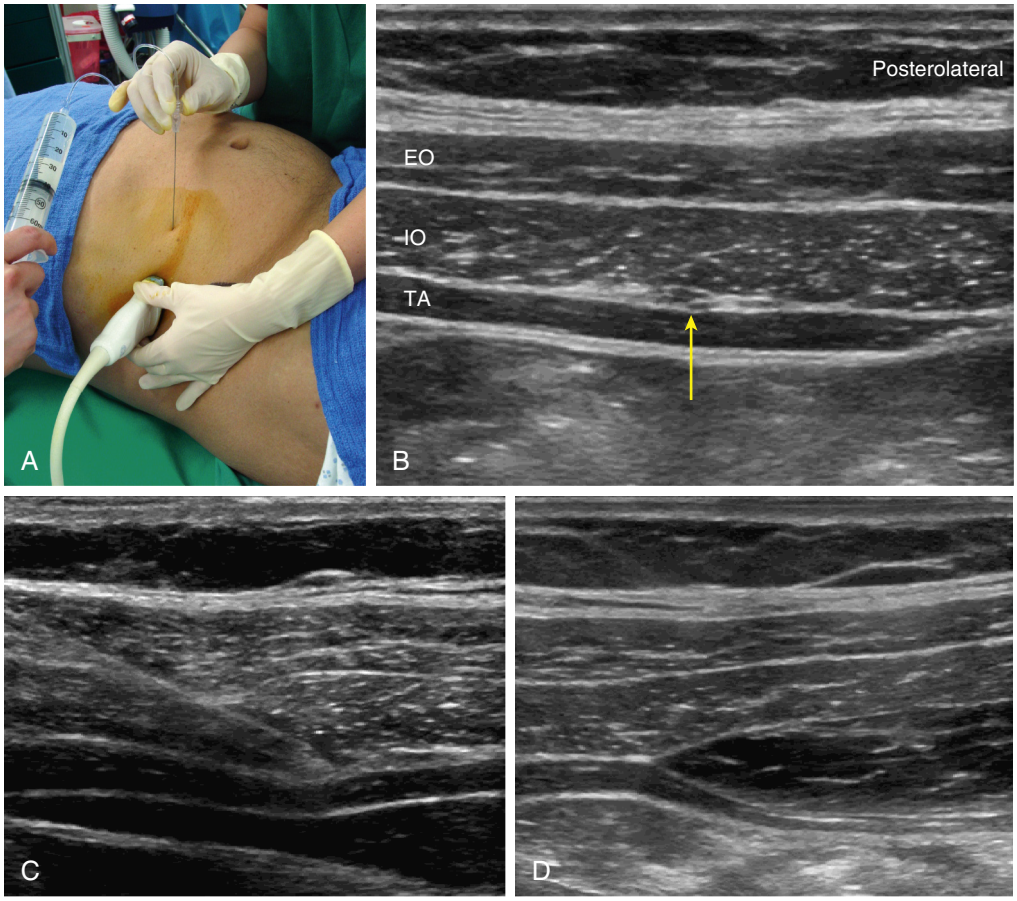

Figure 58-19. Transversus abdominis plane (TAP) block with ultrasound guidance. **A,** Abdominal wall image demonstrates the approach for TAP block. **B,** In this sonogram the external oblique *(EO),* internal oblique *(IO),* and transversus abdominis *(TA)* muscles are identified (the *three layer cake* appearance). Nerves *(yellow arrow)* are seen entering the plane between the IO and TA muscles. **C,** The needle approaches in-plane and is directed toward the posterolateral edge of the TA muscles. **D,** The *kayak* sign demonstrates successful TAP injection. The fascia between the IO and TA muscles is split apart in the shape resembling a kayak.

Injection is in the fascial layer that separates the internal oblique and the transversus abdominis muscles. Direct visualization and proximity to the nerves is not critical if 15 to 20 mL of dilute local anesthetic is injected in this layer. The needle approach is in-plane from the anterior side and directed toward the posterolateral corner of the transversus abdominis muscle. The respiratory motion of the peritoneal cavity and influence of muscle contraction makes general anesthesia an appealing option for performing this block. The transversus abdominis muscle is relatively thin; therefore, careful placement of the needle tip is necessary. Ilioinguinal nerve blocks (Fig. 58-20) can be performed in a similar fashion above the iliac crest.[21]

FEMORAL NERVE BLOCKS

The advantages of using ultrasound to guide femoral nerve block include a more complete block, local anesthetic volume sparing, and fewer vascular punctures.[22] The femoral nerve usually lies lateral to the femoral artery in the groove formed by the iliacus and psoas muscles. The nerve can be oval or triangular in cross-sectional shape with an anteroposterior diameter of approximately 3 mm and a mediolateral diameter of 10 mm. The best depiction of the femoral nerve is from 10 cm proximal to 5 cm distal to the inguinal ligament. According to the pelvic inclination, some tilting of the ultrasound probe is necessary for the sound beam to meet the nerve perpendicularly for optimal scanning. In addition, the femoral nerve has a slight medial-to-lateral course; therefore, some rotation of the probe is also necessary for the best view of the nerve. Because the femoral nerve is covered by echobright adipose tissue and fascia, the echogenic outer sheath of the nerve is difficult to establish. In some patients, the psoas tendon can appear similar to the femoral nerve. However, the psoas tendon lies deep within the muscle. If the profunda femoris artery (i.e., the deep branch of the femoral artery) is visualized, then the transducer is usually too distal for complete femoral nerve block. The femoral nerve is often identified as a slight indentation in the surface of the iliacus and psoas muscles.

For femoral nerve block, a broad (35- to 50-mm footprint) linear transducer is used (Fig. 58-21). Both in-plane (from lateral to medial) and out-of-plane (from distal to proximal) approaches can be used. The advantage of in-plane approach is visualization of the approaching needle. The disadvantages are the longer needle path and a tendency of the needle to skim over the fascia iliaca by deforming it rather than puncturing it. The out-of-plane approach is often used for catheter placement.

For either approach, the needle tip is positioned between the fascia iliaca and the iliopsoas muscle near the lateral corner of the femoral nerve to avoid the femoral vessels, similar to the method for fascia iliaca block. The fascia iliaca has a characteristic mediolateral slant. The desired distribution is local anesthetic layering under or completely around the femoral nerve. When layering of local anesthetic is restricted over the nerve, the concern is that the fascia iliaca is intact and that block failure will result. For patients who are obese, femoral nerve imaging

Figure 58-20. Ilioinguinal nerve block with ultrasound imaging. The transducer is rotated and placed near the iliac crest for ilioinguinal nerve block.

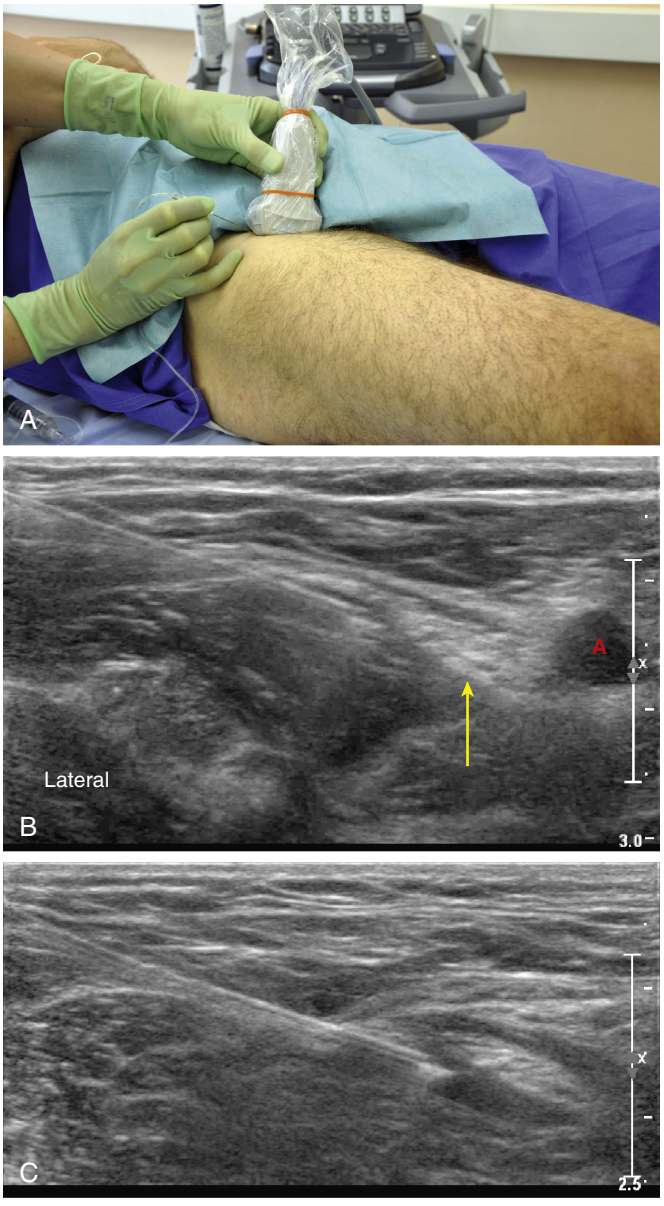

Figure 58-21. Femoral nerve block with ultrasound imaging (in-plane approach). **A,** External photograph shows the setup for femoral nerve block. **B,** The needle tip is in position before injecting adjacent to the femoral nerve *(yellow arrow)*. The femoral nerve lies lateral to the femoral artery *(A)*. **C,** Local anesthetic surrounds the femoral nerve after injection. *(Modified from Gray AT:* Atlas of ultrasound-guided regional anesthesia*, ed 2, Philadelphia, 2012, Saunders.)*

is challenging. Ultrasound can be combined with nerve stimulation for successful block in these patients. After successful injection of a local anesthetic, distal branches of the femoral nerve can be appreciated by sliding the transducer along the known course of the nerve.

The saphenous branch of the femoral nerve can be blocked in the midthigh, deep to the sartorius muscle using ultrasound guidance (Fig. 58-22). This approach has the advantage that the quadriceps motor block is reduced.[23]

SCIATIC NERVE BLOCKS IN THE POPLITEAL FOSSA

The sciatic nerve can be blocked anywhere along its course from the gluteal region to the popliteal fossa.[24-26] Many approaches have been described, including those from the anterior aspect of the thigh.[27] One of the most common approaches is to block the sciatic nerve in the popliteal fossa using a lateral approach in supine position with the leg elevated.[28] In this anatomic location, the block can be performed close to the skin surface. The division of the sciatic nerve provides a broad target with large surface area to promote clinical block characteristics. For this technique, the needle tip is positioned between the tibial and common peroneal components of the sciatic nerve near the division so that a single injection distributes to both nerves (Fig. 58-23). By sliding the transducer along the known course of the sciatic nerve, its characteristic division in the popliteal fossa can be identified. This method of sliding assessment is also important to verify the local anesthetic distribution after injection. The tibial nerve has a straighter course than the common peroneal nerve and has approximately twice the cross-sectional area. The tibial nerve lies posterior to the popliteal artery and vein at the popliteal crease, and this location can be a

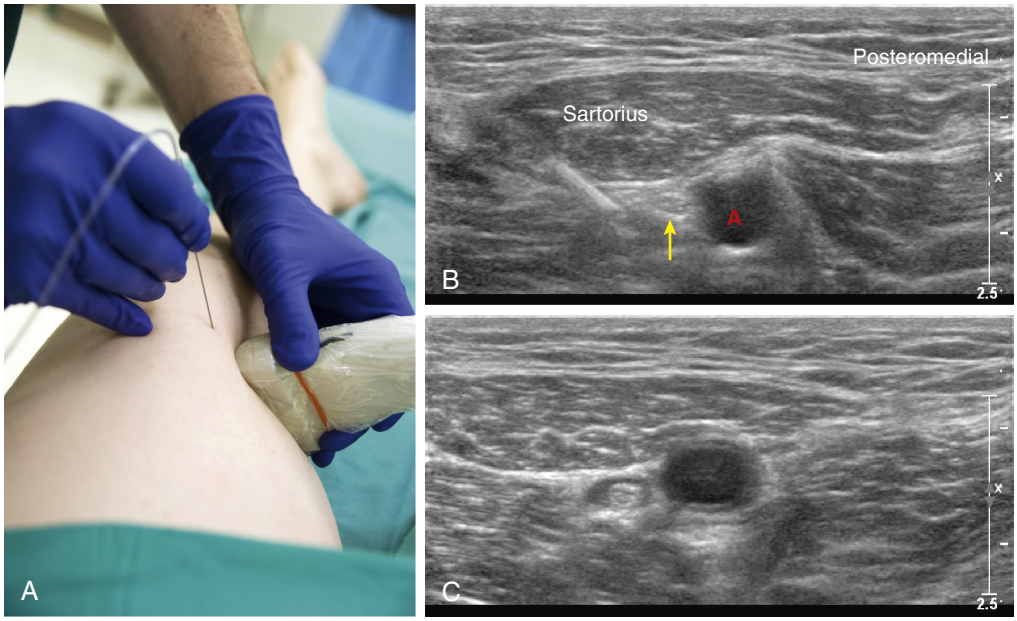

Figure 58-22. Saphenous nerve block in the middle thigh with ultrasound imaging (in-plane approach). **A,** External photograph shows the setup for saphenous nerve block. **B,** The needle tip has been placed through the sartorius muscle adjacent to the saphenous nerve *(yellow arrow)* and superficial femoral artery *(A)* before injection. **C,** Local anesthetic surrounds the saphenous nerve after injection deep to the sartorius muscle. *(Modified from Gray AT:* Atlas of ultrasound-guided regional anesthesia, *ed 2, Philadelphia, 2012, Saunders.)*

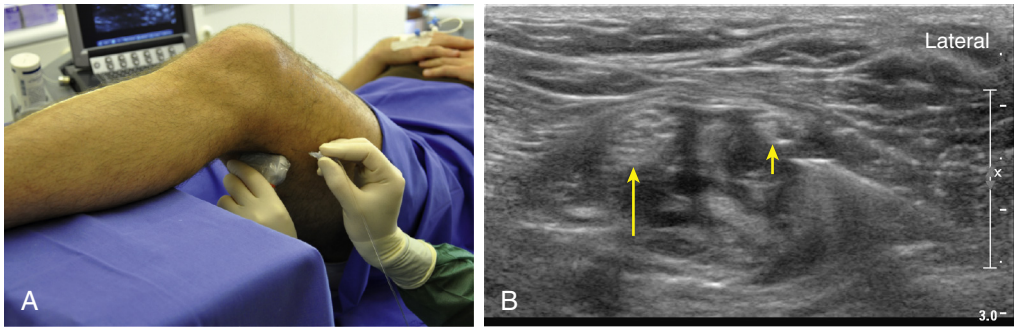

Figure 58-23. Popliteal block with ultrasound imaging (in-plane approach). **A,** External photograph shows the setup for popliteal nerve block in the supine position. The leg is elevated, and the transducer is applied to the posterior surface of the leg. **B,** The needle approaches the bifurcation of the sciatic nerve in the plane of imaging from the lateral aspect of the leg. The needle tip is positioned between the tibial *(long yellow arrow)* and common peroneal *(short yellow arrow)* nerves.

useful starting point when imaging is difficult. When the foot is moved, the nerves of the popliteal fossa have characteristic motions that can be helpful for nerve identification in some patients. The advantages of this approach are the convenient position, the transducer position is remote from the site of needle entry, and the parallel in-plane approach of the block needle results in optimal needle tip visibility. After injection, following the local anesthetic distribution around and along the nerve path (Fig. 58-24) is relatively easy.

TRAINING AND SAFETY

Interventional sonography is not without risks. Many studies have now demonstrated efficacy of ultrasound-guided regional blockade. Ultrasound has the potential to prevent and detect two important adverse events during peripheral nerve blocks: intravascular injection and intraneural injection of a local anesthetic.[29,30] The characteristic contrast from dissolved gas that is distributed within the vessel lumen can identify intravascular injection. The hallmark sign of intraneural injection is nerve expansion during injection (Fig. 58-25). Although ultrasound has tremendous promise in improving the safety of regional blockade, confirmatory studies of clinical practice are in progress. Many of these adverse events have only been recognized in retrospect by the review of recorded sonograms, which is a valuable training practice.

One of the original techniques developed for training novices in ultrasound-guided interventions was use of a tissue-equivalent phantom.[31] The phantom consisted of simulated tissue for needle placement practice (Fig. 58-26). To be realistic, the speed of sound must be similar as in soft tissue. In the first prototype, the phantom and container were clear; as a result, visual confirmation was possible. Several phantoms are now marketed for regional anesthesia purposes, and biologic tissue models that simulate nerve blocks have been developed.

A number of other effective teaching tools are being used. Cadavers have the advantage of realistic regional

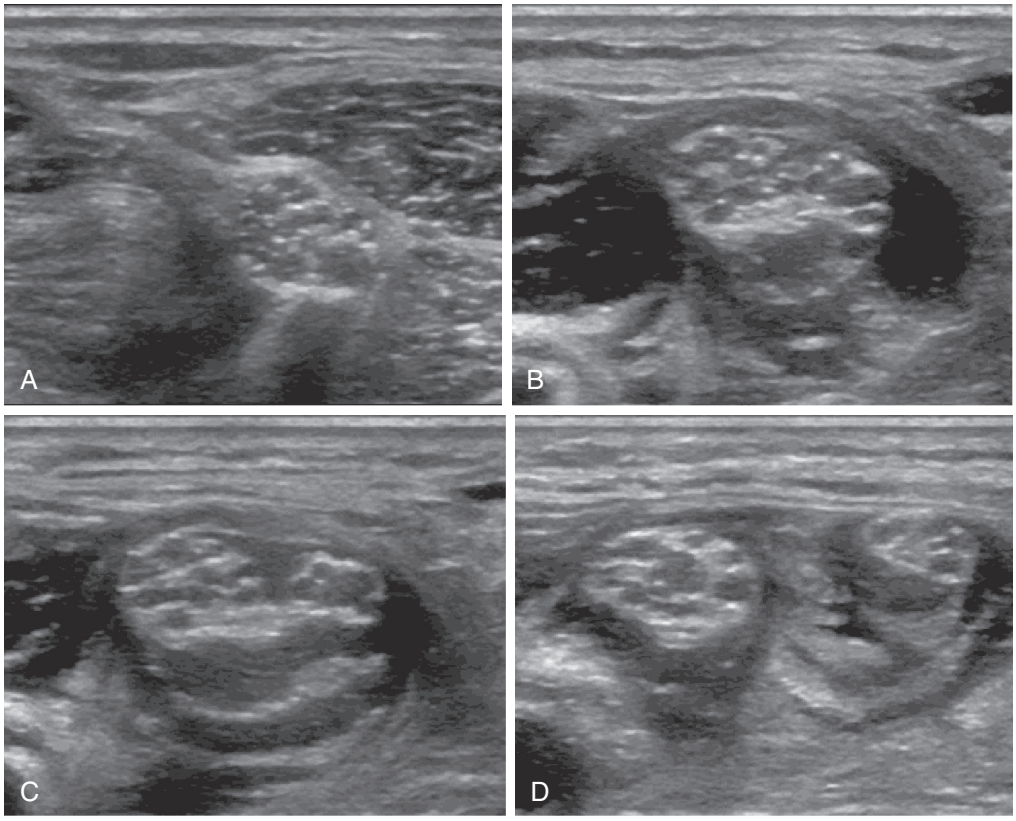

Figure 58-24. Sciatic nerve imaging in the popliteal fossa before (**A**), during (**B** and **C**), and after (**D**) division into the tibial and common peroneal nerves. Local anesthetic tracks with both individual nerves, thereby confirming a successful block.

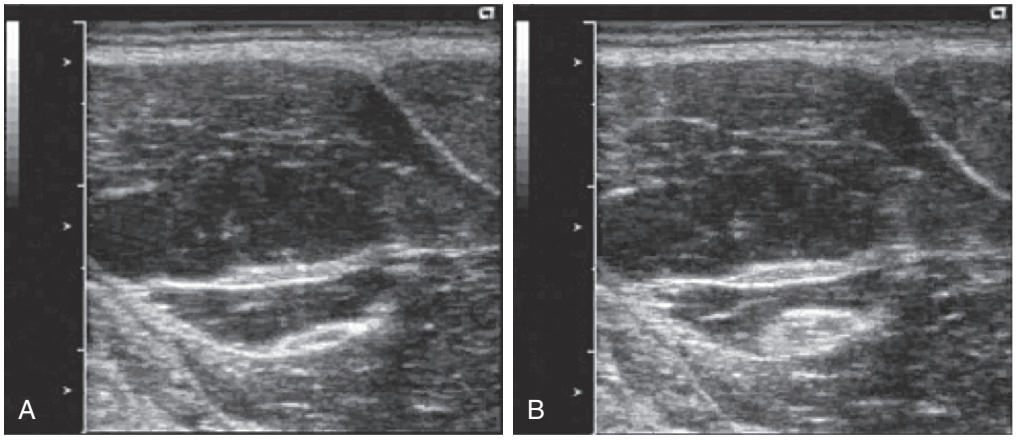

Figure 58-25. Ultrasound image reveals intraneural injection. These sonograms were obtained in the axilla before (**A**) and after (**B**) injection in the musculocutaneous nerve. Nerve expansion is detected but with preservation of the overall integrity of the nerve borders. No paresthesias were observed during or after the procedure. Neurologic outcome was favorable after this low-volume, low-pressure injection.

anatomic structures and can be used for simulated interventions.[32] The cost and use of specialized embalming methods that preserve nerve imaging and cadaver flexibility have limited this approach to a few specialized institutions. Most training studies have concluded that skills for ultrasound-guided procedures can be rapidly acquired.

One training study has identified common errors of novices while learning ultrasound-guided regional blocks.[33] These errors included advancing the needle when it was not visualized and unintentional probe movement. Novices often advance the needle even when it is not visualized, presumably because the natural inclination is to assume the needle has not reached the field of view. The potentially quality-compromising behaviors were largely eliminated by the end of the study period, which ranged from 66 to 114 blocks per training participant.

CONCLUSIONS

Ultrasound is a guidance tool that many people are electing to choose for regional anesthesia blocks. Once proficiency is established for a particular procedure, starting to use ultrasound for other interventional applications is relatively easy. Ultrasound imaging can prevent and

Figure 58-26. Tissue equivalent phantom for training in ultrasound-guided interventions.

detect critical events such as intravascular or intraneural injection that may improve safety during regional anesthesia procedures.[34] However, if safety outcomes are to improve, then education and training play key roles in reducing these relatively uncommon adverse events.

Chapter 59

Perioperative Fluid and Electrolyte Therapy

MARK R. EDWARDS • MICHAEL P.W. GROCOTT

Acknowledgment: The editors and the publisher would like to thank Drs. Alan D. Kaye and James M. Riopelle, who were contributing authors to this topic in the prior edition of this work. It has served as the foundation for the current chapter.

Key Points

- Intravenous fluid therapy is a core part of perioperative practice, with the potential to influence patient outcomes.
- Water makes up approximately 60% of total body weight, varying widely with age and body composition. The ratio between the water volume within the intracellular and functional extracellular compartments is approximately 2:1.
- The endothelial glycocalyx forms a protein-poor intravascular fluid layer at the vessel perimeter; it has been integrated into a revised version of the Starling equation and updated model of capillary fluid movement.
- Sodium is the dominant extracellular cation and is responsible for much of extracellular fluid osmolality; dysnatremia is typically associated with disturbed extracellular fluid volume.
- Potassium is the dominant intracellular cation with a key role in the maintenance of transmembrane potentials; dyskalemia may be accompanied by impaired function of excitable tissues.
- Calcium is a key intracellular second messenger with roles in neuromuscular function, cell division, and oxidative pathways.
- Magnesium has a diverse range of physiologic effects, underlined by the increasing range of therapeutic applications of supplemental magnesium in the perioperative setting.
- Acid-base balance is relevant to fluid therapy because fluids containing supraphysiologic levels of chloride may cause an iatrogenic acidosis; the clinical relevance of this acidosis is debated.
- Intravenous fluids have a range of physiologic effects and should be considered to be drugs with indications, dose ranges, cautions, and side effects.
- The physiologic insult of the perioperative period may lead to a wide variety of disturbances in fluid and electrolyte balance.
- Clinical evidence to guide perioperative fluid therapy is lacking in many areas, and cannot be directly extrapolated from general critical care trials.
- A balance must be found between inadequate fluid administration—allowing tissue hypoperfusion—and the adverse effects of excess intravenous fluids and toxicities related to fluid constituents.
- Goal-directed fluid therapy (GDT) may help in finding this balance for an individual patient in the perioperative setting, with evidence of reduced postoperative morbidity supporting its use in many surgical settings.
- No clear consensus exists on which intravenously administered fluid is associated with the best clinical outcomes in the perioperative setting. Comparisons of "balanced" with "unbalanced" and "crystalloid" with "colloid" fluids are being studied in many clinical settings; definitive conclusions are often lacking.
- The approach to fluid and electrolyte management may need adapting to numerous patient and surgical factors.

The administration of intravenous (IV) fluid is a core expertise for anesthesia providers and an area in which we have an important role in advising clinical colleagues. Alongside the traditional triad of maintenance of unconsciousness, pain relief, and neuromuscular relaxation, IV fluid therapy is a core element of the perioperative practice of anesthesia. The aims of perioperative fluid administration should be to avoid dehydration, maintain an effective circulating volume, and prevent inadequate tissue perfusion during a period when the patient is unable to achieve these goals through normal oral fluid intake.

Knowledge of the clinical effects of different fluids has increased substantially in recent years. The choice of fluid type in a variety of clinical situations can be rationally guided by an understanding of the physicochemical and biologic properties of the various crystalloid and colloid solutions available in combination with the available clinical trial data. Each clinical decision about fluid therapy has two key elements: which fluid to use and how much fluid to give. Recently, several clinical studies have changed our concepts regarding both of these questions. However, we should be cautious about overinterpreting data from nonperioperative contexts. Despite recent high-quality "mega-trials" involving thousands of critically ill patients, key questions remain unresolved in the perioperative setting. Goal-directed fluid therapy (GDT) is a good example of an intervention that is effective in the perioperative phase, but ineffective in established critical illness, and this should alert us to other possible such distinctions.

This chapter reviews the physiology and pharmacology of IV fluid therapy in humans before discussing the clinical practice of fluid and electrolyte management and the impact of alternative approaches on clinical outcomes.

PHYSIOLOGY

FLUID COMPARTMENTS

Water makes up approximately 60% of total body weight in the average adult, varying with age, gender, and body composition. Adipose tissue contains little water compared with other tissues, leading to marked variability in total body water (TBW) proportion between lean (75%) and obese (45%) individuals. Variation in adipose tissue also contributes to differences in TBW between adult males and females; these differences are reduced in old age as adipose tissue is reduced. The variations in body composition with age lead to a wide variation in TBW (Table 59-1). TBW is divided between anatomic and functional fluid compartments within the body, with the major division between intracellular fluid (ICF) and extracellular fluid (ECF). The size of these compartments and their widely differing composition are shown in Figure 59-1 and Table 59-2. The extracellular fluid can be subdivided into the following compartments:

- Interstitial fluid (ISF): Lymphatic fluid and protein-poor fluid occupying cell spaces.
- Intravascular fluid: Plasma volume, including a proportion contained within the subglycocalyx (see later discussion).

TABLE 59-1 AGE-RELATED VARIATION IN TOTAL BODY WATER AND EXTRACELLULAR FLUID AS PERCENT OF BODY WEIGHT (MULTIPLY BY 10 FOR mL/kg)*

Age	TBW (%)	ECF (%)	Blood Volume (%)
Neonate	80	45	9
6 mo	70	35	
1 yr	60	28	
5 yr	65	25	8
Young adult (male)	60	22	7
Young adult (female)	50	20	7
Elderly	50	20	

Data from references 226 to 229.
ECF, Extracellular fluid; *TBW,* total body water.
*In pregnancy, blood and plasma volumes increase by 45% and 50% respectively by term.

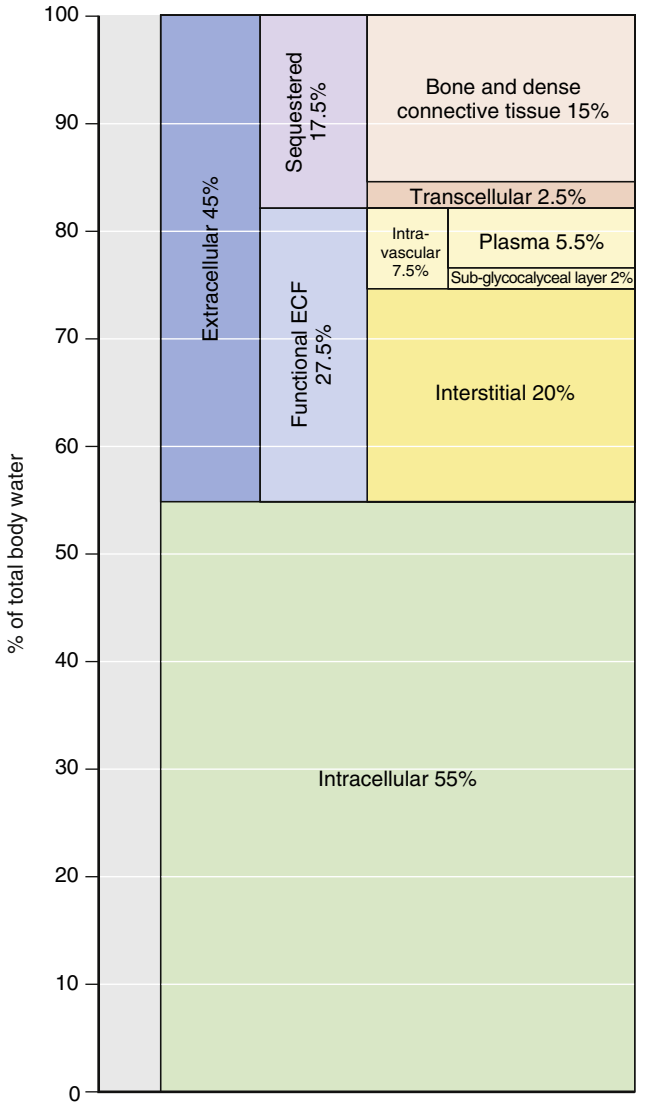

Figure 59-1. Distribution of total body water between fluid compartments. "Sequestered" extracellular fluid (ECF) refers to water associated with bone and dense connective tissue or within the transcellular compartment and therefore not immediately available for equilibration with the other fluid compartments.

- Transcellular fluid: Includes gastrointestinal (GI) tract fluid, bile, urine, cerebrospinal fluid, aqueous humor, joint fluid, and pleural, peritoneal, and pericardial fluid. These are functionally important fluids of widely varying composition contained within epithelia-lined spaces and regulated by active cellular transport (Table 59-3).
- Water in bone and dense connective tissue: Constitutes a substantial proportion of TBW but not part of the functional ECF because of slow kinetics of water distribution between this and other compartments.[1]

Total blood volume comprises extracellular (plasma and subglycocalyx compartments) and intracellular (blood cells) elements. With the nonfunctional ECF compartment (bone and connective tissue) excluded, the ratio between ICF and functional ECF is approximately 2:1 (ICF 55% of body weight to ECF 27.5% of body weight).

TABLE 59-2 COMPOSITION OF INTRACELLULAR AND EXTRACELLULAR FLUID COMPARTMENTS (IN mOsm/L WATER)

	Intracellular	Extracellular	
		Intravascular	Interstitial
Cations			
Na^+	10	142	145
K^+	157	4	4
Ca^{2+}	0.5*	2.5	2.5
Mg^{2+}	20	0.8	0.7
Anions			
Cl^-	10	103	117
HCO_3^-	7	25	27
$HPO_4^{2-}/H_2PO_4^-$	11	2	2
SO_4^{2-}	1	0.5	0.5
Organic acids		6	6
Protein	4	1.2	0.2

Data from references 230 to 232.

*Total intracellular Ca^{2+} concentration may be as high as extracellular levels; however, this is largely sequestered or buffered, such that the cytoplasmic ionized Ca^{2+} concentration is approximately 1000 times lower than extracellular fluid (0.3 to 2.6 μEq/L).[124] The intracellular content of anions such as PO_4^{3-} has been difficult to establish for similar reasons.

Physicochemical Laws Governing Fluid and Electrolyte Movement

The movement of water and solutes is governed by a variety of physicochemical and biologic processes, discussed in the following section.

Diffusion. Diffusion is the process by which solute particles fill the available solvent volume by motion from areas of high to low concentration. The speed of this equilibration is proportional to the square of the diffusion distance. Diffusion also may occur across permeable membranes, according to Fick's law of diffusion:

$$J = -DA\left(\frac{\Delta c}{\Delta x}\right) \quad (1)$$

where J is the net rate of diffusion, D is the diffusion coefficient, A is the cross-sectional area available for diffusion, and $\Delta c/\Delta x$ is the concentration (chemical) gradient.

Diffusion also may be driven by the tendency of charged solutes to move down electrical gradients.

Osmosis. If a semipermeable membrane (one that is permeable to water but not a solute) separates pure water from water in which solute is dissolved, water molecules will diffuse across the membrane into the region of higher solute concentration. The hydrostatic pressure required to resist the movement of solvent molecules in this way is osmotic pressure. This is one of the fundamental colligative properties of a solution—that is, it depends on the number rather than the type of osmotically active particles in a solution, which may be complete molecules or dissociated ions. Osmotic pressure in an ideal solution is affected by temperature and volume:

$$P = \frac{nRT}{V} \quad (2)$$

where P is the osmotic pressure, n is the number of particles, R is the gas constant, T the absolute temperature, and V the volume. n can be calculated by multiplying (mass of solute/molecular weight of solute) by the number of particles into which the solute dissociates.

However, body fluids are not ideal solutions, because interionic interactions reduce the number of particles free

TABLE 59-3 COMPOSITION OF TRANSCELLULAR FLUIDS (mEq/L UNLESS STATED)

	Daily Volume (L)	Cations				Anions		pH
Fluid		Na^+	K^+	Ca^{2+}	Mg^{2+}	Cl^-	HCO_3^-	
Gastrointestinal tract								
Saliva	1-1.5	30-90	20-40	2.5	0.6	15-35	10-40	6-7
Gastric	1.5-2.5	20-60	10-20			20-160	0	1-3.5
Bile	0.7-1.2	130-150	5-12	10-50		25-100	10-45	7-8
Pancreatic	1-1.5	125-150	5-10			30-110	40-115	8-8.3
Small bowel (concentrations from proximal to distal)	1.8	140-125	5-9			110-60	100-75	7-8
Large bowel	0.2 (lost in feces)	20-40	30-90			0-15	40	7-8

Data from references 233 to 235.

to exert an osmotic effect. The total osmotic pressure of plasma is approximately 5545 mm Hg.

Osmolality. Molality is the number of moles (each containing 6×10^{23} particles of a specific substance) present in 1 kg of solvent. Osmolality may be used to describe solutions containing many different types of particles and is the number of osmoles (each containing 6×10^{23} of any type of particle present) present in 1 kg of solvent. Normal body osmolality is 285 to 290 mOsm/kg and is the same in intracellular and extracellular compartments because of the free movement of water between compartments that consequently prevents the development of any osmotic gradients. The largest contribution to plasma osmolality is made by sodium and its related anions chloride and bicarbonate. It can be estimated by:

$$\textit{Serum osmolality} = \begin{pmatrix} (2 \times Na) + (glucose \div 18) \\ + (urea \div 2.8) \end{pmatrix} \quad (3)$$

where *Na* is the serum sodium concentration (mEq/L), *glucose* is the serum glucose concentration (mg/dL), *urea* is the blood urea nitrogen concentration (mg/dL), and the (2 × Na) component reflects both Na and its associated anions (predominantly Cl^- and HCO_3^-). Alternatively, osmolality can be measured by depression of plasma freezing point. *Osmolarity* is the number of osmoles of solute per liter of solution; unlike osmolality, this may be affected by temperature changes as a result of the volume-expanding effect of increasing temperature.

Tonicity. This is the *effective osmolality* of a solution with respect to a particular semipermeable membrane and takes into account solutes that do not exert an in vivo osmotic effect. For example, Na^+ and Cl^- do not cross cell membranes freely and therefore exert an effective osmotic force across these membranes, whereas urea freely diffuses across cell membranes and therefore does not exert an osmotic effect here. Similarly, glucose is normally taken into cells by insulin-stimulated facilitated diffusion, so it is an ineffective osmole. Tonicity is important in determining in vivo distribution of fluids across a cell membrane and is sensed by the hypothalamic osmoreceptors. It can be estimated by subtracting urea and glucose concentrations from measured osmolality.

Oncotic Pressure. Oncotic pressure is the component of total osmotic pressure that is due to the colloids—that is, large-molecular-weight particles, predominantly proteins (albumin, globulins, fibrinogen). Of the total plasma osmotic pressure of 5545 mm Hg, 25 to 28 mm Hg is due to plasma oncotic pressure. The negative charge on proteins has the net effect of retaining a small excess of Na^+ ions within the plasma (the Gibbs-Donnan effect), which effectively increases the oncotic pressure above what would be predicted by calculations based purely on protein concentration. As the most abundant plasma protein, albumin is responsible for 65% to 75% of plasma oncotic pressure.

Fluid Compartment Barriers and Distribution

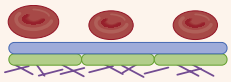
The volume and composition of each fluid compartment depends on the barriers separating it from neighboring compartments.

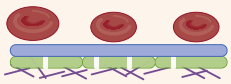
Cell Membrane. The cell membrane separates the intracellular and extracellular compartments and as a lipid bilayer is impermeable to large hydrophilic molecules and charged particles such as free ions. Other than by passive diffusion of certain molecules, solutes may cross cell membranes in several ways.

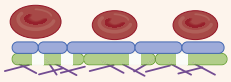
Carrier Proteins

Primary Active Transport. Solute transport against a concentration gradient requires energy and is therefore directly coupled to adenosine triphosphate (ATP) hydrolysis—for example, by Na^+/K^+–adenosine triphosphatases (ATPases). This is the fundamental mechanism by which ionic concentration gradients are maintained, which in turn drive a variety of biologic processes, including water and solute movement and electrical impulse transmission in excitable tissues.

Secondary Active Transport. The process of secondary active transport uses concentration gradients set up by ATPases to transport a solute driven by an ion moving down its concentration gradient, typically Na^+. This process is termed cotransport when the solute is also moving down its concentration gradient or countertransport when the solute is being moved against its concentration gradient.







Solute Channels. The solute channels allow much faster transport of solutes than by ATPases or transmembrane diffusion. Examples include voltage-gated Na^+ channels and the glucose transporter GLUT1, which when inserted into the plasma membrane allows glucose to travel down its concentration gradient. This process is termed facilitated diffusion.

Endocytosis and Exocytosis. The processes of endocytosis and exocytosis are involved in the transport of large proteins and polypeptides across cell membranes.

Vascular Endothelium. The barrier function of the vascular endothelium is particularly relevant perioperatively because of its key role in maintaining intravascular fluid volume. Surgical tissue trauma typically leads to loss of intravascular volume through surgical blood loss or inflammation-related shifts to other tissue compartments. The physiologic effect of IV fluid administered to overcome these losses and maintain adequate tissue oxygen delivery is highly dependent on fluid handling at the capillary level. Our understanding of this area has been refined by experimental physiologic models and techniques.

Capillary Structure. As shown in Table 59-4, the structure of capillaries varies depending on the underlying organ function. The most common capillary type is the nonfenestrated capillary, comprising continuous basement membrane and a single layer of endothelial cells joined by junctions that are punctuated by breaks. These intercellular clefts are the primary channel for transcapillary fluid flow. The intravascular aspect of the endothelial cells is covered by a continuous network

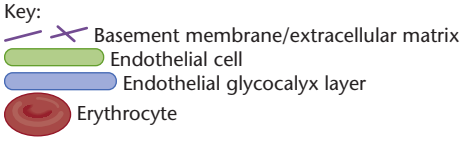


TABLE 59-4 **CAPILLARY CHARACTERISTICS**

Capillary Type	Site	Large Pores	Basement Membrane	Glycocalyx Layer	Notes on Function
Nonfenestrated (continuous) 	Muscle, connective tissue, lung, nervous tissue	None	Continuous	Continuous	Intercellular clefts are the main route for fluid filtration. These are partly occluded by junctional strands with multiple breaks. In the blood-brain barrier these breaks are small (1 nm) and infrequent (zona occludens tight junctions), permitting passage of only the smallest non–lipid soluble molecules. In other tissues the breaks are larger (5-8 nm) and more frequent (macula occludens loose junctions).
Fenestrated 	Endocrine, gut mucosa, choroid plexus, lymph nodes	Pores within endothelial cells with covering diaphragm 6-12 nm size	Continuous	Continuous	Fenestrations allow capillary reabsorption of fluid from ISF, in contrast to other capillary types.
	Glomeruli	Endothelial pore size up to 65 nm	Continuous	Discontinuous over pores, reducing *effective* pore size	Numerous pores allow large-volume filtration at the glomerulus. The effective pore size is reduced further to 6 nm by podocytes; thus, proteins not usually filtered.
Sinusoidal 	Liver, spleen, bone marrow	Large intercellular gaps up to 120 nm	Discontinuous	No effective layer because of endothelial uptake of hyaluronic acid	Large fenestrations allow macromolecules (lipoproteins, chylomicrons) to pass between plasma and ISF; the result is no COP to oppose filtration, and the ISF in these tissues is effectively part of the plasma volume. Large volume filtration to the ISF here cannot be accommodated by tissue expansion because of fibrous capsules and is returned via lymphatics (e.g., liver lymph production accounts for 50% of total body lymph production)

Modified from Woodcock TE, Woodcock TM: Revised Starling equation and the glycocalyx model of transvascular fluid exchange: an improved paradigm for prescribing intravenous fluid therapy, Br J Anaesth *108:384, 2012.*

COP, Colloid oncotic pressure; *ISF,* interstitial fluid.

Key:

of glycosaminoglycan (GAG) chains, including syndecan-1, hyaluronic acid, and glypican, associated with membrane-bound proteoglycans; and glycoproteins, together forming the endothelial glycocalyx layer (EGL). The EGL covers fenestrations and intercellular clefts and has a thickness of up to 1 μm. In addition to its functions in preventing platelet and leukocyte adhesion, it has emerged as an important semipermeable layer contributing to endothelial barrier function.[2] Water and electrolytes can move freely across the vascular endothelial barrier through the EGL and then intercellular clefts or through fenestrations in the more specialized capillaries. Proteins were previously thought to be excluded from the ISF at the level of endothelial cells; however, it now appears that this occurs at the level of the glycocalyx. The subglycocalyceal layer (SGL) therefore contains protein-poor fluid; slower protein transport into the ISF may occur across the endothelial cells by endocytosis and exocytosis and by transport through a small number of large pores, forming a gradient in protein concentration from SGL to ISF compartments. The volume of the SGL may be as much as 700 to 1000 mL; this

volume therefore forms part of the intravascular volume and has an electrolyte composition in equilibrium with the plasma but a much lower protein concentration because of the effective exclusion of larger molecules by the glycocalyx.

Capillary Function. The movement of fluid across the capillary membrane was initially described by Starling and then further refined. A hydrostatic pressure gradient at the arteriolar end of the capillary, greater than the inward oncotic pressure gradient, leads to net filtration of water into the ISF. Much of this water was previously thought to be reabsorbed into the vascular space toward the venular end of the capillary, where the outward hydrostatic pressure is less and the inward oncotic pressure gradient is increased by exclusion of proteins from the capillary filtrate by the capillary endothelium. The water not reabsorbed by the capillary is removed from the ISF by the lymphatics.

More recent experimental and modeling techniques have integrated the role of the glycocalyx into a revised Starling equation and updated model of capillary fluid movement:

$$J_v = K_f([P_c - P_i] - \sigma[\pi_c - \pi_{sg}]) \quad (4)$$

where J_v is the transcapillary flow, K_f is the filtration coefficient, P_c is capillary hydrostatic pressure, P_i is the interstitial hydrostatic pressure, σ is the reflection coefficient (the degree to which the tendency of a macromolecule to cross the endothelial barrier is resisted), π_c is the capillary oncotic pressure, and π_{sg} is the subglycocalyx oncotic pressure.

The key differences and their clinical relevance are as follows[3]:

- At steady state, continuous capillaries *do not* exhibit fluid reabsorption toward the venous end of the capillary (the "no-absorption" rule). However, overall measured capillary filtration (J_v) is much less than predicted by the Starling principle, consistent with the larger colloid oncotic pressure (COP) gradient between SGL and capillary (opposing filtration) than between ISF and capillary. The smaller volume of filtrate is returned to the circulation by lymphatics.
- Plasma-SGL COP difference, not plasma-ISF COP difference affects J_v. However, the no-absorption rule means that artificially raising COP (e.g., by albumin infusion) may reduce J_v but will not lead to reabsorption of fluid from the ISF into the plasma.
- An exception to the no-absorption rule occurs in acutely subnormal capillary pressures; a transient period of autotransfusion may occur, limited to approximately 500 mL. If subnormal pressures persist beyond this, J_v will approach zero, but ongoing reabsorption does not occur. Infusion of colloid in this setting will expand plasma volume, whereas infusion of crystalloid will expand total intravascular volume (plasma and EGL); J_v will remain close to zero in both cases until capillary pressure rises to normal or supranormal levels.
- At supranormal capillary pressures, COP difference is maintained and J_v is proportional to the hydrostatic pressure difference. In this setting, colloid infusion will maintain plasma COP but raise capillary pressure further and increase J_v. Crystalloid infusion will also increase capillary pressure, but reduce plasma COP and therefore increase J_v to a greater extent than colloids.

The revised EGL model of fluid distribution, including the proposal that the intravascular volume effects of crystalloids and colloids are partly dependent on the preexisting capillary pressures (context sensitivity) helps explain some of the apparently conflicting findings in clinical fluid research.

Crystalloid Versus Colloid Intravascular Volume Effects. Infused crystalloid has been thought to distribute evenly throughout the extracellular compartments as a result of capillary filtration (J_v), leaving approximately one fourth or one fifth of the original volume within the circulating blood volume, whereas colloids were presumed to initially remain largely within the intravascular volume. However, many studies of the effects of fluids on blood volume are based on red blood cell (RBC) dilution and changes in the hematocrit and do not take into account the influence of the SGL volume, from which RBCs are excluded. Colloids are also excluded from the SGL; by remaining in the plasma volume they will have a diluting effect on the hematocrit and appear to remain within the circulating volume. Crystalloids initially distribute throughout the plasma and SGL volumes. As a result, their RBC dilutional effects are less than those of colloids. This has previously been interpreted as crystalloid leaving the circulating compartment and entering the ISF; however, a proportion of the infused crystalloid will remain in the blood volume within the SGL. Furthermore, context sensitivity is responsible for the observation that clearance of crystalloid from its central compartment (the intravascular volume) is slower under anesthesia than in awake subjects.[4] It may also help to explain why the amount of isotonic crystalloid required to give early intravascular volume effects similar to those from isotonic colloid in low capillary pressure situations such as resuscitation is in the ratio 1.5:1 rather than the predicted 4:1.[5-7] The value of this ratio in the perioperative context is less clear and has been inferred from large clinical trials in critically ill patients. However, it is likely to be closer to the measured values in critical illness than the theoretic values traditionally used.

Failure to Reduce Edema by Increasing Capillary Colloid Oncotic Pressure. Hypoalbuminemia is well recognized as a marker of disease severity in critical illness. However, administering exogenous albumin or other colloids to increase capillary COP does not reduce peripheral or pulmonary edema, nor improve overall outcomes in sepsis. The no-absorption rule can provide a partial explanation; even increasing COP gradient across the capillary wall by administration of albumin or synthetic plasma substitutes will not lead to reabsorption of fluid from edematous tissues. Again, previous studies showing apparent shifts of fluid from the interstitial to the intravascular compartment based on a reduced hematocrit after albumin infusion do not account for the potential role of compaction of the glycocalyx layer and transfer of fluid from the SGL to the plasma volume in reducing the hematocrit.

Finally, the importance of the endothelial glycocalyx is highlighted by studies showing that its degradation significantly impairs endothelial barrier function.[8] A range of physiologic insults may lead to glycocalyx injury and shedding, with the subsequent appearance of free heparin, chondroitin, and hyaluronic acid in the plasma. These include natriuretic peptides (which may be released in acute excessive intravascular volume),[9] hyperglycemia, and inflammatory mediators released during surgery, trauma, and sepsis, such as C-reactive protein, bradykinin, and tumor necrosis factor (TNF).[10] Glycocalyx degradation may make an important contribution to the already well-characterized endothelial dysfunction seen in inflammation, in which phenotypic changes in endothelial cells. Here, an increase in the number of large pores, and a reduction in interstitial hydrostatic pressure favor J_v, with an increase in edema in compliant tissues such as the lung, muscles, and loose connective tissue. Impaired glycocalyx function will further favor J_v and lead to endothelial platelet aggregation and leukocyte adhesion. Maintenance of glycocalyx integrity is therefore gaining interest as a therapeutic target in perioperative fluid management.[11]

Physiologic Control of Overall Fluid Balance

In health, 60% of daily water loss is through urinary excretion, although this proportion is less when sweating and insensible losses are increased. Integrated cardiovascular and renal neuroendocrine mechanisms attempt to maintain fluid volume homeostasis in response to perioperative challenges, such as reduced oral fluid intake, increased lower GI tract loss as a result of bowel preparation, blood loss, and IV infusion of fluids.

TBW volume is controlled by a system of sensors, central control, and effectors. The sensors are the hypothalamic osmoreceptors, responding to changes in ECF tonicity, low-pressure baroreceptors in the large veins and right atrium that sense central venous pressure, and high-pressure baroreceptors in the carotid sinus and aortic arch. The latter are important if changes in intravascular volume are sufficient to affect arterial blood pressure. The sensory inputs are integrated within the hypothalamus, which then triggers the effector mechanisms to either increase water intake from thirst or modulate output via antidiuretic hormone (ADH, arginine vasopressin) secretion. Thirst and ADH release may be triggered by increased plasma tonicity, hypovolemia, hypotension, and angiotensin II. ADH release also may be stimulated by stress (including surgery and trauma) and certain drugs (e.g., barbiturates). Water intake does not usually depend on thirst because of social drinking behavior; thirst acts as a backup mechanism when the normal intake is inadequate. ADH, produced in the hypothalamus and released from the posterior pituitary, acts on the principal cells of the renal collecting ducts, which in the absence of ADH are relatively impermeable to water. ADH combines with the vasopressin 2 (V2) receptors on the basolateral membrane of the cells, triggering cyclic adenosine monophosphate (cAMP)-mediated insertion of aquaporin 2 water channels into the apical membrane. This results in water reabsorption down its osmotic gradient and formation of low volumes of concentrated urine.

Acute Disturbances in Circulating Volume. Acute variation in the intravascular volume leads to compensatory mechanisms over minutes to hours in an attempt to correct the acute abnormality. The homeostatic processes occurring in response to rapid blood loss are aimed at minimizing the change in effective blood volume (venoconstriction and mobilization of venous reservoirs, limited autotransfusion from ISF to plasma, reduced urine production) and maintenance of cardiac output and arterial pressure (tachycardia, increased inotropy, and vasoconstriction). The sensor organs for the acute change are the low-pressure and high-pressure baroreceptors, and initial changes are mediated through increased sympathetic outflow. Renal vasoconstriction leads to a reduced volume of filtrate, and activates the renin-angiotensin-aldosterone (RAA) axis. Renin is released from the juxtaglomerular cells and cleaves angiotensinogen to form angiotensin I, which is rapidly converted to angiotensin II. This induces further sympathetic activity and vasoconstriction, aldosterone release from the adrenal cortex, and hypothalamic ADH production. The overall result is increased renal salt and water retention, increased peripheral vascular resistance, and increased cardiac output. In the absence of ongoing loss, the delayed responses to major blood loss restore plasma volume within 12 to 72 hours, increase hepatic plasma protein synthesis, and restore RBC levels by erythropoiesis within 4 to 8 weeks.

Conversely, the rapid infusion of fluid to a normovolemic healthy adult leads to an initial rise in venous and arterial pressure and cardiac output. Several mechanisms act rapidly to bring these cardiovascular parameters toward normal, including pressure receptor–mediated venodilatation and venous blood pooling and reduction in systemic vascular resistance. At a tissue level, autoregulatory responses lead to arteriolar vasoconstriction to maintain constant blood flow in the face of increased perfusion pressure. Multiple mechanisms then act to return circulating volume toward normal. A proportion of the infused fluid will be lost as a result of capillary filtration, particularly if the infused fluid reduces COP. Low-pressure baroreceptor stimulation leads to a decrease in pituitary ADH secretion, allowing diuresis, and atrial stretch leads to atrial natriuretic peptide (ANP) release, favoring natriuresis. Further ADH-independent renal mechanisms include glomerulotubular imbalance resulting from the marginal reduction in plasma COP; this rapidly increases the glomerular filtration rate (GFR) and reduces proximal tubule water and Na^+ reabsorption, increasing urine volume. Finally, increased arterial blood pressure promotes the excretion of excess water and salt (i.e., pressure natriuresis and pressure diuresis). This is the pressure-volume control mechanism, one of the key mechanisms for the long-term maintenance of normal blood volume. However, arterial blood pressure is only slowly restored by cardiovascular reflexes after acute hypervolemia. It may take several days for a 20 mL/kg dose of isotonic salt solution to be fully excreted. Excretion of excess Na^+ and water depends more on these passive processes and suppression of the RAA axis than on natriuretic peptide activity.[12] The contrast between this inefficiency and the rapid, effective mechanisms for dealing with reduced fluid volume and Na^+ content reflects

the evolution of physiology in an environment with a paucity of salt and variable water availability; excess Na^+ intake is a feature of modern diets.

Long-Term Control of Circulating Intravascular Volume. The Guyton-Coleman model is the archetypal representation of the circulation. Despite calls to refine the mathematic modeling of the long-term control of arterial blood pressure, it remains the most widely used model to explain the chronic control of blood volume and arterial pressure.[13-15] In health, short-term variations in blood volume are very small and the cardiovascular system behaves as a closed system with arterial pressure a product of peripheral resistance, vascular compliance, and the Starling curve.[16] In the chronic setting or in acute alterations in blood volume, as described earlier, the circulating volume will vary and equality of input and output must be restored to avoid chronic fluid retention or dehydration; thus the circulation acts as an open system. The kidneys are the primary organ regulating this equilibrium, largely through pressure natriuresis and diuresis. Indeed, in the chronic setting, arterial pressure subserves the renal requirement to excrete ingested Na^+ and water rather than simply being a product of cardiac output, vascular compliance, and resistance. A recent interpretation integrates the Guyton-Coleman model with experimental observations (Fig. 59-2).[16] In health, the pressure-natriuresis curve is relatively flat, and excess intake of salt and water can be excreted without long-term rises in circulating volume or blood pressure. In many models of chronic hypertension, the renal excretion mechanism is reset such that natriuresis occurs only at higher arterial pressures and excessive exogenous water and salt results in higher blood pressure.

Electrolyte Physiology

Sodium Physiology. Na^+ is the dominant extracellular cation, and along with its associated anions accounts for nearly all of the osmotically active solute in plasma and interstitial fluid. The relatively free movement of water throughout the fluid compartments means that Na^+ is therefore the prime determinant of ECF volume. Total body Na^+ content is approximately 4000 mmol, of which only 10% is intracellular. The concentration gradient between the intracellular and extracellular compartments (ratio 1:15) is maintained by ATPases and is vital for the function of excitable tissues, including action potentials and membrane potential, and for the handling of renal solute.

Na^+ intake is typically far in excess of minimum daily requirements, which are 2 to 3 mEq/kg/day at birth and decrease to 1 to 1.5 mEq/kg/day in adulthood.[17,18] Na^+ is actively absorbed from the small intestine and colon under the influence of aldosterone and the presence of glucose in the gut lumen. Loss is predominantly by the renal route, with minor contributions from feces, sweat, and skin (10 mEq/day each). Na^+ is freely filtered at the glomerulus, of which 99.5% is reabsorbed, mainly at the proximal convoluted tubule. Serum Na^+ concentrations are maintained within a tight range (138 to 142 mEq/L) despite wide variation in water intake by the systems

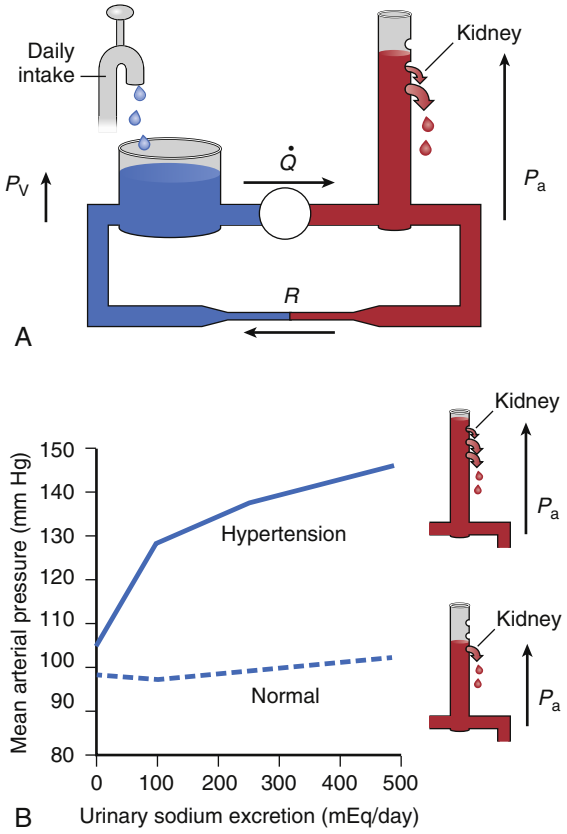

Figure 59-2. Long-term control of blood volume in health and hypertension. **A,** Representation of the open circulation model. In the chronic setting arterial pressure (*Pa*) depends on daily water and sodium intake (*dripping tap*) and the renal pressure-natriuresis relationship (*represented by the height of the holes in the arterial column*) rather than cardiac output ($\dot{Q}$) and peripheral resistance (*R*). **B,** Experimental models of hypertension (e.g., long-term angiotensin II infusion) with controlled sodium intake (and therefore excretion) demonstrate a reset pressure-natriuresis curve in hypertension. This may be represented by kidney *holes* positioned further up the arterial column. Natriuresis occurs to a degree similar to that in normotension, so as to maintain a stable body water volume, but requires a higher arterial pressure to do so. *Pv*, Venous pressure. *(**A,** Redrawn from Dorrington KL, Pandit JJ: The obligatory role of the kidney in long-term arterial blood pressure control: extending Guyton's model of the circulation,* Anaesthesia *64:1218, 2009; and **B,** Data from Hall JE: The kidney, hypertension, and obesity,* Hypertension *41:625, 2003.)*

involved in the control of circulating volume outlined previously, as follows:

- Hypothalamic osmoreception: ADH release
- Atrial volume sensing: ANP release
- Juxtaglomerular apparatus (renal arteriolar baroreception and filtrate NaCl content sensing): RAA activation

The excretion of total body excess Na^+ relies on inefficient passive mechanisms, particularly the pressure-volume effect. Long-term ingestion of excess salt combined with low potassium ingestion contributes to hypertension, a condition not seen in populations with daily salt intake less than 50 mmol. The mechanism involves renal salt retention and initial extracellular volume expansion (later mitigated by pressure natriuresis), with release of an

endogenous digitalis-like factor and stimulation of renal Na^+ pumps, furthering renal Na^+ retention. Low K^+ combined with the chronic action of digitalis-like factor inhibits vascular smooth muscle cell Na^+/K^+ATPases, resulting in excess intracellular Na^+ content and reduced intracellular K^+, smooth muscle contraction, and increased peripheral vascular resistance.[19]

Potassium Physiology. K^+ is the dominant intracellular cation in the body, with a total body content of approximately 4000 mmol, 98% of which is intracellular, particularly in muscle, liver, and RBCs. The ratio of ICF to ECF K^+ balance is vital in the maintenance of cellular resting membrane potential, and K^+ therefore has a key role in the behavior of all excitable tissues. Daily requirements reflect age and growth, with more K^+ required in higher metabolic rates. Term infants require 2 to 3 mEq/kg/day and adults 1 to 1.5 mEq/kg/day. Nearly all ingested K^+ is absorbed by the intestine, and minimal amounts are excreted in feces; the acute and chronic handling of K^+ must therefore maintain a stable plasma K^+ concentration and resting membrane potential in the face of a daily K^+ intake of a similar magnitude to the entire ECF K^+ content. Transmembrane potentials particularly depend on K^+ permeability, with K^+ egress occurring through ion channels down its concentration gradient. This leaves behind intracellular anions, with a resultant negative transmembrane potential. The resting value of this potential is achieved when the tendency of K^+ to move extracellularly as a result of its concentration gradient is matched by the tendency of K^+ to move intracellularly because of the electrical gradient.

Acute K^+ distribution involves shifts in K^+ between the ECF and ICF, performed by ion transport systems under the influence of insulin, catecholamines, and ECF pH. The cell membrane Na^+/K^+ATPase exports three Na^+ for every two K^+ imported and is the means by which the gradients of these ions are maintained. Insulin, released after ingestion of K^+-containing food, stimulates the Na^+/H^+ antiporter, increasing intracellular Na^+, which is then removed by Na^+/K^+ATPase with the net cellular uptake of K^+. Conversely, in the presence of hypokalemia, skeletal muscle expression of Na^+/K^+ATPase is reduced, allowing a "leak" of K^+ from the ICF to ECF.[20] Catecholamines activate β_2-adrenoceptors, which ultimately stimulate Na^+/K^+ATPase activity, leading to increases in ICF K^+, a mechanism that counteracts the release of K^+ from muscle cells during exercise.[21] ECF pH also has a bearing on K^+ handling. The presence of mineral organic acids (where the acid anion is unable to diffuse into the cell) leads to increased cellular H^+ uptake in exchange for K^+ ions with consequent increases in ECF K^+. Organic acids (e.g., lactic acid and ketone bodies) are more able to diffuse across cellular membranes and H^+/K^+ exchange is much less. Hyperkalemia may be observed in the setting of organic acidemia resulting from alternative mechanisms, such as insulin deficiency and osmotic drag in diabetic ketoacidosis or a failure of ATP production for Na^+/K^+ATPase in situations typified by anaerobic metabolism and lactic acidosis. Other factors that may influence ECF to ICF K^+ balance include aldosterone (which at high levels may induce intracellular K^+ shift, beyond its renal effects), hyperosmolar states (solvent drag of K^+ along with water efflux), and digoxin (inactivates Na^+/K^+ATPase and may cause hyperkalemia).

Chronic K^+ distribution involves renal mechanisms. K^+ is freely filtered at the glomerulus, then undergoes extensive unregulated reabsorption along the proximal tubule, with only 10% to 15% reaching the distal nephron, where its reabsorption or secretion is tightly controlled. This occurs predominantly in two cell types found in the collecting ducts.

Principal Cells. The principal cells have the ability to secrete K^+ under the electrochemical gradients set up by basal Na^+/K^+ATPases, which maintain low intracellular Na^+ concentrations (aiding Na^+ reabsorption from the tubule via Na^+ channels) and high intracellular K^+ concentrations (favoring K^+ secretion into the tubule via K^+ channels). Principal cell behavior is influenced by the following:

- Aldosterone, synthesized and released by the adrenal glands in response to raised K^+ concentrations. This mineralocorticoid increases the synthesis and activity of both basal Na^+/K^+ATPases and luminal K^+ channels to drive urinary K^+ secretion.
- Tubular Na^+ delivery. Increased distal tubular Na^+ content leads to a steeper Na^+ concentration gradient and increased principal cell reabsorption of Na^+. To maintain electroneutrality of the tubular fluid, K^+ efflux into the tubule increases; this is partly responsible for the hypokalemia associated with diuretics that increase delivery of Na^+ to the cortical collecting ducts (thiazides and loop diuretics). In contrast, amiloride blocks the principal cell luminal Na^+ channel and therefore does not affect K^+ efflux here.

Intercalated cells. In addition to basal Na^+/K^+ATPases, these cells have luminal H^+/K^+ATPases that excrete one hydrogen into the tubule for every K^+ reabsorbed. Low K^+ settings lead to up-regulation of this luminal antiporter, reabsorbing more K^+ at the expense of renal acid loss.

In addition to mechanisms involving aldosterone in a feedback loop, it is likely that feed-forward mechanisms also exist to rapidly modulate renal K^+ handling when K^+ is sensed in the GI system, even before plasma K^+ levels rise.[20]

Calcium Physiology. Beyond its role in bone structure, where 98% of body Ca^{2+} is stored, Ca^{2+} is one of the body's most important intracellular second messengers, playing a key role in muscular contraction, neuromuscular transmission, cell division and movement, and oxidative pathways. Intracellular Ca^{2+} entry may have direct effects—for example, leading to neurotransmitter release or inducing further large-scale release of Ca^{2+} from intracellular stores (Ca^{2+}-induced Ca^{2+} release), in cardiac and skeletal muscle contraction. A large ECF-to-ICF gradient of ionized Ca^{2+} is maintained by ATPases, and cytoplasmic free Ca^{2+} levels are kept low by pumping into the sarcoplasmic reticulum. Increases in cytoplasmic free Ca^{2+} concentration occurring as a result of cellular energetic failure and impaired Ca^{2+} transport are a key mediator of cell death pathways.[22] Ca^{2+} also plays a key role in coagulation by linking coagulation factors to the negatively

charged plasma membrane of activated platelets (see also Chapter 62).

Homeostatic mechanisms maintain serum Ca^{2+} concentrations between 4.5 and 5 mEq/L (8.5 to 10.5 mg/dL), largely under the influence of vitamin D and parathyroid hormone (PTH). Ionized Ca^{2+} is sensed by the extracellular domain of a G-coupled receptor expressed on parathyroid cells (the Ca^{2+}/Mg^{2+}-sensing receptor), inhibiting PTH release.[23] When ionized Ca^{2+} levels decrease, PTH is rapidly released with the following actions:

- Stimulates osteoclast bone resorption, releasing Ca^{2+} into the ECF
- Stimulates distal tubule calcium reabsorption
- Stimulates the renal conversion of 25-(OH)-vitamin D to 1,25-$(OH)_2$-vitamin D (calcitriol, the most active vitamin D metabolite)

The manufacture of active vitamin D involves cholecalciferol formation in the skin during exposure to ultraviolet light, which then undergoes hepatic hydroxylation to 25-hydroxy-calciferol, then renal hydroxylation under the influence of PTH to 1,25-dihydroxycalciferol (calcitriol). As with PTH, this stimulates osteoclastic bone resorption and additionally stimulates absorption of Ca^{2+} from the GI tract. Other hormones, such as calcitonin[24] and stanniocalcin,[25] have Ca^{2+}-lowering effects that are not necessary for normal long-term maintenance of normal ECF Ca^{2+} content. For example, Ca^{2+} levels remain normal after loss of the calcitonin-secreting parafollicular (C-) cells during thyroidectomy.

Ca^{2+} homeostasis is interlinked with that of other anions. In particular, magnesium is also able to modulate PTH levels, and hypocalcemia and hypomagnesemia frequently coexist. The homeostasis of PO_4^{3-} is effectively the converse of Ca^{2+} (e.g., renal hydroxylation of vitamin D is inhibited by hyperphosphatemia), and in health the (calcium × phosphate) product is kept relatively stable. An increase in the (calcium × phosphate) product may be seen in advanced chronic kidney disease and is associated with ectopic bone deposition.

Approximately 50% of circulating Ca^{2+} is in the biologically active ionized form (normal range 2 to 2.5 mEq/L), 40% bound to proteins, predominantly albumin and globulins, and 10% complexed to anions such as HCO_3^-, citrate, sulfate, PO_4^{3-}, and lactate. Hypoalbuminemia decreases the total serum Ca^{2+} but has less effect on the biologically important ionized form. To calculate the corrected total Ca^{2+} concentration, 0.8 mg/dL is added per 1 g/dL decrease in albumin concentration below 4 g/dL. The degree of albumin-protein binding is affected by pH, with acidemia reducing protein binding and increasing the ionized fraction. Ionized Ca^{2+} rises by approximately 0.1 mEq/L per 0.1 decrease in pH.[26] Given the approximate nature of estimates of corrected total Ca^{2+}, biologically active ionized Ca^{2+} should be measured when possible, by using ion-specific electrodes. Specimens should ideally be taken without tourniquet (uncuffed), because local acidosis increases the ionized fraction.

Magnesium Physiology. Mg^{2+} has a diverse range of cellular actions, including modulation of ion channel activity and as an essential component of ATP production and hydrolysis. It is primarily an intracellular anion, although most is sequestered within organelles, bound to phospholipids, proteins, and nucleic acids. Free ionized Mg^{2+} levels within the cytoplasm and ECF are therefore low (0.8 to 1.2 mM), and chemical concentration gradients are much less than for other anions. Of total body Mg^{2+}, 50% is within bone, 20% within muscle, and the rest in liver, heart, and other tissues. Only 1% is within the ECF, and normal plasma levels may be maintained in the face of total body Mg^{2+} depletion. Within the plasma, total Mg^{2+} concentration is 1.5 to 2.1 mEq/L, of which approximately 25% is protein (mostly albumin) bound, 65% is in the biologically active ionized form, and the remainder is complexed to phosphates, citrates, and other anions.[27] Measurement of ionized Mg^{2+} can be performed, although correction is required for interference from Ca^{2+} ions.[28] The key roles of Mg^{2+} (Table 59-5) are underlined by its diverse range of clinical applications when administered exogenously and stem from the following three main cellular actions:

1. Energy metabolism: Mg^{2+} is required for ATP phosphorylation reactions, interacting with the outer two PO_4^{3-} groups of ATP. Intracellular Mg^{2+} deficiency therefore impairs any enzyme systems using high-energy PO_4^{3-} bonds, such as glucose metabolism.[27]
2. Nucleotide and protein production: Mg^{2+} acts as a cofactor in every step of DNA transcription and replication and translation of messenger RNA (mRNA).
3. Ion transport: By supporting the activity of ion-pumping ATPases, Mg^{2+} helps maintain normal transmembrane electrochemical gradients, effectively stabilizing cell membranes and organelles. In addition, effects on ion channels underlie one of the core functions of Mg^{2+}, namely physiologic competitive antagonism of Ca^{2+}. This is mediated through inhibition of L-type Ca^{2+} channels and extracellular local modification of membrane potential, preventing the intracytoplasmic influx of Ca^{2+} from both the ECF and within intracellular sarcoplasmic reticulum stores. Mg^{2+} also effectively antagonizes *N*-methyl-D-aspartate (NMDA) receptors within the central nervous system, reducing Ca^{2+} entry by specific ion channels. These effects result in inhibition of a diverse array of excitable tissue cellular actions, including neurotransmitter release, muscular contraction, cardiac pacemaker and action potential activity, and pain signal transmission.

Mg^{2+} is absorbed from the GI tract by a saturable transport system and passive diffusion, in quantities inversely proportional to the amount ingested. Excretion is via the GI tract (~60% of the ingested amount) and kidneys. Seventy-five percent is freely filtered at the glomerulus, and proximal tubule reabsorption is minimal, with 60% to 70% being reabsorbed at the thick ascending loop of Henle and 10% reabsorbed under regulation in the distal tubule. The regulation of total body Mg^{2+} levels by GI uptake and control of renal excretion is not under the control of a well-defined hormonal feedback loop. Although many factors can influence Mg^{2+} reabsorption (particularly PTH but also calcitonin, glucagon, acid-base

TABLE 59-5 PHYSIOLOGIC ROLES OF MAGNESIUM

System	Effect	Mechanism and Clinical Relevance
Neurologic	Reduction in pain transmission	NMDA antagonism. Mg^{2+} treatment provides effective perioperative analgesia.[236]
	Reduces neuromuscular transmission	Inhibition of neuronal Ca^{2+} influx reduces neuromuscular junction ACh release (and motor end-plate sensitivity to ACh). Hypermagnesemia potentiates the effects of neuromuscular blockade.
	Sympatholysis	Inhibition of neuronal Ca^{2+} influx reduces catecholamine release from adrenal medulla and adrenergic nerve endings. Pharmacologic use of Mg^{2+} in obtunding pressor response to intubation or during surgery for pheochromocytoma.
	Anticonvulsant	Mechanism may relate to NMDA antagonism or cerebral arteriolar vasodilation, possible mechanisms for its efficacy in eclampsia, in which vasospasm has been observed.[29]
	Cortical depression at high levels	
Cardiovascular	Vasodilation	Predominantly arteriolar, because of inhibition of Ca^{2+} influx–mediated vascular smooth muscle contraction. Mg^{2+} administration typically leads to a minor reflex increase in inotropy despite the direct action of Mg^{2+} on reducing cardiac contractility.[237]
	Antiarrhythmic effects	Mixed class IV (Ca^{2+} channel inhibition) and weak class I (Na^{+} channel inhibition) effects. Increases atrioventricular nodal conduction time and refractory periods, suppresses accessory pathway transmission, and inhibits early and delayed afterdepolarizations. Clinical use is in supraventricular tachycardias, atrial fibrillation rate control and postoperative prophylaxis, and tachyarrhythmias associated with dyskalemia, digoxin, bupivacaine, or amitriptyline.[29]
	Improved myocardial O_2 supply-to-demand ratio	Coronary vasodilation in combination with reductions in heart rate and contractility; however, no clear evidence of benefit in the setting of acute myocardial infarction.
Respiratory	Bronchodilation	Smooth muscle relaxation. Pharmacologic use of Mg^{2+} is in acute bronchospasm.
Renal	Renal vasodilation and diuresis	Ca^{2+} antagonism–related smooth muscle relaxation
Immune	Antiinflammatory	Pharmacologic doses of magnesium sulfate reduce monocyte inflammatory cytokine production.[238]
	Adaptive immunity	Mg^{2+} is required as a second messenger during T-lymphocyte activation.[239]
Obstetric	Tocolysis	May be due to smooth muscle relaxation

ACh, Acetylcholine; *NMDA, N*-methyl-D-aspartate.

balance, Ca^{2+} and K^{+} levels), the main determinant is the plasma Mg^{2+} concentration, sensed by Ca^{2+}/Mg^{2+}-sensor receptors present on the basal aspect of thick ascending loop cells. Other influences may alter the intracellular-extracellular balance of magnesium distribution. Catecholamines, acting by both α-adrenoreceptors and β-adrenoreceptors, and glucagon lead to extrusion of magnesium from intracellular stores. Although experimental models have shown that adrenergic stimulation may increase serum Mg^{2+} concentrations, decreases in serum Mg^{2+} concentrations actually occur after stressors such as cardiac, orthopedic, and abdominal surgery, trauma, burns, and sepsis.[27, 29] This may be due to a later phase of catecholamine-driven cellular uptake after the initial Mg^{2+} efflux.[30]

Phosphate Physiology. PO_4^{3-} is the most abundant intracellular anion and helps form some of the most important biologic molecules, including ATP, DNA, and RNA, membrane phospholipids, 2,3-diphosphoglycerate (2,3-DPG), and hydroxyapatite in bone. PO_4^{3-} is therefore required for energy metabolism, cellular signaling through phosphorylation reactions, cellular replication and protein synthesis, membrane integrity, and O_2 delivery. In addition, the PO_4^{3-} buffer system is one of the key intracellular buffers. Of total body phosphorus, 80% to 90% is stored in bone, with the remainder in the intracellular (soft tissues and erythrocytes) and extracellular fluid compartments.[31] Normal plasma inorganic phosphates are maintained at 3 to 5 mg/dL, and at normal pH 80% exists in the divalent (HPO_4^{2-}) rather than monovalent ($H_2PO_4^{-}$) form. Plasma phosphates also include lipid phosphates and organic ester phosphates. Most intracellular PO_4^{3-} is organic.[18]

The typical daily intake of PO_4^{3-} (~1 g) outweighs metabolic requirements, yet 70% is absorbed, leading to postprandial increases in serum PO_4^{3-} levels that are rapidly dealt with by increased renal excretion. GI uptake occurs predominantly by paracellular diffusion and is unregulated unless PO_4^{3-} ingestion is reduced, when vitamin D and PTH-stimulated active transport intervene.[32,33] Plasma inorganic PO_4^{3-} is freely filtered at the glomerulus, 80% of which is reabsorbed in the proximal tubule and a smaller amount in the distal tubule. Proximal tubule reabsorption is via Na^{+}-dependent cotransporters, the expression and activity of which are under the influence of PTH and PO_4^{3-} intake.

The regulation of normal PO_4^{3-} levels is mediated primarily by the PTH and vitamin D systems. Low plasma PO_4^{3-} levels stimulate 1-hydroxylase activity, with the formation of active vitamin D (1,25-dihydroxycalciferol), which increases GI and renal PO_4^{3-} absorption. Conversely, PTH release (stimulated by reduced plasma Ca^{2+}) reduces renal PO_4^{3-} reabsorption. PO_4^{3-} plasma levels also may be reduced in the short term by cellular uptake in response to dopamine and adrenergic activity and alkalosis and intestinal factors (phosphatonins) released in response to increased intestinal luminal PO_4^{3-}.[31]

Chloride Physiology. As the second most abundant electrolyte in the extracellular compartment, Cl^{-} has a

key role in the maintenance of plasma osmolality, preservation of electrical neutrality, and acid-base status (explained by the Stewart model, see later discussion). Normal plasma values are 97 to 107 mEq/L; Cl^- is therefore responsible for nearly a third of plasma osmolality and two thirds of plasma negative charge.[34] Most Cl^- intake is derived from dietary NaCl, and the GI tract absorbs and secretes large amounts of Cl^-, primarily as gastric hydrochloric acid, but also throughout the intestinal lumen. This cellular Cl^- secretion leads to paracellular movement of Na^+ into the lumen, with water moving down its osmotic gradient to form GI secretions. Cl^- excretion is primarily renal, largely in the proximal tubule by passive reabsorption or cotransport. More regulated control of Cl^- excretion is performed in the intercalated cells of the distal nephron under the influence of plasma acid-base balance—for example, by exchange of HCO_3^- for Cl^-.

Acid-Base Disturbances and Fluid Therapy

Acid-base balance in general is discussed in Chapter 60; however, the two key areas in which intravascular fluid therapy may affect acid-base balance are iatrogenic acidosis caused by the administration of Cl^--rich fluids and administration of sodium bicarbonate to correct acidosis. In summary, the interpretation of acid-base balance can be viewed in three main ways: by the Henderson-Hasselbach equation, by anion gap, or by Stewart's strong ion model. The Henderson-Hasselbach equation represents the HCO_3^- buffer system and has plasma HCO_3^- concentration as an independent determinant of plasma pH (see Chapter 60). The anion gap model is consistent with the Henderson-Hasselbach equation, because it places changes in plasma HCO_3^- at the core of plasma acid-base balance. It represents a simple method for differentiating causes of metabolic acidosis and is defined as the difference between the most abundant measured cation and anion concentrations in the plasma ($[Na^+] + [K^+]$) – ($[Cl^-] + [HCO_3^-]$). The normal anion gap is 4 to 11 mEq/L, and this difference is represented by "unmeasured" anions (PO_4^{3-}, sulfate, and anionic proteins). In the presence of excess organic acids (e.g., lactic acid or ketoacid), the accumulation of unmeasured anions is accompanied by a reduction in HCO_3^- to buffer the excess H^+ ions, leading to an increase in the anion gap. In cases in which Cl^- is administered, even if HCO_3^- falls, the anion gap will remain normal.[35]

Stewart's model of acid-base balance has a different approach and proposes that plasma pH is dependent on the following three independent variables:

1. P_{CO_2} (the plasma CO_2 tension)
2. A_{tot}, the total plasma concentration of all nonvolatile buffers (albumin, globulins, and PO_4^{3-})
3. Strong ion difference (SID), the difference between the total charge of plasma strong cations (Na^+, K^+, Mg^{2+}, and Ca^{2+}) and strong anions (Cl^-, lactate, sulfate, and others). In a more simplified approach, apparent SID is defined as ($[Na^+] + [K^+]$) – ($[Cl^-]$ + [lactate]). Normal plasma SID is approximately 42 mEq/L, and reductions in SID will lead to a fall in plasma pH.

The Stewart model has caused some controversy by representing HCO_3^- as a dependent variable,[36] but it has utility in explaining acid-base disturbances caused by fluid administration.[37]

Hyperchloremic Acidosis. Administration of fluid with a Cl^- concentration higher than that of plasma will in sufficient quantities (e.g., 30 mL/kg/hr of 0.9% saline) cause a metabolic acidosis because of the Cl^- content.[38] This hyperchloremic acidosis may be explained by the Henderson-Hasselbach model of acidosis, in which saline infusion causes dilution of HCO_3^- and a resultant base deficit, or by the Stewart model. Here, the increasing plasma Cl^- concentration reduces apparent SID and therefore reduces plasma pH. The SID of completely ionized saline is zero; therefore, its infusion progressively dilutes the normal plasma SID. Similar changes are not seen with solutions containing other anions, which are metabolized after infusion, such as lactated Ringer solution. Although in vitro as an electroneutral solution, it also has a SID of zero; after administration the lactate undergoes metabolism in patients with intact hepatic function, giving it an effective in vivo SID of approximately 29 mEq/L. This is slightly less than the plasma SID and is enough to counteract any alkalosis caused by dilution of A_{tot}.

Saline-induced hyperchloremic acidosis is recognized to have a variety of potentially deleterious physiologic effects. These include renal vasoconstriction, reduced GFR, reduced renin activity (shown in animal models[39-41]), and reduced renal cortical perfusion (in healthy volunteers[42]). Coagulopathy and GI dysfunction also have been suggested.[43] However, it is not clear that acidosis purely attributable to iatrogenic hyperchloremia leads to clinically important morbidity. A meta-analysis of studies comparing saline with balanced perioperative fluid regimens confirmed the presence of hyperchloremia and acidosis postoperatively in the saline groups, but typically these biochemical abnormalities had cleared by the first or second postoperative day.[38] No overall differences in markers of kidney injury or need for renal replacement therapy were found, nor in other morbidities such as clinically important coagulopathy or GI symptoms. However, the available trials were relatively small, and higher risk surgical groups (those with preexisting impairment of acid-base status or emergency and major surgery) were underrepresented. Interestingly, in one trial of patients undergoing renal transplant, saline administration was associated with significant hyperkalemia, presumably caused by cellular K^+ extrusion resulting from extracellular acidosis.[44] It is therefore possible that the acidosis observed as a result of saline administration has a greater clinical effect on a selected high-risk group; further focused large-scale clinical trials are required.

Bicarbonate Administration. The administration of IV $NaHCO_3$ to treat metabolic acidosis should be reserved for the emergency treatment of select conditions, including severe hyperkalemia and arrhythmias associated with tricyclic antidepressant overdose. In many other situations, clinical benefit is not apparent, a finding that highlights an important pathophysiologic concept. Acidosis

in itself may not be physiologically deleterious; indeed it is a normal event during strenuous exercise, in which it may aid O_2 offloading to tissues. Rather, perhaps acidosis serves as a marker for the severity of underlying disease processes, such as hypoxia, ischemia, or mitochondrial dysfunction, which cause morbidity without adequate correction.[43] HCO_3^- administration also has the following negative effects[18]:

1. Carbon dioxide production. Most of the HCO_3^- administered is converted to CO_2, with two important consequences. First, excess CO_2 requires excretion by hyperventilation. Converted HCO_3^- of 100 mEq represents an excess of 2.24 L of CO_2 to be exhaled, which may present a significant physiologic challenge to critically ill patients with preexisting ventilatory impairment. Second, the excess CO_2 may diffuse into the intracellular space, aggravating intracellular acidosis, although this is disputed.[18]
2. IV HCO_3^- brings a significant Na^+ content and therefore osmotic load. This may lead to hyperosmolar hypernatremia, ECF expansion, and volume overload.
3. If renal HCO_3^- distribution is impaired, there may be an "overshoot" toward metabolic alkalosis once the underlying disease process causing the initial acidosis is resolved.

In situations in which HCO_3^- administration is required, the total dose required to correct the base deficit can be calculated using the equation:

$$\text{Dose (mEq)} = 0.3 \times \text{weight (kg)} \times \text{base deficit (mEq/L)} \qquad (5)$$

although half this dose is usually given, because of the problems outlined before, and treatment should stop once the pH rises above 7.2.

FLUID PHARMACOLOGY

Given the diverse range of physiologic effects of administered fluids, and the potentially large volumes that can be administered perioperatively, they should be considered as drugs with specific indications, cautions, dose ranges, and side effects. Many of the fluids available currently were developed several decades ago and entered clinical practice without rigorous analysis of their clinical benefits or knowledge of their effects at an organ or cellular level. Newer colloid solutions have been approved by regulatory authorities and entered widespread clinical usage based on relatively small trials of efficacy. In some cases, safety concerns such as the impact of colloid-related renal dysfunction have been highlighted only by much later adequately powered trials.[45] Furthermore, lack of knowledge of fluid composition is common among the clinicians who are most often responsible for postoperative fluid administration, which may be linked to poor prescribing practices and increased postoperative morbidity.[46-48] The composition of available fluids is shown in Table 59-6, although not all fluids are available in all countries. This table includes an example of renal dialysate fluid, which in special circumstances may be suitable for IV infusion.

Crystalloids

Crystalloids are solutions of electrolytes in water. They may be classified by their tonicity after infusion or their overall composition; crystalloids containing a range of electrolytes also found in plasma and a buffer such as lactate or acetate may be referred to as balanced solutions. Crystalloids are indicated for replacement of free water and electrolytes but also may be used for volume expansion. Conventional concepts of fluid compartments dictate that infused electrolytes will distribute freely throughout the ECF, that water will follow down osmotic gradients, and that the net result is a distribution of infused crystalloids throughout the entire ECF, with only 20% remaining in the intravascular compartment. This is challenged by large clinical trials and current knowledge of microvascular fluid handling (see section on vascular endothelium), which suggest that isotonic crystalloids may have a larger intravascular volume expanding effect than this, particularly in patients with low capillary hydrostatic pressures. The study of volume kinetics has quantified the redistribution of crystalloids from the central (intravascular) volume to the larger peripheral (total extracellular) volume. Perhaps up to 70% of a crystalloid infusion remains in the intravascular compartment at the end of a 20-minute continuous infusion, decreasing to 50% after 30 minutes.[4] Nevertheless, more fluid will ultimately be filtered out of the capillary with crystalloids than with colloids, owing to colloids' effects on oncotic pressure, and patients resuscitated with crystalloids have a more positive fluid balance for the same volume expansion effect.[49] Tissue edema may increase in compliant tissues such as the lung, gut, and soft tissues, particularly when crystalloid solutions are infused into normovolemic subjects. Large-volume crystalloid infusion also may be associated with a hypercoagulable state caused by dilution of circulating anticoagulant factors; the clinical significance of this is not currently known.[50]

Saline Solutions

0.9% Sodium Chloride. One of the most commonly administered crystalloids is 0.9% NaCl solution, yet it is not clear historically how it entered routine clinical practice. Although many of the crystalloids being examined for in vivo clinical usage during the 1800s had a composition much closer to that of plasma, Hamburger ascertained using in vitro red cell lysis experiments that 0.9% was the NaCl concentration that was isotonic with human plasma. Therefore, 0.9% saline was not initially developed with the aim of in vivo administration, yet has entered widespread clinical use despite having a Na^+ and Cl^- concentration far in excess of that of plasma.[51] Its osmolarity, calculated as the sum of the solutes present, is slightly higher than that of plasma, although the osmolality (measured by freezing point depression) is 285 mOsm/kg, very similar to that of plasma. This discrepancy reflects the nonideal behavior of solutions. Both ions present remain in the ECF after infusion, and it can be said to be isotonic—that is, of a similar *effective osmolarity* to that of plasma with respect to the cell membrane.

A 2-L infusion of 0.9% NaCl leads to an increase in ECF volume, dilutional decrease in hematocrit and albumin, increase in Cl^- and K^+ concentrations, and decrease in

†The NaCl content and osmolarity of albumin solutions varies dependent on formulation. Osmolarity values are calculated in vitro.

plasma HCO_3^-.[42] The expansion of the ECF is more persistent than with balanced crystalloid solutions; although both fluids induce diuresis, this has a later onset and is less extensive with isotonic saline (see section on acute disturbances in circulating volume), and the excess salt and water load may take multiple days for even a healthy subject to excrete.[12]

Infusion of saline leads to a hyperchloremic metabolic acidosis and reduced renal perfusion. Although important differences in clinical outcomes in the surgical populations are not clear,[38] in the wider critical care population an increased incidence of kidney injury and requirement for renal replacement therapy are seen when compared with the use of lower Cl^- solutions.[52] In healthy volunteers, the large-volume (50 mL/kg) infusion of 0.9% NaCl led to abdominal discomfort, nausea, and vomiting.

These side effects mean that the volume of saline administered perioperatively should be limited, unless there are compelling indications such as the following:

- Situations in which increased plasma Na^+ may be beneficial, such as in the presence of cerebral edema.
- Preexisting Na^+ or Cl^- total body depletion, such as gastric outlet obstruction (see later discussion). However, 0.9% NaCl is not suitable for the treatment of acute severe hyponatremia, because it has little effect on plasma Na^+ levels in this situation.

Hypertonic Saline. Solutions of 1.8%, 3%, and 7.5% NaCl are available. Their uses include the following:

- Plasma volume expansion: The hypertonic nature of these solutions draws water out of the intracellular

compartment and into the extracellular (including plasma) volume and may therefore achieve plasma volume expansion while minimizing the volume of fluid administered. Although it has not been studied extensively in the perioperative phase, use of hypertonic saline for trauma resuscitation, particularly in the prehospital phase, has been considered, with no convincing benefit. In fact, one large trial showed no improvement in outcome and was stopped early.[53]

- Correction of hypoosmolar hyponatremia (see later discussion).
- Treatment of increased intracranial pressure (see also Chapter 70). The increased plasma osmolality reduced cerebral edema and increased intracranial pressure. Hypertonic saline may be superior to mannitol in this regard.[54] However, as with its use in hypovolemic trauma, hypertonic saline used early in traumatic brain injury without knowledge of intracranial pressure is not beneficial in clinical trials.[55]

At NaCl concentration greater than 7.5%, these solutions may cause endothelial damage; indeed 11.7% NaCl may be used as a sclerosant agent and should therefore be administered into a central vein.

Balanced Crystalloid Solutions. Intravenous crystalloid solutions were initially used clinically for the management of cholera in 1832 by O'Shaughnessy and Latta and then further developed by others. Interestingly, Latta's early solutions were more closely matched to physiologic plasma composition than NaCl solutions, containing 134 mEq/L Na^+, 118 mEq/L Cl^-, and 16 mEq/L HCO_3^-.[51] However,

clinical interest in more balanced solutions waned until Hartmann used a lactated modification of Ringer solution for pediatric patients with acidosis associated with hypovolemia and liver and renal failure in 1932.[56] By this time, NaCl solutions were already in use for resuscitation from hemorrhage and trauma.[51]

Currently available balanced crystalloid solutions have lower overall osmolarity than 0.9% NaCl, with a lower Na^+ concentration and much lower Cl^- concentration (see Table 59-6). The reduction in anionic content is compensated for by the addition of stable organic anionic buffers such as lactate, gluconate, or acetate. The measured osmolality of balanced solutions (265 mOsm/kg) is slightly lower than that of plasma, and they are therefore mildly hypotonic. Fluid compartment distribution of balanced solutions is similar to that of other crystalloids. After administration, the buffer is metabolized to produce HCO_3^- in equimolar quantities by entry into the citric acid cycle. Lactate undergoes predominantly hepatic oxidation or gluconeogenesis to yield HCO_3^- at a maximum rate of approximately 200 mmol/hr.[57] Acetate is normally present in trace quantities in the plasma (0.2 mM), being rapidly oxidized by liver, muscle, and heart to yield HCO_3^- at a maximum turnover of 300 mmol/hr, beyond which zero-order kinetics intervene.[58] A small proportion may be converted to the ketone body acetoacetate. The metabolism of gluconate is less well characterized in terms of location and kinetics, but it is converted to glucose with subsequent entry into the citric acid cycle.[59] Although balanced crystalloids can be constituted with HCO_3^- as a main anion, this is limited by two factors. First, HCO_3^- reacts with water to form CO_2, which is able to diffuse out of most packaging materials. This has been addressed by some products, although availability is limited.[60,61] Second, the pH shift induced by the presence of HCO_3^- can lead to precipitation of Ca^{2+} (and Mg^{2+}) if present.

The excretion of the excess water and electrolyte load with balanced crystalloids is more rapid than with isotonic saline.[62] This is due to the transient decrease in plasma tonicity after infusion, which suppresses ADH secretion and allows diuresis in response to the increased intravascular circulating volume. Balanced crystalloids do not reduce plasma SID to the same degree as NaCl solutions and therefore do not cause an acidosis; HCO_3^- concentration is maintained or slightly elevated.

Some potential negative effects have been identified with balanced crystalloid solutions. Lactated Ringer solutions contain racemic (D- and L-) lactate, although D-lactate is only found in trace quantities in vivo. Concerns that large doses of D-lactate may be associated with encephalopathy and cardiac toxicity in patients with renal failure[63,64] have not been confirmed in human studies at plasma levels achievable by the use of racemic lactated Ringer solution; the metabolism of D-lactate appears to be nearly as rapid as that of L-lactate.[65] The reliance on hepatic metabolism of most of the infused lactate means that lactated solutions should be avoided in severe liver failure. Concerns over the effects of excess exogenous acetate have been raised by the well-recognized syndrome of acetate intolerance experienced by patients undergoing hemodialysis with acetate-based dialysate. The proinflammatory, myocardial depressant, vasodilatory, and hypoxemia-promoting effects of high acetate levels manifest as nausea, vomiting, headaches, and cardiovascular instability and have led to the removal of acetate from contemporary dialysis fluids.[58,66-70] Acetate turnover is limited in patients with end-stage kidney disease and by the presence of other substrates for oxidation—for example, during lactic acidosis or proteolysis. It is therefore possible that critically ill patients or those with advanced kidney disease may exhibit biochemical acetate intolerance, although this possibility has not been explored in patients receiving acetate-based balanced crystalloids. Unlike acetate, much less is known about the effects of increased gluconate levels, which occurs with the infusion of fluids containing this as an anion.[71] Indeed, this area requires investigation at a cellular, organ, and whole organism level, particularly because data in animal studies suggest poorer outcome and late increases in lactate in a hemorrhage model when acetate/gluconate-containing crystalloids are compared to lactated Ringer solution or isotonic saline for resuscitation.[72]

Dextrose Solutions. Dextrose solutions have the following two main indications in the perioperative setting:

1. As a source of free water: An infusion of 5% dextrose effectively represents administration of free water. In vitro osmolality is similar to that of plasma so that infusion does not lead to hemolysis, but soon after infusion the dextrose is taken up into cells in the presence of insulin, leaving free water. These solutions are therefore hypotonic with respect to the cell membrane and in excess can dilute plasma electrolytes and osmolality. They should therefore be used with care in the postoperative period, during which the relative syndrome of inappropriate secretion of antidiuretic hormone (SIADH) leads to water retention, increasing the risk for hyponatremia (see later discussion). Nevertheless, in carefully controlled volumes and with regular monitoring of serum electrolytes they are a useful source of free water for maintenance requirements postoperatively, particularly if combined with a low concentration of NaCl. Dextrose solutions are less suitable for intravascular plasma volume expansion, because water is able to move between all fluid compartments and a very small volume therefore remains in the intravascular space.
2. Source of metabolic substrate: Although the caloric content of 5% dextrose is inadequate to maintain nutritional requirements, higher concentrations are adequate as a metabolic substrate, such as 4000 kCal/L for 50% glucose. Glucose solutions also may be coadministered with IV insulin to patients with diabetes to reduce the risk for hypoglycemia, such as 10% dextrose at 75 mL/hr.

Colloids

Colloid is defined as large molecules or ultramicroscopic particles of a homogeneous noncrystalline substance dispersed in a second substance, typically isotonic saline, or a balanced crystalloid (see also Chapter 61). These particles cannot be separated out by filtration or centrifugation. Although not all solutions are available in all countries, those in production include semisynthetic colloids and

human plasma derivatives. Semisynthetic colloids have a range of molecular sizes (polydispersed) in contrast to human albumin solution, which contains more than 95% albumin molecules of a uniform size (monodispersed). Colloid molecules above 70 kDa are too large to pass through the endothelial glycocalyx and are excluded from the subglycocalyx layer, with their initial volume of distribution as the plasma (rather than the entire intravascular) volume (see discussion of vascular endothelium). In contrast to pure electrolyte solutions, colloids have a higher COP and minimize transcapillary filtration, particularly at low capillary hydrostatic pressures. This maximizes their potential intravascular plasma volume expansion effect. However, at normal or supranormal capillary pressures, hydrostatic pressure will be increased and transcapillary filtration will occur.[3] In addition, colloid molecules may be lost from circulation in several ways—by filtration across capillaries whose barrier function is impaired by glycocalyx shedding, endothelial cell pore formation in inflammation or other stressors, or both; by renal filtration of smaller colloid molecules; or by removal from the circulation by metabolism. Therefore, colloids have variable effective plasma half-lives, as outlined later. Colloids alter blood rheology, typically improving blood flow by hemodilution effects, reductions in plasma viscosity, and red cell aggregation effects.[50] In contrast to their beneficial effects, the introduction of a large dose of semisynthetic molecules (typically 40 to 60 g/L) to a complex physiologic system may bring a variety of undesired effects on the immune, coagulation, and renal systems. In an attempt to limit these toxicities, maximum recommend doses are produced for most colloids, but adverse effects may still occur with smaller administered doses. As the potential clinical relevance of toxicity is highlighted by large clinical trials, the use of colloids, at least in critical care, is increasingly cautious.[73] Whether these trials in critical care can be applied to the entire perioperative period is not established (also see Chapter 61).

Semisynthetic Colloids

Gelatins. Gelatins are derived from the hydrolysis of bovine collagen, with subsequent modification by succinylation (Gelofusine, B Braun, Bethlehem, Pa; Geloplasma, Fresenius, Waltham, Mass) or urea-linkage to form polygeline (Haemaccel, Piramal, Orchard Park, NY). These forms have a similar molecular weight (MW), but the succinylated version undergoes conformational change as a result of increased negative charges, such that it is a larger molecule. The wide range of MWs present means that much of an infused gelatin bolus will rapidly leave the circulation, predominantly by renal filtration. Despite this, a recent study suggests that 60 minutes after the end of infusion, 50% of the infused fluid volume remains in the intravascular space, similar to larger MW colloids.[74] Excretion is primarily by the renal route. In terms of negative effects, the gelatins have the least impact on clinically relevant hemostasis of all the semisynthetic colloids despite reductions in von Willebrand factor (vWF), factor VIIIc, and ex vivo clot strength,[75] but the highest estimated incidence of severe anaphylactic and anaphylactoid reactions (<0.35%).[50] The high Ca^{2+} content of Haemaccel is a contraindication to coadministration of citrated blood products in the same infusion set. No known cases of variant Creutzfeldt-Jakob disease transmission have occurred involving pharmaceutical gelatin preparations. Gelatins are commonly used in perioperative practice in Europe but are not approved by the U.S. Food and Drug Administration.

Hydroxyethyl Starches. Hydroxyethyl starches (HESs) are modified natural polymers of amylopectin derived from maize or potato (see also Chapter 61). Substitution of hydroxyethyl radicals onto glucose units prevents rapid in vivo hydrolysis by amylase, and the degree of substitution both in terms of hydroxyethyl substitutions per glucose unit (maximum three) and total number of glucose units with substitutions is a determinant of HES kinetics of elimination. The degree of substitution (DS) is expressed as the number of substituted glucose molecules present divided by the total number of glucose molecules present. An alternative measure of substitution is the molar substitution (MS) ratio, calculated as the total number of hydroxyethyl groups present divided by the quantity of glucose molecules. MS is used to define starches as hetastarches (MS 0.7), hexastarches (MS 0.6), pentastarches (MS 0.5), or tetrastarches (MS 0.4). The pattern of substitution may vary because hydroxyethylation can occur at carbon positions 2, 3, or 6 of the glucose unit. The substitution type is defined by the C2/C6 hydroxyethylation ratio, and a higher ratio leads to slower starch metabolism. Starches are also classified by in vitro MW into high MW (450 to 480 kDa), medium MW (200 kDa), and low MW (70 kDa). However, HES solutions are very polydispersed and the MW quoted is an average. Although the size of starch molecule is responsible for both the therapeutic volume effects and adverse side effects, this changes when infused; smaller HES molecules (<50 to 60 kDa) are rapidly excreted and larger molecules are hydrolyzed to form a greater number of smaller molecules at a rate depending on the degree of substitution and C2/C6 hydroxyethylation ratio. The in vivo MW is therefore smaller and has a narrower distribution.[76] Ongoing renal excretion accounts for the elimination of smaller HES molecules, with medium-sized molecules being excreted in the bile and feces. A proportion of larger molecules, particularly those resistant to hydrolysis, is taken up by the mononuclear phagocyte (reticuloendothelial) system, where they may persist for several weeks or more.[77] The prolonged metabolism of HES means that their plasma volume effects typically last longer than those of gelatins or crystalloids, with larger MW starches increasing intravascular volume by approximately 70% to 80% of the infused dose at 90 minutes.[78] Smaller MW starches with a low MS may have even larger volume effects as a result of the rapid initial metabolism with the formation of a large number of oncotically active molecules.[79] Yet studies in healthy human volunteer experiments suggest a similar volume effect to that of gelatins.[74] Also, starch-related side effects may be associated with adverse outcomes in critical illness (see also Chapter 61). Problems such as coagulopathy, accumulation, and renal dysfunction initially appeared to be related to larger MW starches, but now smaller tetrastarches are a concern as well. Despite this, study populations with critical illness, particularly sepsis, cannot be compared directly with elective perioperative patients. These trials should be interpreted with

caution when considering the relevance of HES to surgical patients. Nevertheless, the official recommendations against the use of HES are clearly negative.

Coagulation. As with other synthetic colloids, HES products affect coagulation through dilutional effects in the circulation and MW-dependent reductions in vWF, factor VIII, and clot strength. The effect is most likely to occur with larger MW or slowly degraded medium MW (200 kDa/MS 0.62 or 200 kDa/MS 0.5/C2:C6 13) HES preparations and larger amounts of perioperative blood loss. This clinical effect is less marked with more rapidly degraded medium and small MW starches.[50] In patients with sepsis, even lower MW HES is associated with an increased risk of bleeding and blood transfusion, but it is unclear whether this also occurs in the perioperative setting.[80,81]

Accumulation. The accumulation of HES molecules in the mononuclear phagocyte system and skin, liver, muscle, and gut is a dose-dependent effect that gradually decreases over time. However, the accumulation may persist for several years, and a larger degree of tissue deposition is associated with pruritus.[77]

Anaphylactoid Reactions. The estimated incidence of severe anaphylactoid or anaphylactic reactions with HES products is less than with other colloids (<0.06%).[50]

Renal Dysfunction. HES products with medium to high MW are associated with oliguria, increased creatinine, and acute kidney injury in critically ill patients with preexisting renal impairment.[6,82] Although newer solutions with low MW (130 kDa/MS 0.4) were initially thought to be safer in this respect, recent large-scale trials have shown a similar effect on the need for renal replacement therapy in severe sepsis, particularly when compared with balanced crystalloids.[80,81] A recent large trial in a mixed critical care population comparing HES with isotonic saline also reported an increase in renal replacement therapy with the starch solution. This study is more difficult to interpret given the potential renal effects of saline, and, as with previous studies, the possibility that patients were given study fluids after partial resuscitation had already been achieved.[49] Currently no similar data are available from large-scale studies on the intraoperative use of HES solutions, and a recent meta-analysis examining perioperative use of 6% HES concluded that although no increase in mortality or kidney injury was seen, the available evidence lacked statistical power to definitively answer this question.[83] Meanwhile, the use of starch-based colloids has been restricted or even completely suspended by regulatory authorities in both the United States and Europe (see also Chapter 61).

Dextrans. Dextrans are highly branched polysaccharide molecules produced by the bacterium *Leuconostoc mesenteroides* after conversion of sucrose in the growth medium by bacterial dextran sucrase (see also Chapter 61). The large MW dextrans produced undergo acid hydrolysis to yield smaller MW molecules, which are then separated by fractionation to produce a solution with a restricted range of MWs. Available dextrans have an average MW of 40 kDa or 70 kDa. As with other colloids, the polydispersal nature of dextran solutions means that a proportion of smaller MW molecules are present that are rapidly filtered at the glomerulus; 70% of a dextran dose is renally excreted within 24 hours. Higher MW molecules are excreted into the GI tract or taken up into the mononuclear phagocyte system, where they are degraded by endogenous dextranases.[50] Dextrans have a plasma volume effect similar to that of starches, with a duration of 6 to 12 hours. In addition to their use in volume expansion, dextran 40 may be used in microvascular surgery, where its dilutional effects on blood viscosity and anticoagulant effects (see later discussion) favor flow in the microcirculation. Overall, the use of dextrans is limited by their range of toxicities, as follows:

- Antithrombotic effect: This is particularly marked in lower MW dextrans and is mediated through a range of mechanisms, including red cell coating and inhibition of aggregation, factor VIIIc and vWF reductions, and impaired activity of factor VIII. Platelet aggregation is also inhibited. The result is clinically impaired hemostasis and increased perioperative blood loss.[75]
- Blood cross-matching: Dextrans coat the erythrocyte cell membrane and may interfere with blood type cross-matching.
- Anaphylactoid reactions: Dextrans have an intermediate risk for serious anaphylactic and anaphylactoid reactions (<0.28%). Preemptive treatment with dextran 1, a hapten inhibitor, may reduce this incidence to less than 0.0015%.[50]
- Renal dysfunction: Renal dysfunction resulting from osmotic nephrosis is recognized after low-MW dextran infusion,[84] although the true incidence of this phenomenon in perioperative patients is difficult to estimate because of the limited use of dextrans in contemporary practice.

Human Plasma Derivatives. The human plasma derivatives include human albumin solutions, plasma protein fractions, fresh frozen plasma, and immunoglobulin solution. Preparation techniques result in relatively purified solutions with the elimination of infective agents, although the theoretic risk for transmission of variant Creutzfeldt-Jakob disease remains, associated with bovine spongiform encephalopathy. One U.K. case of presumed prion transmission has been described in association with factor VIII transfusion, although without clinical manifestation.[85] The ongoing transmission risk has been mitigated by sourcing many plasma derivatives from non-U.K. sources. Solutions such as 5% albumin have a near-physiologic COP of 20 mm Hg and are used for volume expansion. Despite the association of hypoalbuminemia with worse outcomes from critical illness, the administration of exogenous albumin does not improve outcome in these situations. Early concerns that resuscitation with albumin may actually increase mortality in critical illness were not confirmed by a large controlled trial that found no difference in outcomes whether albumin or isotonic saline was used for resuscitation.[5] In this heterogeneous population, the albumin group required less fluid to attain similar endpoints (ratio 1:1.4), although in the subgroup of patients with trauma, and particularly brain injury, albumin may be associated with an increased incidence of mortality.[5,86] Conversely, in a subgroup analysis

of patients with sepsis, albumin administration trended toward a decreased frequency of mortality that was supported by a subsequent meta-analysis.[87]

CLINICAL FLUID AND ELECTROLYTE MANAGEMENT

Pathophysiologic Fluid Alterations in the Perioperative Phase

Before recommending practical approaches to administering fluid in the perioperative phase, it is important to consider the pathophysiologic processes that may occur perioperatively and affect not just the body's requirement for exogenous fluid and electrolytes but also the manner by which those fluids are distributed by the body. The patient may enter the perioperative phase with abnormalities of intravascular fluid volume and distribution. Subsequent trauma (including surgery) induces a range of evolutionarily conserved neurohumoral and inflammatory changes, termed the *stress response*, which may have a significant impact on fluid and electrolyte responses and distribution. When the stress response is of an appropriate magnitude and duration, it can be a beneficial process for recovery from trauma; however, it could become pathologic if it is either exaggerated or prolonged or presents a physiologic burden to patients with limited baseline physiologic reserves.

Preoperative. Patients may enter the perioperative phase with established derangements of fluid and electrolyte balance. Hepatic, renal, and cardiac dysfunction are all associated with disordered Na^+ distribution (see later discussion), which has profound secondary effects on ECF volume. Patients with oligoanuric end-stage renal disease depend on dialysis for fluid removal, and the timing of dialysis relative to surgery is critical. Chronic treatment with diuretics may also lead to electrolyte depletion. Depending on treatment, hypertensive patients may have a volume-contracted circulation, making them prone to marked intraoperative relative hypovolemia (see Chapter 39).

The effects of preoperative fasting also should be considered, although its influence on fluid balance has perhaps been overstated. Modern perioperative practice mandates cessation of oral fluids only 2 hours before elective surgery, and even overnight fasting results in a normal blood volume when measured using robust experimental techniques.[88] Conversely, bowel preparation can cause a weight loss of 1.5 to 1.7 kg[89,90] with a high water and K^+ content. The potentially deleterious effects of this should be limited by restricting bowel preparations when possible and compensating for fluid loss with the simultaneous IV infusion of 1 to 2 L of crystalloid with K^+ supplementation. This intervention improves hemodynamics and lowers serum creatinine.[90]

More severe disturbances of fluid and electrolyte balance can occur in patients presenting with acute disease requiring surgical intervention. This may be influenced by one or more of the following:

- Direct intravascular depletion resulting from bleeding.
- Loss of fluid from the GI tract. This results in ECF depletion and loss of electrolytes, depending on the site of loss. Excess gastric loss because of obstruction, vomiting, or excess nasogastric suction results in loss of Na^+, K^+, Cl^-, and acid. Loss of small bowel secretions results in high losses of Na^+, Cl^-, and HCO_3^- with lesser K^+ losses. Large bowel losses, such as in diarrhea, deplete large quantities of K^+ with lesser losses of Na^+ and HCO_3^-. Pathologic fluid sequestration within the bowel lumen may have similar effects without external signs of fluid loss.
- Inflammation-related redistribution from the intravascular to the extracellular compartment (see later discussion).
- Fluid sequestration in the physiologic third space, with edema, pleural effusions, and ascites.

Intraoperative. Many factors influence intraoperative fluid balance, such as the following:

- Altered distribution of intravascular volume. Vasodilation caused by anesthetics affects both the venous and arterial systems and may reduce cardiac preload and afterload. This reduction may be exacerbated by sympathetic blockade caused by central neuraxial blockade, and cardiac output also may be decreased by the negative inotropic effect of anesthetic drugs. The distribution of blood within the vascular system is also influenced by the differential blunting of autoregulatory responses within organ beds caused by anesthesia. Microcirculatory dysfunction related to the effects of anesthesia and the inflammatory response to surgery may result in impaired functional matching of local O_2 delivery with tissue O_2 requirements, which may not be responsive to intravascular fluid therapy.
- Direct loss of intravascular volume as a result of bleeding. The clinical manifestation of surgical blood loss may vary greatly depending on the volume and time course of the blood loss.
- Insensible losses. The opening of anatomic compartments leads to evaporative fluid loss from mucosal surfaces, although estimating the extent of this loss may be difficult. Humidity chamber studies indicate that the loss may be as little as 1 mL/kg/hr even during a major laparotomy with extensive bowel exposure.[91]
- Inflammation-related redistribution. Major surgery induces an inflammatory response that favors redistribution of fluid from the intravascular to the extracellular compartment. This typically manifests in the postoperative phase (see later discussion), although it may become clinically apparent intraoperatively during surgery of sufficient magnitude and duration.
- Renal output. The suppression of renal urine production is related to perioperative ADH secretion and may also be influenced by the effects of positive-pressure ventilation. Increased intrathoracic pressure reduces venous return and cardiac output, which combine with a variety of neurohumoral responses such as sympathetic activation and suppression of ANP release to decrease GFR and urine output.[92] As a result, intraoperative urine output may be small regardless of the volume of IV fluid administered.[93]

The early phase of the stress response is triggered during major surgery. Absolute or relative (redistributive) hypovolemia during the intraoperative phase invokes a range of conservative responses—described in the section on acute disturbances in circulating volume—that are aimed at redistributing blood away from the periphery and toward vital organs, and maintaining circulating volume by retaining salt and water. The tissue trauma of surgery also triggers a well-described inflammatory and immune response, and together these changes may persist into the postoperative phase. The inflammatory response elicited by tissue trauma may be aggravated by periods of hypotension and tissue hypoperfusion, as described in the following discussion.

Postoperative. As a result of the preoperative and intraoperative factors outlined previously, patients may start the postoperative phase with significant derangements of intravascular volume and fluid compartment distribution. The stress response triggered by surgery may have an ongoing influence on postoperative fluid balance.

Inflammation and Immune Response. Tissue injury leads to local vasodilation, increased endothelial permeability, and influx of leukocytes to the damaged area, with consequent production of proinflammatory cytokines for up to 72 hours, particularly interleukin-1 (IL-1), TNF-α, and IL-6. Cardiopulmonary bypass, extensive tissue trauma, or surgery in areas with subclinical preoperative inflammation, such as tumor or infection, may lead to a postoperative systemic inflammatory response syndrome (SIRS). An alternative trigger for SIRS is GI hypoperfusion. The physiologic response to hypovolemia is preservation of cardiac and brain perfusion at the expense of kidney, gut, and peripheral perfusion. The intestinal villi have a countercurrent blood supply that shunts blood away from the mucosa in this situation, leading to mucosal necrosis and further impairment of gut barrier function by luminal digestive enzymes and bacteria. This allows gut bacterial endotoxin to translocate into the systemic circulation, acting as a potent trigger for systemic inflammation.[94,95] The reactive O_2 species released on reperfusion of compromised bowel further aggravate the inflammatory cascade.

Systemic inflammation impairs endothelial barrier function through changes in endothelial cell phenotype, increases in endothelial large pores, and degradation of the endothelial glycocalyx.[2] Hypervolemia caused by excessive fluid infusion leads to the release of cardiac natriuretic peptides, which may further degrade the endothelial glycocalyx.[9,96] In severe cases, inflammation-related endothelial dysfunction leads to a capillary leak syndrome, with loss of water, electrolytes, and proteins into the interstitial space causing edema in the lungs, bowel, and connective tissue. Reduced plasma oncotic pressure facilitates ongoing capillary fluid filtration into the extravascular space and consequent hypovolemia.

Catabolic Metabolism. The response to tissue injury requires an increase in energy substrate delivery, particularly to leukocytes involved in the acute inflammatory and immune reaction. This metabolic shift is mediated by catecholamine and cortisol release and involves muscle protein catabolism, with associated hepatic gluconeogenesis, acute phase protein production, and increased substrate delivery to damaged tissues. An increase in basal metabolic rate and adequate circulating volume are required to meet the needs of increased fuel mobilization, processing, and delivery.

Regulation of Salt and Water Balance. As described in the section on physiologic control of overall fluid balance, ADH release is induced during surgery, leading to postoperative retention of water. This may be a direct result of the acute stress response, and IL-6 has been proposed as a key mediator.[97] In addition, periods of hypovolemia and hypotension further stimulate ADH release and activate the RAA system with further water and salt retention and amplified ADH production. This may lead to a temporary period of oliguria despite a restored circulating volume and the risk for postoperative fluid overload and hyponatremia or Na^+ overload depending on ongoing fluid infusions. Na^+ retention postoperatively is more pronounced in the hypercatabolic state after major surgery, as excess nitrogen competes with Na^+ for renal excretion.

In addition to these processes, fluid may be lost from the circulating volume as a result of rapid reaccumulation into third spaces drained intraoperatively (ascites or pleural effusions), by sequestration into the bowel lumen or through vomiting, nasogastric drainage, or stoma losses. Intravascular fluid distribution is also a dynamic situation postoperatively because of changes in vascular tone caused by rewarming, evolving epidural sympathetic blockade, or systemic inflammation.

Assessment and Treatment of Perioperative Fluid and Electrolyte Imbalance

Intravascular Volume. As a key variable influencing cardiac output (preload), and therefore tissue O_2 delivery, intravascular volume is at the core of adequate tissue perfusion. Although the assessment of intravascular volume is an important part of perioperative fluid therapy, it may be challenging. Clinical history suggesting abnormal volume status should be sought (see earlier discussion) and accompanied by frequent clinical examinations, although many of the conventional markers of volume status are not reliable when taken in isolation. Obvious hypovolemia may manifest with tachycardia, reduced pulse pressure, hypotension, and increased capillary refill time, but the abnormalities of these individual physiologic variables may have numerous causes in the perioperative phase. Conversely, loss of up to 25% of blood volume may not be accompanied by significant hemodynamic alterations in healthy patients.[98] Urine output, frequently taken as a measure of adequate end-organ perfusion, may also be reduced postoperatively, even in the presence of normal circulating volume, as a result of ADH and RAA activation. More invasive measures of intravascular volume also have limitations. Central venous pressure (CVP) is used as a marker of central venous volume, yet is clearly also influenced by venous compliance; CVP may be normal or high in venoconstricted states even when the absolute vascular volume is reduced (see also Chapter 45). Furthermore, the relationship between right-heart and left-heart filling pressures is not reliable in the presence of cardiopulmonary pathologic processes. Trends in CVP values over time may be a more useful marker, because static CVP readings are poorly predictive

of subsequent responses to intravascular fluid challenges.[99] Stroke volume (SV) and cardiac output may be measured using a variety of techniques (see also Chapter 45), and targeting these variables has been widely investigated in perioperative fluid management, as described later. Alternatively, the adequacy of tissue perfusion may be assessed at a whole organism level using blood lactate concentrations (which may also be elevated during reperfusion of ischemic tissue or in advanced liver failure), or mixed venous O_2 saturation, which identifies a mismatch between global O_2 delivery (DO_2) and O_2 usage (VO_2). Techniques used to assess the perfusion of individual organs have the potential to detect clinically occult hypovolemia affecting those tissue beds or surgical sites most at risk for hypoperfusion, such as the gut. These include near-infrared spectroscopy,[100] microdialysis,[101] and GI CO_2 and pH measurement. The latter technique is gastric tonometry and is based on the association between inadequate gut perfusion and mucosal hypercarbia and acidosis.[102] It may detect hypovolemia of a magnitude not detectable by changes in systemic blood lactate, SV, or other cardiovascular parameters[98] that is nevertheless associated with increased postoperative morbidity.[103] Despite some encouraging findings in early research studies, none of these monitors is currently in routine use for guiding perioperative hemodynamic therapy.

Both excessive and inadequate intravascular volume can have a range of adverse physiologic effects, and achieving the fine balance between the two is a key goal of perioperative fluid administration. Modest hypovolemia, through its effects on gut perfusion and stimulation of protective neurohumoral reflexes, may exacerbate the inflammatory and antidiuretic aspects of the surgical stress response. More severe hypovolemia reduces preload, cardiac output, and therefore DO_2. The result may be inadequate DO_2 to meet metabolic demands, with an increase in O_2 extraction ratio (reflected in reduced mixed venous O_2 saturation), progressing to inefficient anaerobic ATP production, if there is inadequate O_2 delivery to sustain mitochondrial oxidative phosphorylation. This situation may be aggravated by insufficient compensatory increases in cardiac output, impaired microvascular blood flow, or failure of cellular O_2 usage. Lactate is a byproduct of anaerobic metabolism and accumulates with a consequent metabolic acidosis. At its most extreme, ATP production to support normal cell functions in those tissues with the worst perfusion may be inadequate, leading to cell death and organ dysfunction. Inadequate global O_2 delivery has been associated with a range of postoperative morbidities and increased mortality and has been the target of numerous clinical trials. At an individual organ level, particular areas that have been manipulated surgically, such as tissue flaps and bowel anastomoses, may be susceptible to poor healing and failure when local perfusion is insufficient.

Hypervolemia also has adverse effects and is often an iatrogenic problem in the perioperative setting. Crystalloids or colloids administered when capillary hydrostatic pressures are normal or increased lead to increased capillary filtration of fluid into the interstitial space. If this exceeds the capacity of the lymphatics to return the excess fluid to the circulation, edema will develop in compliant tissues such as the lungs, muscle, and bowel. The effect is more pronounced if inflammation or deterioration of the glycocalyx reduces the endothelial barrier function opposing the passage of large molecules into the interstitium. The correction of salt and water overload is a slow process because of inefficient renal handling of excess Na^+ loads, and the effects of postoperative ADH secretion. Clinically significant edema contributes to postoperative GI dysfunction, although this is not well defined by small clinical trials.[104,105] Further potential effects of excessive intravascular fluid include reduced tissue oxygenation with impaired healing, pulmonary congestion predisposing to pulmonary infection, and increased myocardial work resulting from ventricular filling beyond the optimum portion of the Starling curve.[106] Side effects may occur that are attributable to the volume of a particular fluid given, such as hypercoagulability or hypocoagulability, hyperchloremic acidosis, or renal dysfunction. A positive fluid balance and weight gain in the early perioperative period increases postoperative morbidity.[107,108]

Electrolyte Imbalance

Sodium Disorders

Hyponatremia. Hyponatremia may be present preoperatively, develop as a consequence of perioperative events, or both. It is classified as mild (130 to 134 mEq/L), moderate (120 to 130 mEq/L), or severe (<120 mEq/L). Moderate-to-severe hyponatremia, particularly of acute onset, is associated with significant perioperative morbidity.

Causes. Assessment of serum osmolality, TBW status, and urinary Na^+ concentration is vital for the accurate diagnosis of the underlying cause of hyponatremia.[109,110] A diagnostic algorithm with common causes is shown in Figure 59-3. Na^+ is normally the key determinant of serum osmolality, and hyponatremia is usually observed in conjunction with reduced osmolality. In some situations, however, osmolality is normal or raised by the presence of solutes that induce cellular dehydration and translocation of water from cells to the ECF. These include glucose in the absence of adequate insulin, mannitol, maltose, and glycine. Alternatively, hyponatremia may be artifactual (pseudohyponatremia), caused by the presence of high lipid concentrations. In hypoosmolar hyponatremia, imbalanced gains or losses of TBW and Na^+ occur such that serum Na^+ concentration is reduced.

Preoperative Hyponatremia. Hyponatremia may be an incidental finding during preoperative assessment, with the underlying pathologic mechanisms identified in Figure 59-3. Even mild preoperative hyponatremia is associated with increased 30-day mortality, major cardiac events, wound infection, and pneumonia.[111] Whether hyponatremia is a direct causal mechanism in postoperative adverse events or a marker of underlying overt or subclinical pathologic processes, such as cardiac failure, is not clear, although excess risk is seen even in American Society of Anesthesiologists (ASA) class 1 and 2 patients undergoing elective surgery. However, correcting preoperative hyponatremia does not clearly improve outcomes. Pragmatically, the finding of preoperative hyponatremia should prompt a search for, and optimization of, potential

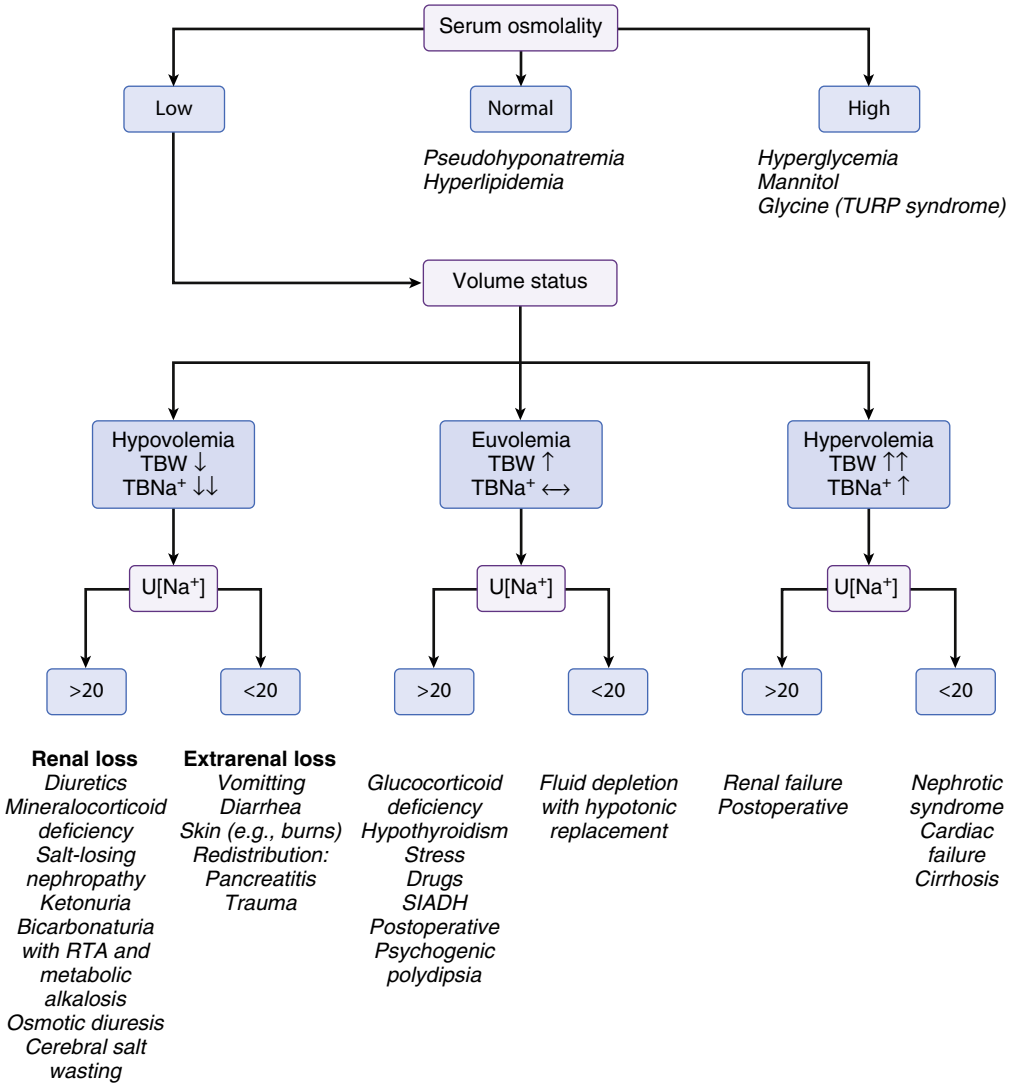

Figure 59-3. Causes and diagnostic algorithm for hyponatremia. The diagnostic criteria for the syndrome of inappropriate secretion of antidiuretic hormone (*SIADH*) include exclusion of adrenal, thyroid, and renal disease or diuretic usage, serum hypoosmolality (<270 mOsmol/kg), clinical euvolemia, increased urinary [Na^+] despite normal water and salt intake and inappropriate urinary concentration (>100 mOsmol/kg). A characteristic response to water restriction occurs, with a 2- to 3-kg fall in weight accompanied by a reduction in salt wasting and hyponatremia over 2 to 3 days. *RTA,* renal tubular acidosis; *TBW,* total body water; *TURP,* tranurethral resection of the prostate; *U[Na^+],* urinary sodium concentration in mEq/L. *(Modified from Kumar S, Berl T: Sodium,* Lancet *352:220, 1998; and Tisdall M, Crocker M, Watkiss J, et al: Disturbances of sodium in critically ill adult neurologic patients: a clinical review,* J Neurosurg Anesthesiol *18:57, 2006.)*

underlying diseases. In moderate-to-severe hyponatremia, nonurgent surgery should probably be postponed to allow the carefully monitored, gradual correction of hyponatremia (see later discussion).

Postoperative Hyponatremia. As previously discussed, the surgical stress response, aggravated by periods of hypotension and pain-related or physiologic stress–related sympathetic activity, can lead to a state of Na^+ and water retention similar to SIADH. Avid water retention puts postoperative patients at risk for hyponatremia, particularly when administration of free water from IV dextrose-containing or other hypotonic solutions is ongoing. The incidence of postoperative hyponatremia is 1% to 5%, with children and premenopausal females at particularly high risk for neurologic symptoms. In these groups, symptoms and neurologic sequelae may occur at Na^+ levels as high as 128 mEq/L, whereas elderly women typically do not become symptomatic above 120 mEq/L unless the decrease is particularly rapid. The potential impact of postoperative hyponatremia is considerable; 8% of hyponatremic patients may develop encephalopathy, of whom 52% suffer permanent neurologic sequelae or death.[112] Failure to recognize hyponatremia as a cause of postoperative symptoms (see later discussion) or inadequate treatment based on fears of causing osmotic demyelination may contribute to these poor outcomes.[113] Prevention of postoperative hyponatremia should be a key goal of postoperative fluid therapy, based on limiting free water administration to pure maintenance requirements (1 to 1.2 mL/kg/hr), replacing losses of Na^+-containing fluids (e.g., GI) with an appropriate isotonic salt solution, stopping IV therapy as soon as the oral route can be used, and daily (or more frequent in high-risk groups) checking of serum electrolytes. The treatment of hyponatremia is outlined later.

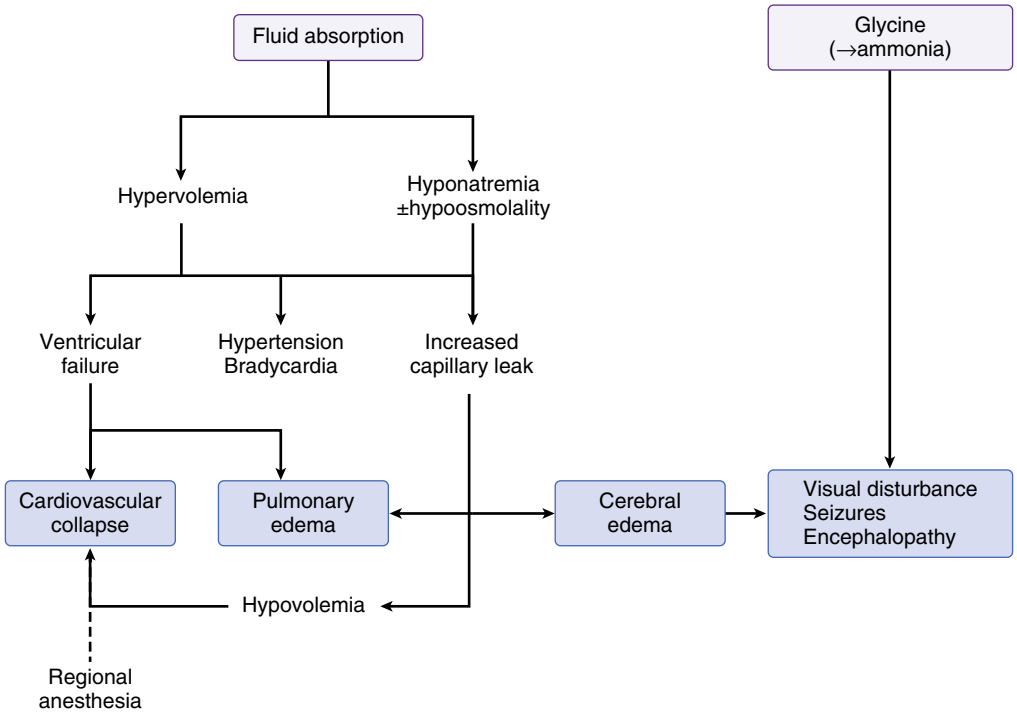

Figure 59-4. The transurethral resection of the prostate (TURP) syndrome. Early hypervolemia-related hypertension may be followed by profound hypotension as a result of increased capillary filtration with hypovolemia, depressed cardiac function, and sympathetic blockade. Glycine itself may lead to seizures through allosteric activation of the *N*-methyl-D-aspartate receptor and is thought to cause the visual disturbance of the TURP syndrome. The hepatic deamination of glycine yields ammonia, which can further contribute to encephalopathy. *(Modified from Gravenstein D: Transurethral resection of the prostate [TURP] syndrome: a review of the pathophysiology and management,* Anesth Analg *84:438, 1997.)*

Transurethral Resection of the Prostate Syndrome. The transurethral resection of the prostate (TURP) syndrome describes symptomatic hyponatremia, excessive intravascular volume, and edema resulting from IV absorption of hypotonic nonconductive (electrolyte-free) irrigation fluid during TURP or, rarely, transurethral resection of the bladder[114] or during ureteroscopic or hysteroscopic procedures (see also Chapters 72 and 87). The syndrome may complicate 10% to 15% of TURP procedures, with onset between 15 minutes and 24 hours after the onset of resection.[115] Risk factors include increased intravesical pressure, prolonged resection, hypotonic irrigants, and open prostatic sinuses. The clinical features (Fig. 59-4) are related to intravascular volume changes, hyponatremia, and absorption of irrigant solutes; the use of distilled water as an irrigant has largely been replaced by solutions of glycine, sorbitol, or mannitol because of the incidence of massive hemolysis. Hyponatremia resulting from free water absorption may lead to hypoosmolality, although the presence of glycine or other osmotically active solutes may maintain osmolality in the normal range. The following measures may help prevent the TURP syndrome:

- The use of conducting (isotonic saline) irrigant with bipolar diathermy.[116]
- Monitoring fluid absorption by comparing the amount instilled with the amount removed. Surgery should be halted if 750 mL (for females) or 1000 mL (for males) has been absorbed and the patient's Na^+ levels and neurologic status (if awake) assessed. Surgery should be terminated if 1000 to 1500 mL (for females) or more than 2000 mL (for males) has been absorbed. If saline irrigant is used, surgery should be terminated after 2500 mL has been absorbed; although the risk for hypoosmolar hyponatremia is removed, the risk for excessive intravascular volume remains.[117,118]
- Limiting the duration of irrigation; irrigation should continue only for longer than 1 hour after careful assessment of the patient for possible TURP syndrome.
- Limiting intravesical pressure to less than 15 to 25 mm Hg or 70 mm Hg for endometrial procedures.
- Monitoring the patient's neurologic status by using regional anesthetic techniques. Symptoms in the awake patient include nausea and vomiting, visual disturbance, reduced level of consciousness, agitation, confusion, and seizures.

Treatment of the TURP syndrome should take into account the patient's intravascular volume status, Na^+ level, and osmolality, but typically involves cessation of irrigation solutions, and water restriction, and, if excessive intravascular volume is present, a loop diuretic should be given to promote free water excretion. In severe hypoosmolar hyponatremia with neurologic symptoms, hypertonic saline may be used. Conversely, when osmolality is normal or marginally decreased, hemodialysis is preferred.[119] Mg^{2+} can be given for seizures, because its negative control of NMDA receptors counteracts dilutional hypomagnesemia and the excitatory effects of glycine.[115]

Presentation and Treatment of Hyponatremia. The symptoms of hyponatremia are related to cerebral edema

and increased intracranial pressure, and are highly dependent on how rapidly hyponatremia occurred. In acute onset, symptoms typically occur when Na^+ concentrations are as low as 120 to 125 mEq/L (higher in children and premenopausal females) with headache, confusion, agitation, vomiting, and lethargy. At Na^+ concentrations less than 110 mEq/L, symptoms progress to seizures and coma. In the chronic setting, clinical features may be absent even at concentrations less than 120 mEq/L. In all cases of hyponatremia, potential underlying causes such as steroid deficiency, renal disease, and cardiac disease should be identified and treated. Treatment should be tailored to the patient's intravascular volume status, the chronicity of onset, and the presence of symptoms. Chronic hyponatremia (>48 hours or of unknown duration) should be treated cautiously because of cerebral compensation for the hypoosmolar state; sudden increases in osmolality lead to cerebral water loss and osmotic demyelination (e.g., central pontine myelinolysis).

- Hypovolemic hyponatremia: Symptoms are unusual because osmotic shifts in the brain are limited by the loss of both Na^+ and water. ECF volume should be restored with isotonic saline, which will also reduce ongoing ADH release.
- Hypervolemic hyponatremia: In chronic cases this should focus on restriction of water intake and optimization of the underlying disease state, such as improving cardiac output with angiotensin-converting enzyme (ACE) inhibitors to reduce the neurohumoral influence on water retention in cardiac failure, and possibly using loop diuretics (rather than thiazides, which impair urinary dilution) to excrete free water once a negative Na^+ balance has been achieved.
- Chronic, asymptomatic hyponatremia: No immediate correction of hyponatremia is required, and the underlying cause should be treated. Fluid restriction, ADH antagonists (lithium, demeclocycline), and loop diuretics may be used.
- Symptomatic hyponatremia (typically euvolemic or hypervolemic): In patients with moderate symptoms (confusion, lethargy, nausea, and vomiting), hypertonic 3% saline may be used at an initial rate of 1 mL/kg/hr with the goal of increasing $[Na^+]$ by 1 mEq/L/hr for 3 to 4 hours, after which electrolytes should be rechecked. The infusion rate should be modified to ensure that $[Na^+]$ is increased by no more than 10 mEq/L in the first 24 hours of treatment. Severely symptomatic hyponatremia (coma, seizures, often with $[Na^+]$ <120 mEq/L) is typically of acute onset and the risks of undertreating are more than those of osmotic demyelination. A bolus of 100 mL of 3% saline should initially be given with the aim of acutely increasing $[Na^+]$ by 2 to 3 mEq/L. If no improvement in neurologic status occurs, this approach may be repeated once or twice at 10-minute intervals. After this, treatment should continue as for moderately symptomatic patients, with a similar goal of increasing $[Na^+]$ by no more than 10 mEq/L in the first 24 hours.[120] Electrolytes and osmolality should be rechecked every few hours, fluid input and output should be carefully monitored, and patients reassessed regularly.

Hypernatremia. Hypernatremia ([Na] > 145 mEq/L) is less common than hyponatremia, but may affect up to 10% of critically ill patients. If severe ([Na] > 160 mEq/L), a 75% mortality may occur depending on the severity of the underlying disease process.[109,110] (Fig. 59-5). The major mechanisms are excessive water loss with inadequate compensatory intake, lack of ADH, or administration of exogenous sodium. Diabetes insipidus (DI) is caused by a lack of ADH action as a result of impaired production or release (central DI) or reduced renal sensitivity to ADH (nephrogenic DI) with consequent failure to concentrate urine and excretion of large quantities of inappropriately dilute urine. If the patient is unable to accept compensatory fluid orally (e.g., because of coma or in the elderly with impaired thirst reflexes), they may rapidly become hypovolemic. Central DI is seen after pituitary surgery, subarachnoid hemorrhage, traumatic brain injury (particularly skull base fractures), and brainstem death. Nephrogenic DI may be due to renal disease, electrolyte disorders, or drugs (lithium, foscarnet, amphotericin B, demeclocycline).

Clinical features of hypernatremia include altered mental status, lethargy, irritability, seizures, hyperreflexia, and spasticity. Diagnosis is based on assessment of intravascular volume status and urinary osmolality and Na^+ concentration. In patients with persistent urine output of more than 100 mL/hr and hypernatremia, DI should be considered. Diagnostic criteria include an inappropriately dilute urine (<300 mOsm/kg) in combination with hypernatremia and high serum osmolality (>305 mOsm/kg). Urine specific gravity (SG) may provide a rapid guide to urine osmolality where urgent treatment is being considered; urine SG less than 1.005 in the context of hypernatremia and a potential underlying cause is consistent with DI.

Treatment is tailored to the intravascular volume status, but as with hyponatremia, correction of the Na^+ concentration should be no more rapid than 10 mEq/L/day unless the onset has been very acute.

- Hypovolemic hypernatremia: Correction of the intravascular volume deficit with isotonic saline and correction of the underlying cause (e.g., insulin to reduce hyperglycemia), then correction of the water deficit with 0.45% saline, 5% dextrose or enteral water to cover the deficit and ongoing losses.
- Euvolemic hypernatremia: Use of 0.45% saline, 5% dextrose, or enteral water to replace the deficit and ongoing losses. In central DI, in which urine output is greater than 250 mL/hr and risk exists for hypovolemia, titrated intravenous doses of desmopressin acetate 0.4 to 1 μg (1-deamino-8-D-arginine vasopressin [DDAVP], an ADH analogue) should be given to reduce the urine output. Higher acute doses may have a prolonged effect with the risk for water intoxication.[109,110]
- Hypervolemic hypernatremia: Stop administration of exogenous Na^+, give furosemide with 5% dextrose or enteral water. Dialysis may be indicated in the presence of renal failure.

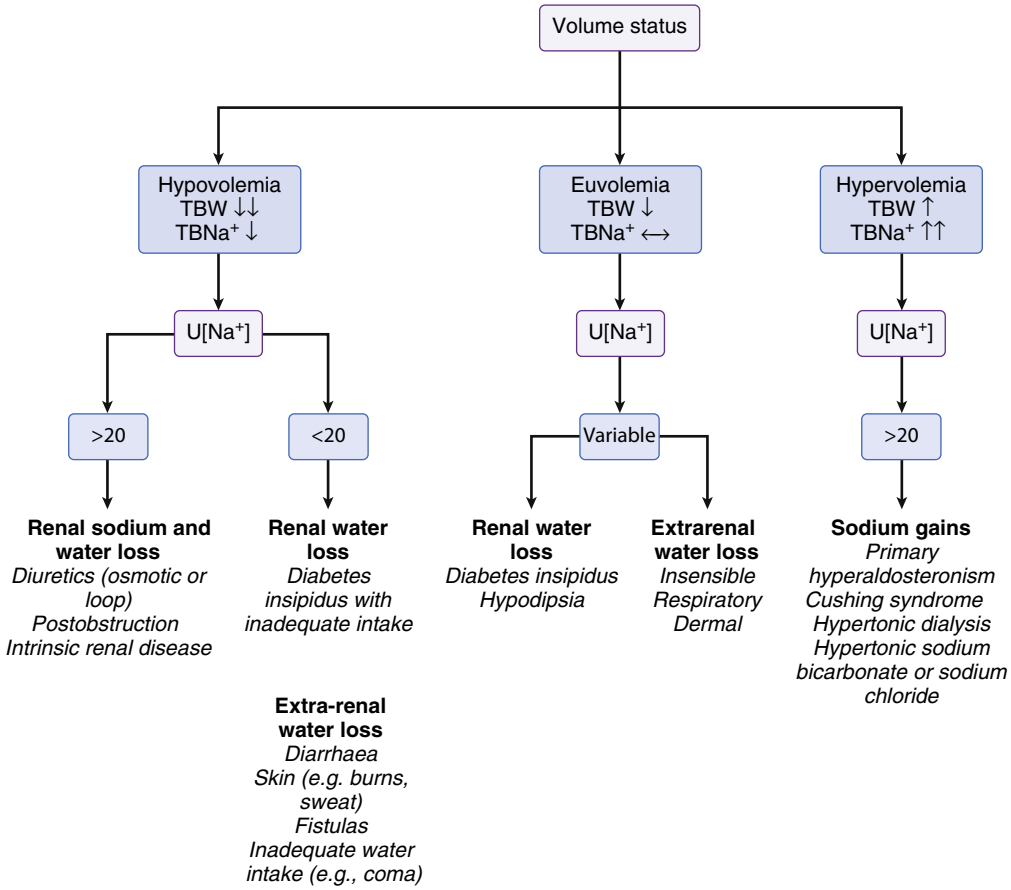

Figure 59-5. Causes and diagnostic algorithm for hypernatremia. *TBW,* Total body water; *U[Na⁺],* urinary sodium concentration in mEq.L^{-1}. *(Modified from Kumar S, Berl T: Sodium,* Lancet *352:220, 1998.)*

Potassium Disorders. Because of the key role of K^+ on excitable tissue resting membrane potential, dyskalemia can lead to life-threatening cardiac arrhythmias in the perioperative period. The normally predominant intracellular distribution of K^+ means that abnormal plasma K^+ levels may reflect abnormal ECF to ICF distribution, derangements of total body K^+ content, or both. Sampling artifacts may be introduced into laboratory tests of K^+; anticoagulated samples typically give results 0.4 to 0.5 mEq/L less than those from clotted samples because of erythrocyte K^+ release during clotting. Hemolysis also artificially increases K^+ levels and may be introduced by poor sampling technique or delayed processing of samples.

Hypokalemia. Hypokalemia (<3.5 mEq/L) may be caused by the conditions outlined in Table 59-7. Moderate-to-severe hypokalemia (2 to 2.5 mEq/L) leads to muscle weakness, electrocardiogram (ECG) abnormalities (ST segment depression, T wave depression, U wave elevation), and arrhythmias (atrial fibrillation and ventricular extrasystoles). All logic dictates that hypokalemia (e.g., as low as 2.6 mEq/L) should be associated with an increased rate of perioperative morbidity or mortality; however, no data support this conclusion.[18] Hypokalemia should be pragmatically corrected in the perioperative phase to optimize neuromuscular function and reduce cardiac irritability. Such treatment is of prime importance when acute arrhythmias exist, and K^+ should be maintained at greater than 4 to 4.5 mEq/L. The speed of the infusion should be slow enough to allow equilibration throughout the entire ECF, typically no faster than 0.5 mEq/kg/hr. K^+ solutions of concentration more than 40 mEq/L may be an irritant to veins and should be administered via a central venous catheter.

Hyperkalemia. Hyperkalemia (>5.5 mEq/L) may result from excess intake, failure of excretion, or shift from the intracellular to extracellular compartment (Table 59-8). Failure of renal secretion is mediated through impaired principal cell function in the cortical collecting duct, which depends on aldosterone-stimulated Na^+/K^+ exchange via basal Na^+/K^+ATPases and luminal Na^+ and K^+ channels. The features of hyperkalemia include muscle weakness, paralysis, and altered cardiac conduction (increased automaticity and enhanced repolarization) with consequent ECG changes as K^+ levels increase[121]:

- 5.5 to 6.5 mEq/L: Tall, peaked T waves
- 6.5 to 7.5 mEq/L: Prolonged PR interval
- Greater than 7.5 mEq/L: Widened QRS
- Greater than 9.0 mEq/L: Sine wave pattern, bradycardia, ventricular tachycardia, increased risk for cardiac arrest

Chronically induced hyperkalemia, (e.g., chronic renal failure), is better tolerated than acute increases in blood K^+ concentrations. Ratios between intracellular and extracellular K^+ concentrations may be very abnormal with acute hyperkalemia. With chronic hyperkalemia, these ratios

TABLE 59-7 CAUSES AND MECHANISMS OF HYPOKALEMIA

Mechanism	Cause	Notes
Inadequate intake	Anorexia nervosa	
	Alcoholism	
	Malnutrition	
Gastrointestinal loss	Vomiting	
	Diarrhea	Especially secretory diarrhea
	Fistulas	
Excess renal loss	Mineralocorticoid excess	Primary and secondary hyperaldosteronism
	Glucocorticoid excess	High concentration of cortisol overwhelms mineralocorticoid receptor despite lower affinity
	Diuretics	Loop or thiazide diuretics deliver increased Na^+ load to principal cells
	Osmotic substances	Glucose, urea, and mannitol also lead to increased collecting duct Na^+ delivery
	Hypomagnesemia	Impairs thick ascending limb Na^+ reabsorption; therefore, increased distal N^+ delivery and K^+ loss via principal cells
	Renal tubular acidosis	Failure of principal cell H^+/K^+ exchange
	Bartter and Gitelman syndromes	Tubule ion transporter mutations mimicking loop or thiazide diuretic effect, respectively
Intracellular K^+ shift	β_2-Agonists	Also seen in sympathetic activity
	Insulin therapy	
	Acute alkalosis	
	Lithium overdose	
	Hypokalemic periodic paralysis	
	Vitamin B_{12} therapy	

Modified from Kaye AD, Riopelle JM: Intravascular fluid and electrolyte physiology. In Miller RD, Eriksson LI, Fleisher LA, et al, editors: Miller's anesthesia, *ed 7. New York, Churchill Livingstone, 2009, p. 1705.*

TABLE 59-8 CAUSES AND MECHANISMS OF HYPERKALEMIA

Mechanism	Cause	Notes
Increased intake	Excessive K^+ treatment	
	Blood transfusion	Typically in patients who also have impaired excretion (i.e., severe chronic kidney disease)
	Antibiotics containing K^+ salts	
Failure of renal secretion	Mineralocorticoid deficiency	Hypoaldosteronism
		Hyporeninemic, hypoaldosteronemic state (diabetic nephropathy, tubulointerstitial disease)
	Drugs causing mineralocorticoid blockade	Spironolactone (blocks mineralocorticoid receptor)
		ACE-I and ARBs (reduce aldosterone production)
		Heparin (selective hypoaldosteronism)
	Collecting duct Na^+ channel blockade	Amiloride
		Trimethoprim
		Triamterene
		Pentamidine
	Tubulointerstitial nephritis	Cause damage or destruction of the cortical collecting duct
	Renal obstruction	
Extracellular K^+ shift	Suxamethonium	
	Reperfusion of ischemic tissues	Cellular ischemia reduces ATP production with failure of Na^+/K^+ATPase activity and K^+ "leak" to the ECF. Cell lysis further releases K^+. On reperfusion, excess ECF K^+ is rapidly delivered to the systemic circulation. During solid organ transplantation this may be combined with residual perfusing solution used for ex vivo organ preservation, which contains a high K^+ content
	Insulin deficiency	
	Acute acidosis	
	Malignant hyperpyrexia	

ACE-I, Angiotensin-converting enzyme inhibitor; *ARBs,* angiotensin II receptor blockers; *ATP,* adenosine triphosphate; *ECF,* extracellular fluid.

have probably been restored to normal. Acute hyperkalemia sufficient to induce electrocardiographic changes is a medical emergency that requires rapid treatment. The acute treatment of hyperkalemia involves shifting K^+ from the ECF to ICF, antagonizing its cardiac toxicity with Ca^{2+}, and increasing renal excretion. Elimination by GI resin exchange also may be used in more chronic cases (Table 59-9). Hyperkalemia greater than 6.5 mEq/L, in the context of anuric renal failure, is an indication for acute renal replacement therapy.

TABLE 59-9 TREATMENTS FOR HYPERKALEMIA

Mechanism	Treatment	Indication	Notes
Antagonize cardiac toxicity	$CaCl_2$ 10% (10 mL) or Calcium gluconate	K^+ >6.5 mEq/L, particularly with ECG changes	Onset of action within a few min, duration 30-60 min
Intracellular potassium shift	Insulin 10-20 units (administered in 50 mL 50% glucose to avoid hypoglycemia)	K^+ >6.0 mEq/L	Onset within 10-20 min, duration 4-6 hr
	β_2-Agonists (e.g., nebulized salbutamol 2.5 mg)		
	Hyperventilation		Induce K^+ uptake by increasing extracellular pH
	$NaHCO_3$ 1 mEq/kg	K^+ >6.5 mEq/L	
Increase renal excretion	Furosemide 20-40 mg IV	Moderate-to-severe hyperkalemia	Increases Na^+ delivery to cortical collecting duct and exchange with K^+
	Volume expansion with isotonic saline		
	Fludrocortisone		Mineralocorticoid effect
Other routes of K^+ elimination	Gastrointestinal resin exchange: Ca^{2+} resonium 15-30 g or sodium polystyrene sulfonate (Kayexalate) 15-30 g PO or per rectum	Any sustained hyperkalemia	
	Hemodialysis	Moderate-to-severe hyperkalemia with oliguria	

Hyperkalemia can be defined as mild (5.5-5.9 mEq/L), moderate (6.0-6.4 mEq.L) or severe (>6.5 mEq/L), with or without ECG changes.[240]
ECG, Electrocardiogram.

TABLE 59-10 CAUSES AND MECHANISMS OF HYPOCALCEMIA

Mechanism	Cause	Notes
Reduced regulatory hormones	Hypoparathyroidism	Postparathyroid or thyroid surgery. May be acute effect of reduced PTH or more long-term hypocalcemia during remineralization of bone after surgery for hyperparathyroidism ("hungry bone syndrome")
		Hypomagnesemia (suppresses PTH secretion)
	Pseudohypoparathyroidism	Reduced receptor response to PTH
	Reduced vitamin D activity	Hyperphosphatemia (inhibits hydroxylation—e.g., in chronic kidney disease)
		Dietary/sunlight deficiency
		Anticonvulsants (increased turnover into inactive forms)
Ca^{2+} chelation	Massive transfusion	Caused by citrate in stored red blood cell solutions
	Cell lysis	Phosphate release as a result of tumor lysis syndrome, trauma, or rhabdomyolysis
	Pancreatitis	Intraperitoneal free fatty acids formed by the action of released pancreatic lipase, which chelate Ca^{2+} salts; further contributions from coexistent hypomagnesemia and hypoalbuminemia
Increased bone deposition	Prostate, breast cancer	Increased osteoclastic activity
Reduced ionized fraction	Alkalosis	For example, acute intraoperative hyperventilation
Reduced bound Ca^{2+}	Hypoalbuminemia	Critical illness (where ionized Ca^{2+} may be normal, and Ca^{2+} replacement not required), poor nutrition
Unknown mechanism	Endotoxemic shock	

PTH, Parathyroid hormone.

Calcium Disorders

Hypocalcemia. The causes of hypocalcemia are related to reduced PTH and/or vitamin D activity, increased bone deposition, Ca^{2+} chelation, or changes in binding protein concentration or ionized fraction (Table 59-10). The following are characteristic symptoms, some of which will be absent in the anesthetized patient:

- Neuromuscular irritability
  - Circumoral and peripheral paresthesia
  - Chvostek sign (facial twitching induced by tapping on the facial nerve)
  - Trousseau sign (forearm muscular spasm induced by inflating a pressure cuff)
  - Muscle cramps
  - Laryngospasm
  - Tetany
  - Seizures
- Cardiac
  - Impaired inotropy
  - Prolonged QT
  - Ventricular fibrillation
  - Heart block

After a rapid large-volume transfusion of citrate-stored blood (>1.5 mL/kg/minute) or fresh frozen plasma, ionized hypocalcemia may occur as a result of citrate chelation. This may be particularly severe and prolonged in patients

TABLE 59-11 **CAUSES AND MECHANISMS OF HYPERCALCEMIA**

Mechanism	Cause	Notes
Increased PTH	Primary hyperparathyroidism	The most common cause, typically manifests with mild hypercalcemia resulting from an isolated parathyroid adenoma
	Secondary and tertiary hyperparathyroidism	The hypocalcemia of kidney disease–related hyperparathyroidism may progress to hypercalcemia with prolonged disease
Malignancy	PTH-related peptide secretion	PTH-rP may be secreted by most solid tumors; mimics PTH effects
	Osteolytic metastases	Breast, lung, lymphoma, thyroid, kidney, prostate, and multiple myeloma
	Calcitriol production	Typical in lymphoma
Excess vitamin D	Ectopic production	Granulomatous disease (e.g., sarcoid), malignancy
	Excess intake	
Decreased renal excretion	Thiazide diuretics	
Increased bone turnover	Hyperthyroidism	
	Immobilization	
Increased Ca^{2+} intake	Milk-alkali syndrome	

PTH, Parathyroid hormone; *PTH-rP,* parathyroid hormone–related peptide.

with hepatic impairment, in whom citrate metabolism is reduced.[122] Citrate intoxication has been described for many years, but is rarely a clinical problem (see also Chapter 61). Although Ca^{2+} plays an important role in coagulation, coagulopathy specifically attributable to hypocalcemia only occurs at ionized Ca^{2+} concentrations less than 1.2 mEq/L; rather, supplemental Ca^{2+} should be given in this situation to support cardiac inotropy and neuromuscular function, aiming for ionized Ca^{2+} more than 1.8 mEq/L.[123] Ca^{2+} also may be given during other situations in which myocardial contractility is impaired, such as during cardiac surgery, to optimize ventricular function (see also Chapter 67). After parathyroidectomy, Ca^{2+} levels should be checked frequently until they have stabilized, because Ca^{2+} and vitamin D supplementation may be required in both the short and long term. In critical illness, total Ca^{2+} levels may be reduced because of hypoalbuminemia; however, Ca^{2+} supplementation should be required only if the ionized levels are low. Ca^{2+} may be given intravenously as 10% (weight/volume) calcium gluconate or 10% (weight/volume) $CaCl_2$. Although in these formulations calcium gluconate contains less elemental Ca^{2+} (0.45 mEq/mL versus 1.36 mEq/mL for $CaCl_2$), they are equally efficacious as long as the total Ca content given is equal. Calcium gluconate may be preferable for peripheral administration because the tissue injury from inadvertent extravasation is less severe than with $CaCl_2$. Mg^{2+} levels are often low during hypocalcemia and should also be corrected, particularly when hypocalcemia has been caused by infusion of isotonic saline or colloids in large volumes.

Hypercalcemia. Hypercalcemia occurs when ECF Ca^{2+} influx from the GI tract, bone, or both outweighs efflux to bone or via the kidneys (Table 59-11). The symptoms are related to the severity and speed of onset of the abnormality, so mild chronic hypercalcemia is usually asymptomatic. More severe hypercalcemia manifests with neurologic symptoms (drowsiness, weakness, depression, lethargy, coma), GI symptoms (constipation, nausea, vomiting, anorexia, peptic ulcers), renal manifestations (nephrogenic diabetes insipidus—which may further aggravate hypercalcemia through dehydration—and renal stones), electrocardiographic abnormalities (shortened QT interval, prolonged PR interval), and potentiation of digoxin toxicity. Treatment should address the underlying cause, including surgical parathyroidectomy in cases of severe hyperparathyroidism, or cessation of thiazide diuretics. In addition, the treatment of symptomatic hypercalcemia should aim to increase renal Ca^{2+} excretion by volume expansion with isotonic saline and possibly loop diuretics. This combination may reduce Ca^{2+} by 0.5 to 1.5 mEq/L in 1 to 2 days.[26] Bisphosphonates enhance osteoclastic bone deposition and are given if the hypercalcemia is severe or in milder cases in which response to hydration has been inadequate. A single IV dose of pamidronate 60 mg (moderate hypercalcemia, up to 13.5 mg/dL) or 90 mg (severe hypercalcemia) should return Ca^{2+} levels to normal within 7 days, and the effect may persist for up to 1 month. Zoledronic acid is a newer bisphosphonate that may be even more effective and is given intravenously at a dose of 4 mg.[124] Bisphosphonates should only be given when any clinical dehydration has been treated to avoid calcium bisphosphonate precipitation and nephrotoxicity. Glucocorticoids may also be given for hypercalcemia associated with lymphoproliferative disease or ectopic vitamin D production.[125] Calcitonin increases renal Ca^{2+} excretion and reduces bone resorption for up to 48 hours when given intramuscularly or intravenously and may contribute to a mild reduction in Ca^{2+} levels during the rehydration phase.

Magnesium disorders

Hypomagnesemia. Serum Mg^{2+} concentration may be a poor indicator of total body content because of its large distribution in the intracellular compartment and slow equilibration with bone stores (see also Chapter 77). Intraerythrocyte or intralymphocyte Mg^{2+} levels may give a better approximation of total body and tissue stores, but are more complex to process.[126,127] Chronic Mg^{2+} deficiency and acute hypomagnesemia increase cardiovascular morbidity[29] and are particularly prevalent in diverse hospital populations (12% of general inpatients, 19% of preoperative cardiac surgery patients, 65% of critical care patients) (see also Chapters 67 and 101). The causes are related to reduced Mg^{2+} intake from the GI tract or increased renal losses (Table 59-12), although relative depletion may occur in times of increased cell turnover and protein production (pregnancy, athletes, cold acclimatization). The clinical presentation of hypomagnesemia may be nonspecific; rather symptoms

TABLE 59-12 CAUSES AND MECHANISMS OF HYPOMAGNESEMIA

Mechanism	Cause
Inadequate gastrointestinal uptake	Malnutrition
	Prolonged vomiting or diarrhea
	Intestinal fistula
	Pancreatitis
	Prolonged nasogastric suction
	Malabsorption syndromes
	Small bowel syndrome
	Primary intestinal hypomagnesemia
Increased renal losses	Chronic parenteral fluid therapy
	Hypercalcemia and hypercalciuria
	Osmotic diuresis
	Drugs: Alcohol, loop and thiazide diuretics, aminoglycosides, cisplatin, amphotericin, cyclosporin, foscarnet
	Phosphate depletion
	Hungry bone syndrome
	Postobstructive nephropathy
	Renal transplantation
	Polyuric phase of acute kidney injury
	Primary hyperparathyroidism
	Bartter and Gitelman syndromes

often relate to common coexisting hypocalcemia or hypokalaemia[32]:

- Neuromuscular: Trousseau and Chvostek signs, vertigo, seizures, weakness
- Metabolic: Carbohydrate intolerance, hyperinsulinemia, atherosclerosis
- Cardiovascular: Wide QRS, prolonged PR, T-wave inversion, ventricular arrhythmias
- Musculoskeletal: Osteoporosis and osteomalacia

Treatment should be tailored to the severity of symptoms and degree of hypomagnesemia. Asymptomatic patients with moderate-to-severe hypomagnesemia should receive oral supplementation as acute IV infusions will stimulate the renal Ca^{2+}/Mg^{2+}-sensing receptor, reducing Mg^{2+} reabsorption and leading to the renal excretion of much of the acute dose. In the presence of symptoms or Mg^{2+} concentration of less than 0.8 mEq/L, IV Mg^{2+} should be administered (50 mEq/day, plus an initial dose of 8 to 16 mEq over 5 to 10 minutes in the presence of seizures or acute arrhythmias).[32] Coexistent hypocalcemia, hypokalemia, or both should also be treated, although are unlikely to improve without replenishment of Mg^{2+}. Mg^{2+} has many other therapeutic indications, even in the absence of hypomagnesemia, as outlined earlier. A few of these patients are likely to have total body Mg^{2+} depletion that has not been detected by serum Mg^{2+} levels.

Hypermagnesemia. Limited GI absorption and efficient renal excretion mean that hypermagnesemia is typically iatrogenic. Symptoms reflect the effect of Mg^{2+} on neurologic and cardiac function and relate to the serum concentration[18]:

- 5 to 7 mg/dL: Therapeutic levels in the treatment of preeclampsia (see also Chapter 77)
- 5 to 10 mg/dL: Impaired cardiac conduction (widened QRS, long PR), nausea
- 20 to 34 mg/dL: Sedation, reduced neuromuscular transmission with hypoventilation, reduced tendon reflexes, and muscle weakness (see also Chapter 18)
- 24 to 48 mg/dL: Diffuse vasodilation with hypotension, bradycardia
- 48 to 72 mg/dL: Areflexia, coma, respiratory paralysis

Mg^{2+} administration should therefore be performed with several important cautions. First, serum Mg^{2+} levels should be monitored closely during therapeutic administration. Second, because excretion is renal, doses should be decreased for patients with kidney disease. Third, it should be used with extreme caution in patients with a background impairment of neuromuscular transmission (myasthenia gravis, Lambert-Eaton myasthenic syndrome). Fourth, coadministration of neuromuscular blockers during anesthesia should be performed in reduced doses titrated to neuromuscular monitoring, because Mg^{2+} potentiates the effects of both depolarizing and nondepolarizing neuromuscular blockers (see also Chapters 34 and 35). Treatment of acute hypermagnesemia includes promoting renal excretion by administration of fluids intravenously and diuresis. IV Ca^{2+} is given to temporarily antagonize Mg^{2+} and avoid diuretic-induced hypocalcemia. Definitive treatment, particularly in the presence of kidney disease, may require dialysis.

Phosphate Disorders

Hypophosphatemia. Hypophosphatemia may be related to impaired enteral uptake, increased renal excretion, or shifts to the cellular compartment or bone (Table 59-13). Symptoms of hypophosphatemia may be precipitated by hyperventilation in patients with chronic depletion. Refeeding syndrome may be observed on commencement of enteral or parenteral nutrition after a period of prolonged starvation and may manifest postoperatively. Insulin secretion is decreased during starvation. The consequent fat and protein catabolism results in intracellular electrolyte depletion despite normal plasma levels, particularly phosphate. On refeeding, a switch back occurs to carbohydrate metabolism, increased insulin secretion, and an increased cellular uptake of PO_4^{3-}, which may lead to profound hypophosphatemia. In the most severe forms (<1.5 mg/dL), features may include rhabdomyolysis, leukocyte dysfunction, cardiac and respiratory failure, seizures, hypotension, and coma. IV PO_4^{3-} replacement carries a risk for precipitating severe hypocalcemia so should be reserved for moderate (<2.2 mg/dL) to severe or symptomatic cases and avoided in cases of ongoing hypocalcemia. Replacement protocols should be based on patient weight and serum PO_4^{3-}.[128]

Hyperphosphatemia. The causes of hyperphosphatemia are shown in Table 59-13. The most common cause in clinical practice is renal failure, in which filtered PO_4^{3-} load is reduced. This may be partly compensated for in mild chronic kidney disease by increased PTH secretion and inhibition of tubular PO_4^{3-} reabsorption, but in more severe kidney disease hyperphosphatemia must be controlled by oral PO_4^{3-} binders. The features of hyperphosphatemia may be related to symptomatic hypocalcemia caused by an acute elevation in PO_4^{3-} levels; hypocalcemia

TABLE 59-13 CAUSES AND MECHANISMS OF PHOSPHATE ABNORMALITIES

Hypophosphatemia		Hyperphosphatemia	
Mechanism	**Cause**	**Mechanism**	**Cause**
Internal redistribution	Respiratory alkalosis	Increased endogenous load	Tumor lysis syndrome
	Refeeding		Rhabdomyolysis
	Hormones (insulin, glucagon, epinephrine, cortisol)		Bowel infarction
	Sepsis		Malignant hyperthermia
	Hungry bone syndrome		Hemolysis
Increased urinary excretion	Hyperparathyroidism		Acidoses
	Disorders of vitamin D metabolism	Increased exogenous load	Intravenous infusion
	Renal transplant		Oral supplementation
	Volume expansion		Vitamin D intoxication
	Malabsorption	Reduced urinary excretion	Renal failure
	Renal tubular defects		Hypoparathyroidism
	Alcoholism		Acromegaly
	Metabolic or respiratory acidosis		Tumor calcinosis
Decreased intestinal absorption	Dietary restriction		Bisphosphonate therapy
	Excess antacids		Magnesium deficiency
	Vitamin D deficiency	Pseudohyperphosphatemia	Multiple myeloma
	Chronic diarrhea		In vitro hemolysis
			Hypertriglyceridemia

			Ureteral diversion
			Posthypocapnia

Data from Yunos NM, Bellomo R, Story D, et al: Bench-to-bedside review: chloride in critical illness, Crit Care *14:226, 2010.*

is mediated via Ca^+ deposition in soft tissues when the calcium × phosphate product is elevated, and by inhibition of renal 1α-hydroxylase.[32]

Chloride Disorders. Disorders of Cl^- have the potential to affect acid-base balance, although this depends on the other constituents of the SID. As described, exogenous Cl^- administration from isotonic saline will increase the plasma Cl^- concentration with a lesser effect on Na^+ concentration, thus reducing the plasma SID and therefore pH. Conversely, disease states typified by both hyperchloremia and hypernatremia or by hypochloremia and hyponatremia will not affect the SID and therefore not alter pH. Many of the causes of Cl^- abnormalities (Table 59-14) are pathologic processes that also affect Na^+ levels. Investigation and treatment of these "matched" electrolyte imbalances should initially target the dysnatremia. In very rare cases it may be necessary to supplement Cl^- ions using 0.1 M hydrochloric acid administered via a central venous catheter. The required Cl^- dose can be estimated as follows:

$$Chloride\ dose = (Cl_{desired} - Cl_{measured}) \times 0.2 \times weight\,(kg) \quad (6)$$

Practical Management of Perioperative Fluid Therapy

At each stage in the perioperative journey, the physician must decide how much and what type of IV fluid is required. Unfortunately, a robust evidence base with answers to these questions is not always available, so a pragmatic approach based on sound physiologic knowledge and the best available evidence is required. To make the process more complicated, fluid and electrolyte requirements are a dynamic situation with great interindividual variability. Different fluid requirements are encountered in the preoperative, intraoperative, and postoperative phases, and these vary depending on patient factors, including weight and comorbidity, and on surgical factors, such as the magnitude and site of surgery (see later discussion). Furthermore, the goals of fluid therapy vary depending on the severity of surgery and its associated morbidity. In "low-risk" minor surgery, fluid strategies may influence the incidence of relatively minor morbidity such as nausea and vomiting[129,130] (also see Chapter 97), whereas in major surgery the focus is on the potential for fluid administration to affect major postoperative morbidity, postoperative length of stay, and possibly postoperative mortality.[107,131,132]

The goals of fluid therapy for major surgery are as follows:

- To ensure adequate circulating volume to support cellular O_2 delivery and avoid the deleterious effects of hypoperfusion on cellular function and survival, inflammation, and neurohumoral responses. This may involve manipulation of not just circulating volume but also of cardiac output and vascular resistance.
- To avoid the iatrogenic side effects of fluid administration; excessive intravascular volume (which may not be readily apparent clinically), edema, excess Na^+ or Cl^- load, toxicities related to synthetic compounds, or unphysiologic quantities of anions (lactate, acetate, gluconate).

Many approaches have been explored in an effort to determine the optimum quantity and type of fluid that should be given to achieve these goals in perioperative care.

Quantity of Fluid. IV fluid quantities may be given in two main ways: by estimating the requirements based on patient weight, the phase of surgery, and nature of losses to estimate the required dose, or by direct measurement of an individual's physiologic variables, and administering fluid in sufficient quantities to achieve an improvement in these physiologic variables, so-called goal-directed therapy.

Targeting Overall Fluid Balance. Traditional approaches to perioperative fluid administration are based on historical estimates of fluid requirements during fasting (e.g., using the "4-2-1" calculation) (Table 59-15[133]) and during episodes of excess loss, such as when body cavities are open or bleeding occurs.

The fluid volumes prescribed are then based on perceived knowledge of the movement of fluids between compartments—for example, crystalloid being used to replace blood loss in a 3:1 ratio to account for crystalloid movement into the extravascular compartment.[18]

TABLE 59-15 THE 4-2-1 ESTIMATION OF MAINTENANCE WATER REQUIREMENTS

Weight	Fluid Prescription
First 10 kg	4 mL/kg/hr
Second 10 kg	2 mL/kg/hr
All subsequent kilograms	1 mL/kg/hr

Worked example: A 25-kg patient would require (4 × 10) + (2 × 10) + (1 × 5) = 65 mL/hr "maintenance" water.

Data from Holliday MA, Segar WE: The maintenance need for water in parenteral fluid therapy, Pediatrics *19:823, 1957.*

However, much of the physiologic basis of this management approach has been questioned recently.[3,11]

An extension of the milliliter-per-kilogram approach to fluid administration has been to examine whether higher (e.g., 12 to 18 mL/kg/hr of intraoperative crystalloid) or lower (5 to 7 mL/kg/hr) fluid doses in the immediate perioperative phase are associated with benefit after major surgery. Unfortunately, this work has been hampered by widely varying definitions of "restrictive/conservative," "standard," and "liberal," differing fluid types (colloids/crystalloids) examined, and different time courses over which the fluid strategy is applied. Despite these differences, a common theme is that when fluid is given based on a milliliter-per-kilogram protocol and on clinical assessment rather than to target defined physiologic endpoints, the administration of more than 3500 to 5000 mL of crystalloid solution in the immediate perioperative period is associated with increased postoperative morbidity in contrast to administration of smaller fluid volumes. This may be reflected in increased weight gain, cardiopulmonary dysfunction, impaired wound healing,[107,129] delayed GI function, and increased hospital length of stay.[134,135] One study gives apparently conflicting results,[136] although this may be partly accounted for by methodologic differences with the other studies here. Very few studies have robustly examined the specific effects of postoperatively administered fluid volumes; of those tackling this area, one showed an earlier return to gut function and hospital discharge when postoperative infusions were limited to 2000 mL of water and less than 100 mEq Na^+/24 hr,[104] whereas another showed no difference.[137] These represent very small studies with methodologic differences.

Although it seems likely that there exists an optimum fluid volume to be given to maximize perfusion while avoiding excessive intravascular volumes (a U-shaped curve when volume is plotted against morbidity), the position of this curve is likely to vary widely across patients and in response to different insults. This is the rationale behind individualization of fluid therapy, whereby objective variables are measured and targeted with fluid therapy.

Goal-Directed Therapy. The practice of goal-directed therapy (GDT) is based on measuring key physiologic variables related to cardiac output or global O_2 delivery and administering fluids, and possibly inotropes, vasopressors, vasodilators, and RBCs as appropriate, to manipulate these variables toward levels associated with improved tissue perfusion and clinical outcome. This approach to fluid administration is a continuous dynamic

process that targets defined physiologic endpoints rather than giving fluids without objective assessments of fluid status. GDT, used both in the perioperative and critical care setting, originated from observations that survivors of high-risk surgery achieved a particular elevation in global O_2 delivery and utilization in the perioperative period.[138] Subsequent trials used hemodynamic manipulation in an effort to replicate these supranormal "survivor values" in patients undergoing major surgery (cardiac index > 4.5 L/min/m, O_2 delivery index (DO_2I)> 600 mL/min/m, O_2 consumption index (VO_2I)> 170 mL/min/m).[139,140] The GDT approach has been studied in a wide variety of surgical settings, and at various time points, including during preoperative optimization, intraoperative management, and the immediate postoperative period. Various tools to measure the physiologic targets of GDT have been studied and are becoming increasingly noninvasive (see also Chapter 45). Most of the evidence in perioperative GDT is based on measurements from two devices, as follows:

- Pulmonary artery catheter (PAC) (see also Chapter 45). Considered to be the gold standard hemodynamic monitor, providing measured and derived values for left-heart and right-heart filling pressures, mixed and central venous saturations, cardiac output, DO_2, and VO_2 while allowing access to the central circulation. This was the tool used in the earlier GDT trials targeting increases in cardiac index and DO_2I, but its use is declining because of concerns about catheter-associated morbidity, reduced expertise in insertion and data interpretation, and the availability of less invasive tools. In countries such as the United Kingdom, its use is typically restricted to cardiac, major liver, and transplant surgery.
- Esophageal Doppler monitor (EDM) (see also Chapter 46). This device uses transesophageal ultrasound measurement of descending aorta blood velocity, integrating this with estimated aortic cross-sectional area to derive SV. Other measurements include peak velocity, used as an indicator of ventricular contractility, and corrected flow time (FTc), the duration of systolic aortic blood flow corrected for heart rate. FTc may be reduced (<330 ms) by increased systemic vascular resistance (SVR), reduced SV, or both. SVR may be calculated by inputting CVP and mean arterial pressure (MAP), helping to identify whether a low FTc is due to inadequate preload or excessive afterload. Variation in SV with positive-pressure ventilation (SV variation [SVV]) is also measured by the latest EDM models. Perioperative GDT trials have targeted increases in SV and FTc, typically aiming to preemptively optimize these values with colloid boluses rather than responding to evidence of overt hypovolemia. Multiple algorithms for EDM-guided GDT have been studied. Some incorporate FTc and SV (Fig. 59-6),[141,142] whereas more simple algorithms rely on repeated fluid boluses until SV does not increase further, presumably corresponding with the peak of the Starling curve.[143]

Other targets for goal-directed therapy are as follows:

- Arterial blood pressure and waveform analysis: These monitors analyze the invasive arterial blood pressure or plethysmograph trace to yield two types of measurement. First, an estimate of SV (and therefore cardiac output and index) based on the principle that pulse pressure is proportional to SV when arterial compliance is constant. Interpatient variation in arterial compliance may be accounted for by regular calibration steps using lithium dilution (LiDCO Plus, LiDCO, Lake Villa, Ill) or thermodilution (PiCCO, Phillips, Andover, Mass) or ignored in uncalibrated monitors (LiDCO Rapid, LiDCO; Vigileo, Edwards, Washington, DC), the latter representing SV trends rather than absolute estimates. Second, SVV, a predictor of fluid responsiveness based on systolic pressure variation with intermittent positive-pressure ventilation, can be measured.
- Thoracic bioimpedance: This has been underexplored in perioperative GDT and outcomes.
- CVP: Despite one study that demonstrated improved outcomes from hip fracture surgery when CVP response to intravascular fluid challenges was compared to unmonitored control,[144] CVP readings are clearly poorly predictive of intravascular blood volume and fluid responsiveness.[145]
- Echocardiography (also see Chapter 46): This advanced technique is used for guiding fluid therapy and yielding information on cardiac performance and filling, but requiring operator expertise and a transesophageal approach in the intraoperative setting.
- Lactate: A reduction in increased blood lactate concentrations is used clinically as a marker of successful resuscitation, and is used as a therapeutic target in very few studies.[146]
- O_2 extraction and venous O_2 saturation (SvO_2) or central venous saturation ($ScvO_2$): Inadequate tissue O_2 delivery may be signaled by increased O_2 extraction and the resultant mixed or central venous O_2 desaturation. Low $ScvO_2$ is associated with poor outcomes after high-risk surgery,[147] although it has been targeted in only one interventional study in major noncardiac surgery.[148]

Recent meta-analyses have highlighted the potential benefits of the GDT process. One meta-analysis with the most tightly defined patient group (surgery but not trauma or sepsis) and all time points (preoperative, intraoperative, and postoperative GDT) and GDT tools (PAC, EDM, and arterial waveform analysis), showed GDT to be associated with a reduction in postoperative morbidity and hospital length of stay.[132] Specifically, GDT leads to a reduction in the number of patients with postoperative renal impairment, respiratory failure, and postoperative wound infection. Many of the individual studies were not powered to detect a mortality difference; however, when analyzed rigorously in this Cochrane systematic review, excluding poorly controlled studies, hospital or 28-day mortality was also reduced by GDT.[132] In another meta-analysis, subgroup analysis of studies using the EDM as the GDT tool was performed, albeit in a more diverse patient group including those with multiple trauma. EDM-guided GDT, even when fluids and not inotropes or vasopressors were used, was again found to reduce postoperative morbidity, but not mortality.[149]

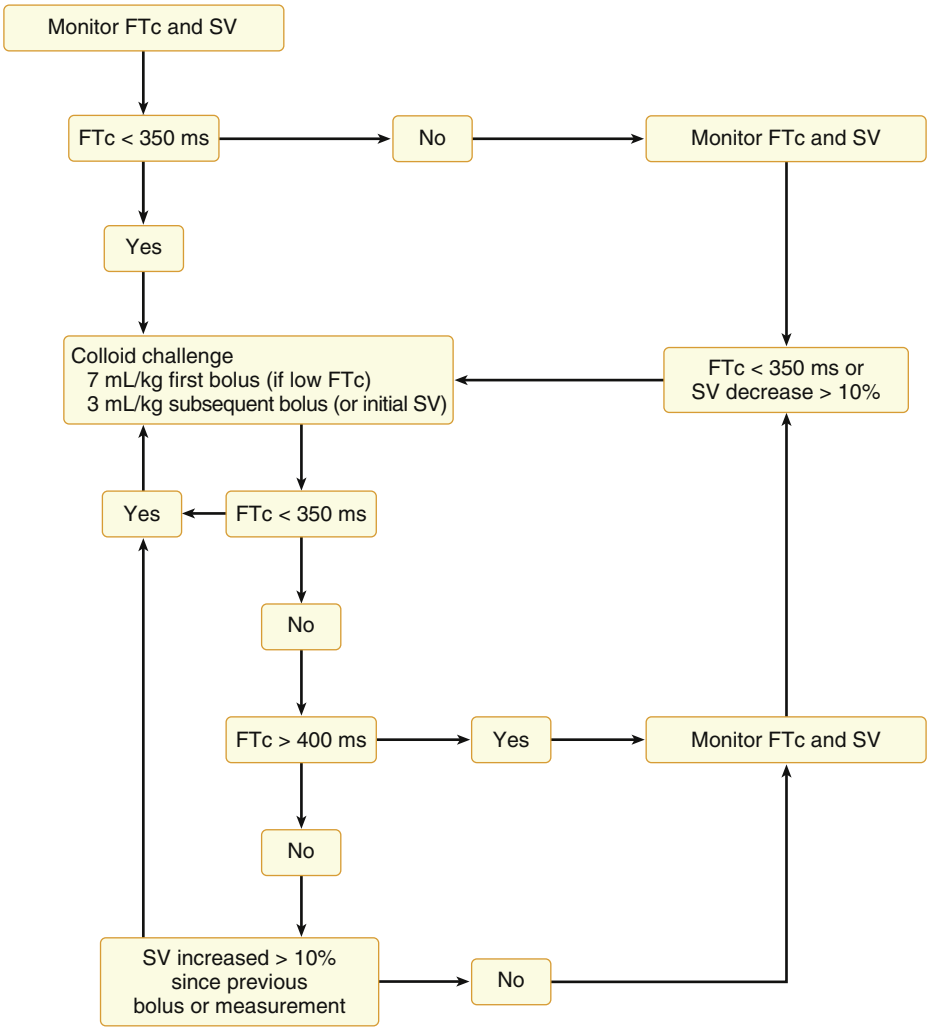

Figure 59-6. Protocol for ODM-based intraoperative goal-directed fluid therapy. *FTc,* Heart rate-corrected descending aorta flow time; *SV,* stroke volume. *(Redrawn from Noblett SE, Snowden CP, Shenton BK, et al: Randomized clinical trial assessing the effect of Doppler-optimized fluid management on outcome after elective colorectal resection,* Br J Surg *93:1069, 2006.)*

A frequent finding in GDT studies is that the intervention group receives more fluid, typically an extra 500 mL of colloid, a finding that has raised questions, as follows:

1. This fluid excess may seem to be at odds with the potential benefits of a conservative fluid strategy. However, it should be noted that the fluid excess in the liberal groups of fluid balance studies is typically of greater magnitude and different type (~1500 mL of excess crystalloid overall) and is indiscriminate, in comparison to the targeted administration to some patients based on specific physiologic variables in GDT. This difference may be partly responsible for the finding that overall outcomes in "liberal" groups are worse than those in GDT groups in their respective trials.[108]
2. The potential benefit of the GDT process is underlined by a failure to replicate the improved outcomes when these fluid balance differences are used as therapeutic targets. This was shown in a study in which the intervention group subjects were uniformly administered an extra 500 mL of colloid compared with the control group, with no improvement in postoperative outcomes.[150] This suggests that it is the individualization of therapy supported by monitored variables that may bring the clinical benefit.
3. Even in GDT trials with few overall differences in intravascular fluid balance between the control and intervention groups, the individualization of patient fluid requirements may be reflected in the timing of intraoperative fluid administration. In one study, early intraoperative EDM-guided fluid administration in the first quarter of surgery increased cardiac output above that of the control group, a difference that was sustained until the end of surgery and reduced postoperative morbidity.[142]

Despite the apparent benefit of GDT in the studies performed so far, further research is still required in large-scale multicenter trials to address the following:

- Although most of the GDT studies have used boluses of a variety of colloids, it is not clear if one colloid is superior or whether crystalloids could be used for boluses instead. This is particularly relevant given the cost and potential toxicities of colloids when

examined in sufficiently powered studies in critical care populations[49,81,151] (see also Chapter 61).
- The benefits of GDT need to be reappraised in the context of current perioperative and surgical practices that have developed since the advent of GDT, including enhanced recovery programs,[136,152] increasing use of laparoscopic surgery, regional anesthesia for orthopedic surgery, and declining control group postoperative mortality.[149]
- Inadequate numbers of certain surgical populations have been studied, in particular those in emergency surgery; meanwhile findings in one subpopulation should not be freely generalized to others undergoing fundamentally different physiologic insults.
- Hemodynamic monitors are currently under rapid ongoing development, and newer devices should be compared with existing ones for their utility in guiding GDT. Ultimately, as newer technologies are evaluated, the potential benefits of GDT may relate to the process of administering fluids based on rational physiologic endpoints rather than to the specific GDT tool used. As previous evaluations of monitoring devices have shown, no benefit is gained from using a device per se, but rather from the therapeutic intervention that the device allows.[153]

Appropriate Fluid Selection

Crystalloids or Colloids for Intravascular Plasma Volume Expansion. Although crystalloids are the most rational choice of fluid for replacement of evaporative losses, maintenance fluid requirements, and expansion of the entire extracellular fluid volume, the choice of crystalloid or colloid for plasma volume replacement in the perioperative phase is not clear. This underlines the lack of adequately powered perioperative studies directly comparing the two fluid types when administered in a similar fashion. Although the majority of GDT studies use colloid for their intravascular volume expansion, these studies are also comparisons of fluid administration guided by physiologic endpoints with nonguided therapy. Whether the same level of benefit can be achieved by crystalloid-based GDT merits further investigation. Crystalloid may be effective in plasma volume expansion (PVE) at amounts less than previously reported, although typically 40% to 50% more crystalloid than colloid must be administered to obtain the same clinical volume effect.[3] When combined with the increased propensity of crystalloid to filter across the capillary membrane, more extravascular volume expansion occurs, potentially causing tissue edema. When compared with colloids, crystalloids may lead to increased GI mucosal edema,[154] with the potential for delayed postoperative GI function and bacterial translocation. The differential effect of crystalloids when compared to colloids on tissue O_2 tension has no clear consensus.[50] The limited data comparing colloid with crystalloid for perioperative PVE may lead clinicians to extrapolate findings from studies in critical care. A Cochrane review highlighted the lack of improvement in all-cause mortality when colloids were used for intravascular volume expansion in unselected critical care populations.[155] In studies specific to patients with sepsis, starch-based colloids, including smaller MW versions, are associated with an increased requirement for renal replacement therapy, blood transfusion, and an increase in severe adverse events.[80] Although these findings may not be directly related to patients undergoing surgery, starch colloids should be avoided in perioperative patients with severe sepsis or at increased risk for renal failure pending the necessary large-scale trials assessing their safety in the perioperative setting (see also Chapter 61). This is reflected in license restrictions for these fluids in the United States, and in the United Kingdom the use of starches has been suspended in all settings. The potential toxicities of colloids must be weighed against the potential for excessive intravascular volume effects of PVE using crystalloids until more data are available informing the debate on crystalloids versus colloids for perioperative PVE.

Saline-Based or Balanced Solutions. Although its clinical relevance has been debated,[43] evidence demonstrates that intraoperative fluid administration based on isotonic saline causes a postoperative hyperchloremic acidosis and increase in spontaneous ventilation for respiratory compensation.[38] The excess NaCl and water load associated with isotonic saline is also excreted more slowly than that associated with balanced crystalloids. More focused trials in groups at risk for renal injury and postoperative respiratory failure will help to determine whether these adverse physiologic effects translate into worse clinical outcomes, as has been found in the general critical care population.[52] More practical problems may include the inappropriate administration of fluid boluses as the result of the finding of a base deficit incorrectly ascribed to tissue hypoperfusion. It is reasonable to restrict isotonic saline solution to the indications outlined in the section on preoperative fluid and electrolyte management and to use balanced crystalloids when required, until further data are available. Very limited data exist on the impact of colloids administered in either saline or balanced crystalloid solutions.

Typical Practical Approach. The following guidance represents an assimilation of the physiology, fluid pharmacology, and available evidence presented in this chapter. However, in many areas of perioperative fluid management the lack of robust evidence means that the choice of fluid and method of administration remains a clinician's choice informed by the balance of risks and benefits. The following overall themes in prescribing fluids in moderate-to-major surgery are important:

- Fluids administered should be individualized. This may be as simple as dosing postoperative maintenance fluids on a milliliter-per-kilogram basis or titrating intraoperative plasma volume expansion to objectively measured physiologic variables.
- Fluid status changes constantly throughout the perioperative period and should be frequently reassessed.
- The approach should be adapted to the patient and surgical factors outlined later.

Preoperative. In preparing for elective surgery, oral clear fluid intake should continue until 2 hours preoperatively and longer fasting discouraged. The use of preoperative bowel preparation should be restricted to carefully selected cases, and in these cases an infusion of 1 to 2 L of

balanced crystalloid with K^+ supplementation should be given in the preoperative period. Chronic comorbidities should be assessed for their influence on fluid and electrolyte balance, as outlined later.

Emergency surgery patients are likely to have acute disturbances of fluid compartments. They require timely resuscitation guided by rational physiologic endpoints such as trends in blood pressure and heart rate, lactate, urine output, and mixed or central venous O_2 saturations. Although preoperative fluid administration using cardiac output monitoring makes clinical sense, often logistical implications are involved with this approach and in some cases (ongoing blood loss or early surgical control of sepsis) surgery should not be delayed. A pragmatic approach is required to provide ongoing fluid resuscitation without compromising early surgical intervention. Upper GI losses should be quantified and replaced with isotonic saline, and lower GI losses (fistula, ileus, or obstruction) with balanced crystalloid. K^+ should be supplemented as appropriate.

Intraoperative. A background infusion of balanced crystalloid should be used to replace the ongoing water and electrolyte losses experienced during surgery. Hypotension caused by general or regional anesthesia is related primarily to vasodilation and reduced inotropy, and, unless the patient is hypovolemic because of preoperative factors, it is more rational to treat this with small doses of vasopressors, inotropes, or both.[11] Fluid therapy in patients considered to be at higher risk should be guided by invasive pressure monitoring to allow early recognition of overt hypovolemia and markers of global tissue perfusion, including lactate and acid-base status. Although no universally accepted definitions of a high-risk case exist,[156] major elective or emergency surgery should be included, especially in patients with advancing age (see also Chapter 80), comorbidities (see Chapter 39), and poor exercise tolerance, whose overall postoperative mortality risk is estimated to be more frequent than 5%. In these cases and particularly in certain orthopedic and intraabdominal operations about which the evidence base is strongest, cardiac output should be optimized by titrating boluses of a suitable colloid to a measured variable such as SV and FTc, cardiac output and O_2 delivery, or SVV, depending on the monitor used. Blood loss should be replaced with colloid or blood and blood products depending on the volume lost and variables suggesting inadequate tissue O_2 delivery (see also Chapter 61). Crystalloid may be used as an alternative for intravascular plasma volume expansion, but the increased volume required and potential for extravascular volume expansion should be considered. Overall the goal should be to achieve euvolemia by the end of surgery or the early postoperative period.

Postoperative. High-risk surgical patients may benefit from an ongoing period of GDT targeting O_2 delivery in the early postoperative period.[157] In all other patients after major surgery, an assessment of fluid status should be made based on clinical examination and supporting physiologic measurements such as lactate, central or mixed venous saturations, and cardiac output variables, if available. If patients are euvolemic and able to return to oral fluid intake, this is the best way of avoiding the iatrogenic effects of postoperative fluid administration. Early oral intake is typically well tolerated and safe, and early oral nutrition may reduce the incidence of postoperative complications.[158]

The following should be done in patients requiring ongoing IV therapy:

1. Electrolytes should be checked at least daily to monitor for hyponatremia and other electrolyte derangements.
2. Fluid requirements should be strictly divided into three categories for their ongoing assessment and treatment:
   a. "Pure" maintenance requirements should be salt-poor and contain a modest volume of free water to account for the postoperative state of salt and water retention. Infusions should therefore consist of the following[159]:
      - 1500 to 2500 mL in 24 hours, depending on weight, or 1 to 1.2 mL/kg/hr. Given the relative reduction in TBW in obesity (see previous discussions on crystalloids, fluid compartments), consideration should be given to dosing this fluid requirement based on ideal body weight in this setting.
      - 50 to 100 mEq Na^+ should be given in 24 hours.
      - 40 to 80 mEq K^+ should be given in 24 hours.
      - It is likely that part of this minimal maintenance volume should comprise hypotonic fluids such as 5% dextrose or 0.18% saline with 4% dextrose. Because of the risk for postoperative hyponatremia, this maintenance intravascular fluid volume should not be increased if suspicion for hypovolemia exists. Rather, the source of the ongoing loss should be identified and treated separately. As oral fluid intake increases, this maintenance fluid should be reduced proportionately.
   b. Replacement of ongoing losses. This fluid requirement requires frequent reassessment to appropriately titrate replacement fluids, if indeed any are needed. Volumes given should reflect measured amounts lost and an assessment of intravascular volume status and adequacy of organ perfusion (mental state, lactate, hemodynamic trends). Losses from the GI tract (vomiting, nasogastric aspirates, stoma) should be replaced with an equal volume of isotonic saline or balanced crystalloid with K^+ as appropriate. Losses to third spaces, such as reaccumulation of ascites, should be treated with a mixture of colloid and crystalloid, and blood loss replaced with colloid, blood, or blood products, as well as definitive intervention, if appropriate.
   c. New requirements (resuscitation). New requirements may relate to the development of postoperative complications such as hemorrhage (absolute hypovolemia) or acute sepsis (relative or absolute hypovolaemia).

Postoperative oliguria should be interpreted cautiously, particularly in the first postoperative 24 hours. The patient should be carefully assessed for corroborative evidence of impaired end-organ perfusion and alternative causes of oliguria, including catheter obstruction and intraabdominal hypertension, considered. In the absence of markers indicating hypovolemia and inadequate tissue perfusion, large volumes of fluid challenge

are inappropriate and may aggravate postoperative positive fluid and Na^+ balance in the face of a normal surgical stress response.

Special Considerations

Patient Factors

Heart Failure. The diverse pathophysiologic effects of heart failure and their treatment may make perioperative fluid management particularly challenging. The hemodynamic effects of chronic heart failure are typified by systolic and diastolic dysfunction of the left, right, or both ventricles with secondary maladaptive neurohumoral responses. These include persistent activation of the RAA axis, with consequent salt and water retention, and chronic sympathetic nervous system (SNS) activation, with persistent tachycardia and vasoconstriction. Undertreated patients may therefore present with edema in both lungs and peripheral tissues and increased central blood volume in the face of poor myocardial function.

Treatments for heart failure attempt to correct many of the neurohumoral responses, and many have been shown to improve long-term prognosis in heart failure. In the perioperative phase they may bring challenges to fluid management, including chronic volume depletion, blunting of normal sympathetic responses, and electrolyte disturbances. They include β-adrenoreceptor antagonists, diuretics, digoxin, and antagonists of aldosterone and angiotensin.

Perioperative fluid therapy in patients with heart failure has two goals. The first is to preserve cardiac output, bearing in mind the influence of preload, contractility, and afterload. The ventricles are typically poorly compliant and require adequate preload, which may be reflected in a relatively high CVP and adequate diastolic filling time to maintain good cardiac output. However, the flattened Starling curve of the failing heart means that excessive intravascular volume infusion and preload may lead to impaired contractility and worsening cardiac output. This leads to "forward failure," manifested as inadequate organ perfusion, and "backward failure," manifested as pulmonary and peripheral edema, particularly in the presence of aberrant salt and water excretion. The second goal is to minimize the cardiac work to avoid a vicious cycle of increased cardiac O_2 demand, inadequate O_2 supply, and worsening myocardial function. In particular, tachycardia triggered by hypovolemia and other stimuli should be avoided. Striking a balance between hypovolemia and hypervolemia is particularly important in patients with heart failure, but it may be difficult to assess clinically.

The practical approach to patients with heart failure involves careful preoperative assessment of fluid status and electrolytes and optimization of heart failure treatments when time allows. The complex cardiovascular situation mandates invasive hemodynamic monitoring for moderate or major surgery with consideration of cardiac output monitoring using modalities such as transesophageal echocardiography or pulmonary artery catheterization,[160] although less invasive modalities may be used. Measurement of cardiac filling and contractility is particularly important because the sources of intraoperative hypotension (reduced preload, contractility, or afterload) require different treatments and, particularly in this group, should not be blindly treated with fluid boluses. Infusion of large volumes of any fluid, including blood and products, should be undertaken only with objective evidence of intravascular volume loss.

The effects of heart failure therapies should be taken into account in the perioperative phase. Diuretics may leave patients in a chronically volume-contracted state that worsens anesthesia-related hypotension. Loop diuretics frequently cause hypokalemia and hypomagnesemia, whereas aldosterone antagonists cause hyperkalemia, which may be severe when combined with ACE-inhibitor treatment or chronic kidney disease. Normalization of electrolytes is particularly important in patients taking digoxin, in whom hypokalemia may potentiate digoxin toxicity. ACE-inhibitors or angiotensin receptor antagonists themselves lead to a blunted sympathetic and angiotensin response to anesthesia-related vasodilation. The hypotension caused by these should be treated appropriately by small doses of inotropes or vasopressors, which may include vasopressin analogues.[160]

Kidney Disease. Patients with dialysis-dependent chronic kidney disease have multiple pathologic features that must be taken into account in perioperative fluid therapy (see also Chapter 75). Overall fluid balance may be disturbed by reduced or absent native urine production, with reliance on dialysis to achieve the target "dry" weight, representing estimated euvolemia. Organ O_2 delivery may be impaired by various factors, including chronic anemia, endothelial dysfunction, and microvascular perfusion abnormalities. The frequent coexistence of heart failure and systemic or pulmonary hypertension and the bleeding tendency caused by platelet dysfunction further increase the perioperative challenge.[161]

Preoperative assessment should focus on the adequacy of chronic dialysis in attaining euvolemia, and estimating the normal volume of native urine output. Comorbidities should be assessed and optimized. Surgery should be undertaken in a facility where preoperative and postoperative dialysis or hemofiltration can be offered, in case of intraoperative fluid overload or hyperkalemia that is not responsive to conservative measures. In elective surgery, preoperative dialysis should be timed such that the patient enters the intraoperative phase with a normal blood volume. Surgery in the presence of hypervolemia increases the risk for pulmonary and peripheral edema, hypertension, and poor wound healing, whereas hypovolemia brings a risk for anesthesia-related hypotension and inadequate tissue perfusion. Practically, this means performing dialysis the day before surgery to allow equilibration of fluid and electrolyte compartments and time for dialysis anticoagulants to be metabolized. Electrolytes should be checked on the morning of surgery; sampling too soon after dialysis, before equilibration, may give an artificially low K^+ result leading to unnecessary exogenous supplementation. Conversely, fasting may actually favor a hyperkalemic state as a result of the reduced presence of insulin; the ideal K^+ value after dialysis is in the low-to-normal range. In emergency surgery, sufficient time to safely dialyze patients preoperatively may not be available. In this case, electrolyte abnormalities must be managed conservatively, with particular care paid to intraoperative fluid balance.

As with other major comorbidities with a critical impact on fluid and electrolyte balance, the importance of avoiding both hypovolemia and hypervolemia and the predisposition to inadequate tissue perfusion mean that detailed monitoring of hemodynamic variables, including invasive central venous and arterial pressure and cardiac output should be considered for moderate-to-major surgery. The amount of fluid administered intraoperatively should be titrated to objective physiologic measurements, although the type of fluid given is open to debate. Large volumes of isotonic saline should be avoided, because the acidosis induced favors extrusion of K^+ from cells. In contrast, K^+-containing balanced crystalloids do not cause hyperkalemia in clinical trials.[44,162] An alternative crystalloid is a K^+-free HCO_3^--buffered dialysis solution such as Hemosol. Colloids may be used for intravascular volume replacement, although owing to their predominantly renal excretion, the volume effect and potential toxicities may be exaggerated in these patients. Liaising with the nephrologist is important before considering blood transfusion; if the patient is awaiting renal transplantation, human leukocyte antigen–matched blood may be required to minimize antibody formation and future difficulties with blood and tissue matching.

Upper Gastrointestinal Loss. Large-volume gastric fluid loss may be caused by congenital or acquired gastric outlet obstruction and causes a distinct pattern of fluid and acid-base abnormalities. Dehydration occurs as a result of water loss, reduced total body Cl^- content, and alkalosis caused by proton loss, with raised serum HCO_3^-. The initial renal response is formation of urine with low Cl^- and high HCO_3^- content. However, progressive dehydration leads to increased aldosterone secretion, aimed at retaining Na^+ and water. Na^+ is retained at the expense of K^+ and H^+ ions, leading to hypokalemia, and worsening metabolic alkalosis with a paradoxically acid urine. The alkalosis also reduces the circulating ionized fraction of Ca^{2+}.

Correction should include gradual rehydration with isotonic saline and K^+ supplementation, changing to dextrose-containing saline solutions depending on electrolyte analysis. Any surgery required to treat gastric outlet obstruction should be scheduled after correction of the volume and acid-base status.

Sepsis and Acute Lung Injury. Patients with infection and sepsis syndromes may be encountered early in their presentations, because surgical source control of infection (drainage of abscesses, debridement of necrotic tissues, removal of infected devices) forms a key part of early sepsis therapy (see also Chapter 101).[163] Cardiovascular instability may be a particular problem, contributed to by endothelial dysfunction and intravascular fluid loss, vasodilation with fluid maldistribution, sympathetic redistribution of blood volume away from the peripheral circulation, and impairment of cardiac function. Fluid resuscitation, with the goal of maintaining adequate end-organ perfusion is therefore a key part of the first 6 hours of sepsis treatment, which may represent the perioperative period for some patients. The following pragmatic targets are suggested for patients with sepsis who have tissue hypoperfusion, defined by blood lactate concentration at or more than 4 mmol/L or hypotension persisting after initial IV fluid challenge[163]:

- CVP 8 to 12 mm Hg (12 to 15 mm Hg in patients on ventilation)
- MAP 65 mm Hg or greater
- Urine output 0.5 mL/kg/hr or greater
- $Scvo_2$ greater than 70% (or mixed venous O_2 saturation > 65%)

Some have criticized the use of fixed CVP targets to guide early sepsis therapy because of their limited value in predicting fluid responsiveness and tissue hypoxia; alternative suggested targets include stroke volume, pulse pressure variation, and echocardiographic assessment of cardiac function.[164] Given the apparent nonsuperiority of colloids for resuscitation in this patient group and concerns about trends toward kidney injury when starches are administered in sepsis, current recommendations are to use 30 mL/kg of crystalloid in a protocolized fashion to achieve the described targets. In patients requiring further fluid, albumin should be considered, along with vasopressors, inotropes, and RBC transfusion to attain these goals. Further fluid challenges may be guided by dynamic measurements of fluid responsiveness, such as SV or pulse pressure variation. In established sepsis, fluid management becomes even more challenging as a result of the frequent presence of microvascular dysfunction, extravascular fluid overload, and disturbed neurohumoral responses to variations in intravascular volume.[165] A disruption occurs in the O_2 delivery and usage relationship as a result of cellular inability to use O_2 (cytopathic hypoxia),[166,167] with the result that strategies to elevate global O_2 delivery may be of little benefit while exposing patients to potential side effects of excessive fluid and catecholamines.[168,169] At this stage a less positive overall fluid balance is associated with improved outcomes.[170]

Patients with established acute respiratory distress syndrome (ARDS) may also present for surgical procedures. Here the focus of fluid therapy is the fine balance between avoiding an increase in lung edema while maintaining adequate tissue perfusion. ARDS is typified by increased pulmonary endothelial permeability, with extravasation of water and protein. The consequences are interstitial and alveolar edema, atelectasis, reduced pulmonary compliance, increased pulmonary artery pressures, and hypoxemia. Meanwhile, organ perfusion may be impaired by increased intrathoracic pressures and a reduction in cardiac filling pressures. Observational studies have highlighted an association between overall positive fluid balance and mortality in ARDS,[171] backed by a large randomized controlled trial demonstrating a reduction in ventilator and intensive therapy unit days in patients treated with a conservative fluid administration strategy.[172] Findings were similar in a subgroup of this trial who had undergone surgery, without any increase in kidney injury in patients treated with lower fluid volumes.[173] Extravascular lung water (EVLW) seems to be important in mediating the worse outcomes associated with a more positive fluid balance, with thermodilution studies showing excess EVLW to have reasonable sensitivity and specificity in predicting intensive therapy unit mortality in

patients with ARDS.[174] Assuming global organ perfusion appears adequate, as demonstrated by normal lactate levels, intraoperative losses should be replaced but otherwise be conservative in the volumes of fluid given to patients with ARDS intraoperatively. There is a lack of adequately powered studies on the choice of colloid or crystalloid for intravascular volume replacement in patients with ARDS.

Burns. Extensive burns create a situation of copious fluid loss from the circulation combined with particular sensitivity to the effects of excess fluid administration. Thermal injury creates an area of necrotic tissue with surrounding ischemic areas. The combination of dead tissue with areas undergoing ischemia and subsequent reperfusion causes localized and systemic inflammatory reactions through histamine, prostaglandin, reactive O_2 species, and cytokine release. Local impairment of endothelial barrier function leads to the loss of oncotically active plasma constituents, increased capillary filtration into the interstitial compartment, and evaporative transcutaneous fluid loss as a result of loss of skin integrity. Through similar mechanisms, extensive burns may lead to the systemic inflammatory response syndrome, with its well-recognized effects on fluid compartments outlined previously. The deleterious role of this inflammatory response is underlined by the reduction in mortality seen with early burn excision compared with conservative care.[175] IV fluid therapy is generally instituted for burns of greater than 15% total body surface area in adults and 10% total body surface area in children.[176] However, increasing uncertainty exists about the volume and type of fluid that should be given to patients with burns. Fluid administration is largely still based on formulas such as the Parkland formula (Box 59-1) or the Muir and Barclay versions. Although these have given a starting point for resuscitation volumes based on patient weight and extent of burn, myriad other patient and pathologic factors put such a recipe-based approach at odds with modern perioperative fluid therapy based on objective physiologic goals. Although the approaches based on these formulas advocate down-titration of administered fluid volumes if urine output is adequate (0.5 to 1 mL/kg/hr),[177] in reality this appears not to be practiced. Indeed, large studies have shown that the majority of burn patients receive fluid volumes in excess of those predicted by the Parkland formula, with a mean of 6 mL/kg/% burn compared with 4 mL/kg/% burn in 24 hours predicted by the formula.[178] Conversely, patients with inhaled and other nonburn injuries, electrical burns, or delayed resuscitation are considered to need increased resuscitation intravascular volumes, yet this is not taken into account by the formula approaches.

BOX 59-1 ***Parkland Burn Fluid Resuscitation Formula***

First 8 hours: 2 mL/kg × % TBSA (lactated Ringer solution)
Next 16 hours: 2 mL/kg × %TBSA (lactated Ringer solution)
Next 24 hours: 0.8 mL/kg × %TBSA (5% dextrose) + 0.015 mL/kg × %TBSA (5% albumin)

Data from Baxter CR: Problems and complications of burn shock resuscitation, Surg Clin North Am *58:1313, 1978.*
%TBSA, Burn size as % of total body surface area. Time periods refer to the time since the burn occurred.

Excessive fluid administration in burned patients ("fluid creep") is not benign. As in all conditions typified by systemic inflammation, excess administered fluid will collect in compliant compartments. Pulmonary edema requiring ventilatory support, fasciotomies in nonburned muscle compartments, raised intraocular pressure, and conversion of superficial to deep burns have been observed and attributed to fluid resuscitation.[176] Intraabdominal hypertension and compartment syndrome are correlated to the volume of fluid administered, with a particular rise when more than 300 mL/kg is administered in 24 hours.[179] These concerns have led to renewed efforts to find the optimum regimen for burn resuscitation in terms of crystalloid versus colloid, newer formulas using lower volumes such as the Haifa formula, and targeting objective physiologic parameters such as SV or intrathoracic blood volume. Pending a consensus from this ongoing work, burn resuscitation should be commenced with one of the currently accepted formulas, but actively down-titrated if a urine output of 0.5 to 1 mL/kg/hr is obtained, and consideration given to using a combination of crystalloids and colloids to reduce the total fluid volume administered.[180] Intraabdominal pressure should be monitored and consideration given to assessing resuscitation endpoints, such as lactate and cardiac output, in addition to urine output.

Pediatrics. Perioperative fluid therapy in pediatric patients has for many years been based on traditional approaches that are increasingly being reexamined (see also Chapter 93). Holliday and Segar[133] proposed a quantity and composition of maintenance fluid in hospitalized children in 1957 based on water requirements to sustain average metabolic activity and the electrolyte composition of milk. This developed into the 4-2-1 volume calculation for maintenance fluid requirements aimed at replacing insensible and urinary losses with hypotonic crystalloids containing glucose to maintain isoosmolality. These concepts were translated into the perioperative phase; glucose-based solutions were administered intraoperatively to reduce the apparently high risk for preoperative hypoglycemia after prolonged fasting,[181] and postoperative maintenance fluids were prescribed based on the 4-2-1 calculation using hypotonic crystalloids. Furthermore, the pediatric population was thought to be at risk for clinically significant preoperative dehydration by fasting, as a result of limited urinary concentrating ability and ongoing insensible losses because of the relatively large body surface area. Intraoperative replenishment of these volumes using 25 mL/kg of isotonic salt solution for those 3 years of age and younger or 15 mL/kg for those 4 years of age and older has been recommended.[182]

Multiple factors have led to a reevaluation of this approach. First, the modern approach to preoperative fasting, such that children may take clear—and potentially carbohydrate-containing—fluids up to 2 hours before surgery, reduces the risk for hemodynamically significant preoperative dehydration. It should therefore be necessary only to replace preoperative deficits using the amounts given previously when fasting has been excessive or preoperative pathologic processes reducing circulating volume intervene.[183] Second, the incidence of preoperative hypoglycemia is infrequent (<2.5%) and

related to inappropriately prolonged fasting or other risk factors, such as premature infants, neonates who are small for gestational age, or those with poor nutritional status.[184,185] Surgery itself increases blood glucose concentration, and administering glucose-containing solutions intraoperatively may cause hyperglycemia,[186] with the potential for osmotic diuresis and electrolyte abnormalities, or even adverse neurologic outcomes in the event of an ischemic or hypoxic event.[185] Glucose-free balanced crystalloid solutions should therefore be used intraoperatively, except in those at particularly high risk for hypoglycemia. Third, increasing awareness of the incidence and potentially disastrous neurologic outcomes from postoperative hyponatremia in pediatric populations has led to a reappraisal of postoperative hypotonic crystalloid maintenance fluids in 4-2-1 volumes. The effective SIADH induced by surgical stress and aggravated by the presence of pain and hypovolemia causes water retention and the risk for hypoosmolar hyponatremia if hypotonic solutions continue to be infused in significant volumes. Proposed strategies to avoid this include using half to two thirds of the calculated 4-2-1 formula maintenance fluids,[183] avoiding the most hypotonic fluids (4% dextrose with 0.18% NaCl),[185] and general measures that should be applied to all patients, as follows:

- Returning to oral fluids as early as possible
- Ensuring euvolemia to minimize the ADH response[187]
- Not confusing *maintenance* requirements with the variable amounts of fluid required because of *ongoing losses* (e.g., GI or blood), which should typically be replaced by isotonic crystalloids, colloids, or blood
- Checking electrolytes at least daily in those still receiving IV fluids

Although isotonic saline has been advocated as a "safer" fluid for postoperative maintenance, this brings the risk for Na^+ overload and hyperchloremic acidosis.

More recent developments in perioperative fluid management remain underexplored in pediatric populations. In particular, there is a dearth of data on whether colloid volume expansion is beneficial or harmful in pediatrics or whether goal-directed fluid therapy may confer the advantages that have been seen in adult populations. These areas require urgent investigation.

Hepatic Failure. Progressive liver disease and cirrhosis cause a distinctive pattern of abnormal fluid balance (see also Chapters 73 and 74). The combination of peripheral vasodilation and relative intravascular depletion can mimic a decrease in intravascular volume. Yet, total body Na^+ and water are retained with ascites and edema.[188]

The widely accepted pathophysiologic mechanisms are that progressive disruption of liver architecture combines with decreased hepatic nitric oxide (NO) bioavailability and increased vasoconstrictor production, leading to sinusoidal hypertension. Compensatory vasodilatory mechanisms, including NO overproduction, lead to splanchnic and systemic vasodilation, relative hypovolemia, and reduced systemic arterial pressure. This triggers baroreceptor-mediated activation of the RAA, SNS, and ADH release. Although cardiac output increases, reduced systemic vascular resistance persists despite these compensatory mechanisms. The state of hyperaldosteronism causes salt and water retention, frequently combined with hyponatremia resulting from a relative excess of water retention. Splanchnic vasodilation and vascular permeability combine with decreased lymphatic drainage to favor the formation of ascites. The neurohumoral response also induces renal artery vasoconstriction, reducing renal blood flow and increasing the risk for hepatorenal syndrome. A range of therapies centered around reduction of total body salt and water may maintain patients in a compensated state. These include dietary fluid and salt restriction, diuretics (particularly the aldosterone antagonist spironolactone and loop diuretics), and intermittent or continuous drainage of ascites. However, the perioperative period presents considerable potential for disturbance of this fine balance. Excessive administration of isotonic saline will aggravate the preexisting salt and water overload, potentially leading to further ascites and edema formation. Conversely, periods of hypovolemia are poorly tolerated, leading to a significant deficit in organ perfusion, further stimulation of the RAA, SNS, and ADH axes, and risk for kidney injury. The approach should therefore be to assess volume status carefully, possibly assisted by cardiac output monitoring, to replace losses with appropriate volumes of isotonic crystalloid, colloid, or blood but to avoid salt and water overload with excessive volumes of saline without clear clinical indication. In instances of large-volume (>6 L) ascites drainage, hemodynamic instability is a risk. Albumin appears to be a more effective prophylactic treatment for this than saline, abrogating the stimulated increase in plasma renin activity and maintaining more stable hemodynamics.[189] Lactate and other buffered fluids may be used in hepatic failure, although their metabolism may be slowed in advanced liver disease.

In decompensated liver disease with encephalopathy, raised intracranial pressure may be present and osmotherapy, such as hypertonic saline, should be used to bring plasma Na^+ into the high-normal range.[190] This is in contrast to chronic compensated liver disease, in which a degree of hyponatremia is well tolerated and does not require acute correction unless it is severe or symptomatic (see earlier discussion).

Obstetrics: Preeclampsia. Preeclampsia is a multisystem disease of pregnancy characterized by hypertension, proteinuria, and multiorgan involvement that may affect the kidneys, liver, pulmonary, and central nervous systems (see also Chapter 77). In contrast to the usual volume-expanded status in pregnancy, patients with preeclampsia have reduced plasma volume, combined with endothelial dysfunction and hypoalbuminemia. Previously IV volume expansion was thought to be beneficial in treating hypertension in preeclampsia. However, this has not been borne out by later studies.[191,192] Furthermore, a clear association exists between positive fluid balance and the incidence of pulmonary edema in this condition.[193] Acute pulmonary edema occurs in between 5% and 30% of cases of preeclampsia, is associated with increased hospital length of stay, and is a leading cause of death in preeclampsia. Most cases present in the postpartum period, perhaps reflecting the autotransfusion into a vasoconstricted circulation that occurs after delivery. Low COP also contributes.

Patients with preeclampsia should receive restricted volumes of IV crystalloid (80 mL/hr, including that received as drug diluents[194]), and fluid balance should be observed carefully. Oliguria should not be treated by administration of large volumes of fluids in the presence of normal renal function. This conservative strategy has not been associated with an increase in kidney injury.[195] Any blood loss in the peripartum or perioperative period should be replaced with an appropriate volume of crystalloid, colloid, or blood, depending on magnitude. Invasive monitoring should be used to direct fluid therapy in cases of severe preeclampsia.

Surgical Factors

Neurosurgery. Multiple physiologic factors mean that fluid and electrolyte therapy are a key component in the perioperative management of intracranial pathology (see also Chapter 70). This management may be complicated by disturbances of water and Na^+ balance caused by neurosurgical diseases themselves. Much of the current fluid management in this area is based on knowledge of this physiology, experimental models, and gradual evolution of interventions investigated in small trials rather than large randomized studies.

The intact blood-brain barrier (BBB) excludes electrolytes and large molecules but allows passage of water. Extravascular brain water is therefore related to plasma osmolality, with cerebral edema a feature of hypoosmolar hyponatremic conditions. Intracranial diseases may compromise the integrity of the BBB, increasing the predisposition to edema. Cerebral perfusion also may be impaired if systemic blood pressure is inadequate in the face of increased intracranial pressure, particularly in pathologic conditions in which autoregulation is impaired. Rational management of fluids in neurosurgical patients should start with maintaining baseline blood volume and cerebral perfusion and avoiding significant decreases in serum Na^+, osmolality, and oncotic pressure. Several situations may require more specific management, as follows:

1. Increased intracranial pressure: Increasing serum osmolality may reduce total brain water and therefore intracranial pressure by creating brain-blood osmotic gradients. Mannitol and hypertonic saline given by bolus have been the pharmacologic mainstays in this area. The osmotic action of these drugs may be reduced to variable degrees by dysfunction of the BBB, frequently seen in brain injury. However, they likely have therapeutic effects beyond simple osmotic effects.[196] Meta-analysis of the small studies available suggests that hypertonic saline may be superior to mannitol in reducing intracranial hypertension, but large-scale controlled studies are required to confirm this.[54] Conversely, using hypertonic saline in all patients with early traumatic brain injury without intracranial pressure monitoring has not been shown to improve outcomes.[55] Similarly, continuous infusion of hypertonic saline to induce persistent hypernatremia in the presence of cerebral edema also lacks evidence of benefit.[197] Restrictive fluid strategies have been advocated to minimize intracranial hypertension in severe traumatic brain injury. Although retrospective data analysis suggests that positive fluid balance is not associated with refractory intracranial hypertension, an association between hypervolemia and pulmonary edema was observed.[198]
2. Cerebral vasospasm: Manipulation of hemodynamics and hematocrit is traditionally used in the treatment of vasospasm after subarachnoid hemorrhage. This "triple-H" therapy (hypervolemia, hemodilution, hypertension) has entered practice based on small trials of efficacy rather than randomized studies.[199,200] Some workers, using extensive animal models, have advocated a hematocrit no lower than 30%, below which the benefits of reducing blood viscosity are outweighed by a reduction in O_2 delivery. They also caution against hypervolemia, both for its potentially injurious effects in the presence of a dysfunctional BBB and for the extracranial effects, particularly pulmonary edema.[201]
3. An intracranial pathologic condition may itself be a cause of disturbances of both water and Na^+ balance through diabetes insipidus, cerebral salt wasting, or SIADH. This should be assessed and treated as described in the section on electrolyte imbalance.

Clear comparisons of crystalloid and colloid in a variety of neurosurgical settings are lacking. Of the available evidence, albumin is associated with an increase in mortality in traumatic brain injury compared with isotonic saline.[5] In the absence of more robust evidence, a mixture of isotonic crystalloids and colloids is advocated in other neurosurgical settings.[200,202]

Trauma. In patients with evidence of major traumatic hemorrhage the key goals are to avoid clot disruption until definitive control of bleeding, to treat the acute coagulopathy of trauma, to maximize tissue O_2 delivery by the early use of packed red cell transfusion, and to avoid hypothermia and acidosis (see also Chapter 81). In the prehospital setting, restrictive fluid therapy may improve outcomes, particularly in penetrating trauma.[203] The approach should initially be one of permissive hypovolemia, with fluid administered to achieve cerebration rather than normotension in awake patients, systolic blood pressure of 70 to 80 mm Hg in penetrating trauma, or 90 mm Hg in blunt trauma.[204] The duration of organ hypoperfusion that may be involved with this approach should be minimized by rapid transfer for damage control intervention to stop bleeding, whether radiologic or surgical. Large volumes of IV crystalloids or colloids in early resuscitation will cause hemodilution and dilute clotting factors, and saline-based fluids may aggravate the acidosis associated with major blood loss. Rather, packed RBCs (PBRCs), clotting factors (e.g., fresh frozen plasma [FFP]) and platelets should be replaced early. Limited evidence, particularly from military populations and retrospective analyses, suggests "high" ratios of FFP to PRBC (e.g., 1:1 to 1:2) are associated with the best outcomes in massive transfusion compared with lower ratios (e.g., 1:9)[204,205] (see also Chapter 61). Active patient and fluid warming should be used and clot stability improved with tranexamic acid.[206] Once hemostasis has been achieved, restoration of normal circulating volume and tissue perfusion is the goal, with ongoing blood, clotting factors, platelet, and fluid infusions targeting normalization of

cardiac output and O_2 delivery, lactate levels, and blood clotting (best checked using near-patient whole-blood tests of clotting, such as thromboelastography). A small number of trials support the practice of GDT in the immediate perioperative trauma setting, but larger controlled trials are required. After surgery and initial resuscitation, much of the evidence for ongoing fluid approaches is derived from unselected critical care populations. As outlined previously, the evidence suggests that in established critical illness, aggressive GDT may be harmful.[203]

Patients with traumatic brain injury in addition to major hemorrhage present a dilemma because the raised cerebral perfusion pressure required for adequate cerebral blood flow in the face of raised intracranial pressure is at odds with the hypotensive resuscitation approach. In isolated head injuries, using fluids and vasopressors to achieve a mean arterial pressure above 90 mm Hg is recommended, with avoidance of hyponatremia and hypoosmolality to minimize cerebral edema.[196,207] Little evidence exists to inform resuscitation treatment in patients with mixed intracranial and extracranial trauma, so the strategy should be a clinically judged compromise prioritizing the requirements of the most severe injuries. Rapid hemorrhage control is particularly important to allow subsequent normalization of systemic blood pressure to meet the need for adequate cerebral perfusion. Even in general trauma, much of the evidence supporting current resuscitation approaches is derived from animal models and limited randomized trials, predominantly in young otherwise healthy subjects in the prehospital setting.[204] The needs of individual patients should therefore be taken into account, particularly because older patients with comorbidities may tolerate periods of hypoperfusion very poorly.

Free Tissue Flap Surgery. Free tissue flaps are frequently used during oncoplastic surgery, typically for breast reconstruction or after resection of head and neck tumors and involve the autologous transplantation of tissue to fill a defect, complete with arterial supply and venous drainage. Transplanted vessels are denervated and lack intrinsic sympathetic tone, but the feeding vessels are not; vasoconstriction in these feeding vessels related to cold and excessive doses of vasopressor must be avoided because it may threaten the perfusion of the flap. Flap blood flow depends on systemic blood pressure and blood viscosity, and hypervolemic hemodilution has traditionally been used to address these requirements. However, given the reduction in O_2 carrying capacity and potential for flap edema that this entails, a more conservative fluid strategy should be used, which may improve flap outcome.[208] The use of dextrans to improve blood flow is not currently favored, because no benefit has been demonstrated and the risks for medical complications is relatively high.[209] Free tissue flaps have disrupted lymphatics, which take several weeks to reconnect, making them particularly prone to interstitial edema. Large volumes of crystalloid—favoring increased capillary filtration—should be avoided and colloids used for blood volume expansion.[210]

Intrathoracic Procedures. Any procedure within the thorax, including upper GI and thoracic surgery, can lead to postoperative respiratory problems, including ARDS and acute lung injury (ALI) (see also Chapter 66). The development of ARDS and ALI is partly due to the proinflammatory nature of one-lung ventilation,[211,212] modified by a host of other patient and surgical risk factors. In esophagogastrectomy, retrospective studies and case series have suggested reduced pulmonary complications with restrictive fluid strategies.[213-216] One retrospective observational study of esophagectomy patients found a cumulative fluid balance greater than 1900 mL from surgery to the second postoperative day to be an independent risk factor for other adverse outcomes, including death.[217] The use of diuretics to actively target fluid balance, degree of cardiovascular support, and presence or absence of epidurals is not explored in this study, and controlled trials of fluid balance approaches are therefore required in this population. However, the potential benefit of conservative fluid administration in this group is consistent with the large randomized study of patients with ARDS demonstrating improved pulmonary outcomes in those treated with a restrictive rather than liberal fluid regimen.[172] While maintaining adequate tissue perfusion, a cautious approach to fluid administration is recommended, both to minimize pulmonary complications and to avoid anastomotic edema.

Hepatic Resection. Blood loss during liver parenchymal resection, a risk factor for worse outcomes, is associated with high venous pressure and backflow of blood through the valveless hepatic veins (see also Chapter 73). One study has shown that a CVP of 5 cm H_2O or lower is associated with significantly lower blood loss and transfusion requirements.[218] Several techniques are used to maintain a low CVP, including conservative fluid management, at least until the hepatic resection is completed. Despite evidence that using a low CVP technique does not have adverse effects on renal or liver function,[219] a pragmatic compromise must be sought for each patient; inducing hypovolemia during liver resection risks hemodynamic instability and end-organ hypoperfusion, particularly in those with preexisting cardiorespiratory morbidity, increases the risk for air embolism, and reduces the physiologic reserve should massive blood loss occur. Once liver resection is finished, a more generous fluid approach can be taken to ensure adequate circulating volume. This may be guided by invasive hemodynamic monitoring and minimally invasive cardiac output monitoring to provide a rational endpoint to fluid therapy in this phase.

Major Intraabdominal Surgery. Major intraabdominal operations, particularly those involving multiple organ resections for tumor require careful perioperative fluid management. Major gynecologic operations such as pelvic exenteration or ovarian debulking and urologic procedures including cystectomy, radical nephrectomy, and major retroperitoneal lymph node dissection can involve dramatic fluid shifts in the perioperative period. Fluid losses during surgery are caused by prolonged peritoneal exposure, significant blood loss, and acute drainage of tumor-related ascites. The total volume lost is difficult to quantify, so cardiac output monitoring is valuable when combined with CVP and arterial pressure monitoring and serial blood gas analysis.[220, 221] Intraoperative drainage of ascites is followed by fluid shift from the vascular space as this reaccumulates postoperatively and may require

large volumes to replace the ongoing loss. Another consequence of fluid redistribution is electrolyte abnormalities; hypokalemia and hypomagnesemia are frequently seen.

Renal Transplant. The key goals of fluid therapy in the perioperative management of renal transplant are to ensure adequate renal perfusion to support early graft function and avoid fluid therapy side effects to which patients with impaired renal function may be susceptible (see also Chapter 74). Traditionally, CVP-guided intraoperative fluid therapy has been advocated, using large volumes of crystalloid (up to 60 to 100 mL/kg) to achieve a CVP of 10 to 12 mm Hg or higher before reperfusion.[222] Recently, more conservative goals have been advocated, limiting crystalloid infusion to 15 mL/kg/hr, aiming for a CVP of 7 to 9 mm Hg[223] with no apparent increase in graft failure. The role of alternative tools such as esophageal Doppler or pulse contour analysis to supplement or replace CVP-guided fluid therapy in this area also has been suggested.[224] Patients with renal failure may develop acidosis-related hyperkalemia when isotonic saline is infused during transplant,[44] so balanced crystalloid solutions, or even K^+-free, buffered dialysate solutions, should be used. The role of colloids in this population requires further study, although concerns over renal toxicity of starches may limit their use.[224] Postoperative fluid therapy should take into account the baseline maintenance requirements and the ongoing losses resulting from urine production.

Liver Transplant. Liver transplantation involves a series of major physiologic disruptions that have direct relevance to fluid and electrolyte management (see Chapter 74).[225] Therapy should be guided by data from invasive monitoring, possibly including pulmonary artery catheterization. During phase I (preanhepatic), large-volume blood loss and further fluid shift resulting from drainage of ascites may occur. During phase II (anhepatic) a major reduction in venous return and therefore cardiac output may occur if (depending on surgical technique) the inferior vena cava, portal vein, and hepatic artery are cross-clamped. Crystalloid and colloid infusion may be required with vasopressors to maintain arterial pressure during this phase, although excessive volume administration risks right heart failure after later unclamping. Absent citrate and lactate metabolism during this phase contributes to acidosis, hypocalcemia, and hypomagnesemia. On reperfusion and unclamping, cold, acidotic, hyperkalemic fluid is released into the circulation. Preparation for this must include normalizing pH and maintaining plasma K^+ in the low-normal range during phase II. This may require Ca^+, insulin-dextrose, hyperventilation, and even $NaHCO_3$ treatment. Phase III (reperfusion) leads to an acute rise in CVP, possibly with hepatic congestion and right heart strain. Systemic vasodilation and cardiac suppression may occur, leading to hypotension requiring vasopressor or inotrope support. If not given already, a bolus of $CaCl_2$ should be used to prevent hyperkalemia-related arrhythmias. Subsequent uptake of K^+ by a working graft may then require aggressive replacement. Ongoing infusion of fluids, red cells, and blood products should be guided by clinical blood loss, maintaining a hematocrit of 26% to 32% and addressing coagulopathy as guided by near-patient tests of clotting.

Chapter 60

Perioperative Acid-Base Balance

PATRICK J. NELIGAN • CLIFFORD S. DEUTSCHMAN

KEY POINTS

- The presence of a significant acid-base abnormality often signals a sinister underlying problem.
- All acid-base abnormalities result from alterations in the dissociation of water.
- Only three factors independently affect acid-base balance—the partial pressure of carbon dioxide in the arterial blood (Pa_{CO_2}), the strong ion difference (SID), and the total concentration of weak acids (A_{TOT}).
- Respiratory acidosis and alkalosis are caused by hypercarbia and hypocarbia, respectively.
- Metabolic acidosis is caused by decreased SID or increased A_{TOT}. Decreased SID results from accumulation of metabolic anions (shock, ketoacidosis, and renal failure), hyperchloremia, and free water excess. Increased A_{TOT} results from hyperphosphatemia.
- Metabolic alkalosis is caused by increased SID or decreased A_{TOT}. SID increases in response to sodium gain, chloride loss, or free water deficit. A_{TOT} decreases in hypoalbuminemia and hypophosphatemia. This is particularly common in critical illness.
- Most acid-base disorders are treated by elimination of the cause.

WHY IS ACID-BASE BALANCE IMPORTANT?

The human body is composed principally of water, partitioned into intracellular and extracellular compartments. The electrolyte composition of each of these spaces is tightly controlled to maintain homeostasis. Alterations in the relative concentrations of electrolytes and of carbon dioxide (CO_2) affect the tendency of water to autoionize into its component parts: hydrogen and hydroxyl ions. The hydrogen ion concentration is conventionally measured as pH, the negative logarithmic value of its concentration. Deviations in extracellular pH away from the resting value of 7.4 have long been associated with acute and critical illness. Such deviations are known as acid-base abnormalities.[1-3] The detection, interpretation, and treatment of acid-base abnormalities have become a core element of clinical care.[4]

All acid-base abnormalities result from changes in the local concentration of strong ions, weak acids, and CO_2.

This chapter first looks at the basic chemistry behind acid-base balance. From there, we explain the various acid-base abnormalities encountered in clinical practice. Subsequently, we explore several different, although interconnected, approaches to acid-base abnormalities that are in widespread use. These approaches can be roughly described as descriptive, based on changes associated with the Henderson-Hasselbalch equation; semiquantitative, based on calculations; and quantitative, based on physical chemistry. Finally, we address acid-base abnormities specific to the practice of anesthesiology in the perioperative and critical care setting.

WHAT ARE ACIDS AND BASES?

The concept of acids and bases is relatively new. In the early part of the twentieth century, it was known that the CO_2 content of the blood decreased in critically ill patients. As early as 1831, O'Shaughnessy identified loss of "carbonate of soda" from the blood as a fundamental disturbance in patients dying of cholera. L.J. Henderson, in 1909, coined the term "acid-base balance."[5] He was able to define this process in terms of carbonic acid equilibrium. Henderson's work was later refined by Hasselbalch in 1916.[6] Their method described acid-base balance in terms of the hydration equation for CO_2.[7]

$$CO_2 + H_2O \rightarrow H_2CO_3 \rightarrow H^+ + HCO_3^-$$

$$pH = pK_a + \log\ [HCO_3^-] / [H_2CO_3]$$

$$\text{Total } CO_2 = [HCO_3^-] + [\text{Dissolved } CO_2] + [\text{Carbamino } CO_2] + [H_2CO_3]$$

$$\approx P_{CO_2} \times 0.03 \text{ mmol } CO_2/\text{L/mm Hg}$$

So, substituting into the foregoing equation:

$$pH = 6.1 + \log [HCO_3^-] / P_{CO_2} \times 0.03$$

This is the Henderson-Hasselbalch equation.

Because the human body contains a large quantity of water, the physical properties of water have enormous implications for maintenance of homeostasis. Water is a simple triatomic molecule. Its chemical formula is H_2O, and its structural formula is H-O-H. The charge distribution of each covalent bond is unequal, and the molecule has a polar conformation and an H-O-H bond angle of 105 degrees. Water molecules attract, and form hydrogen bonds, with one another. Consequently, water has a high surface tension, a low vapor pressure, a high specific heat capacity, a high heat of vaporization, and a high boiling point.

Water molecules are in continual motion. Occasionally a collision generates sufficient energy to transfer a proton from one water molecule to another. Thus, water is always slightly dissociated into a negatively charged hydroxyl (OH^-) ion and a positively charged hydronium (H_3O^+) ion. Conventionally, this self-ionization of water is written as follows:

$$H_2O \leftrightarrow H^+ + OH^-$$

The symbol H^+ is convenient because, although protons dissociating from water have many aliases (such as H_3O^+ and $H_9O_4^+$), most physicians and chemists refer to them as hydrogen ions.

The self-ionization of water is miniscule. In pure water at 25° C, the $[H^+]$ and $[OH^-]$ are 1.0×10^{-7}mmol/L. The tendency for water to dissociate into its component parts is represented by the following expression:

$$K_{eq}H_2O = [H^+][OH^-]$$

The molarity of water is extremely high—55.5M ("there is a lot of water in water"). Because the concentration of water and the K_{eq} are constants, the ion-product dissociation constant for water can be expressed as follows:

$$K_{eq}H_2O = K_{eq}(55.5) = K_w = [H^+][OH^-]$$

The implication is that the product of the concentrations of hydroxyl and hydrogen is constant, so when the concentration of hydrogen ions increases, a concomitant decrease occurs in the concentration of hydroxyl ions, and vice versa.

Pure water is considered neutral because the relative concentrations of hydrogen and hydroxyl are equal at 1.0×10^{-7}mmol/L. A solution is considered *acidic* if the concentration of hydrogen ions exceeds that of hydroxyl ions ($[H^+] > 1.0 \times 10^{-7}$mmol/L, $[OH^-] < 1.0 \times 10^{-7}$mmol/L). A solution is considered *alkaline* if the hydroxyl ion concentration exceeds the hydrogen ion concentration.

Svante Arrhenius (1859 to 1927) established the foundations of acid-base chemistry in 1903. In an aqueous solution, an Arrhenius acid is any substance that delivers a hydrogen ion into the solution.[1] A base is any substance that delivers a hydroxyl ion into the solution. Because of its high dielectric constant, water is a highly ionizing solution. Substances with polar bonds will dissociate into their component parts (dissolve) in water. Brønsted and Lowry (BL) independently advanced this concept using slightly different terminology: an acid is a proton donor, a base a proton acceptor. Water itself is amphoteric, and it can act as either an acid or as a base. Thus, when hydrochloric acid (HCl) is dissolved in water, chloride (Cl^-), the acid, donates a proton to water, the base. Similarly, when potassium hydroxide (KOH) is dissolved in water, potassium (K^+), the base, receives a hydrogen ion from water, the acid or proton donor.

The degree of dissociation of substances in water determines whether they are strong acids or strong bases. Lactic acid, which has an ion dissociation constant (pK_a) of 3.4, is completely dissociated at physiologic pH, and is a strong acid. Conversely, carbonic acid, which has a pK_a of 6.4, is incompletely dissociated, and is a weak acid. Similarly, ions, such as sodium (Na^+), potassium (K^+), and Cl^-, which do not easily bind other molecules, are considered strong ions—they exist free in solution. As each Na^+ delivers a hydroxyl moiety into extracellular fluid (ECF), it is functionally a base because are all cations. As each Cl^- delivers a hydrogen moiety into ECF, it is functionally an acid because are all anions. The hydrogen and hydroxyl ions delivered in this way bind to one another, forming water molecules, and relatively few free hydrogen or hydroxyl ions remain free in solution.

$$HCl + H_2O \rightarrow H_3O^+ + Cl^-$$

In this reaction, HCl acts as a BL acid and water as a BL base.

$$NaOH + H_2O \rightarrow H_2O + OH^- + Na^+$$

In this reaction, water acts as a BL acid and Na^+ as a BL base.

$$OH^- + Na^+ + H_3O^+ + Cl^- = Na^+ + Cl^- + H_2O$$

Because of electrical neutrality, the hydrogen and hydroxyl ions delivered by Cl^- and Na^+ become water.

In summary, all acid-base reactions in the human body relate to the presence of charged particles within an aqueous environment. In the following section, we discuss how the components of ECF influence the acid-base status of the body, as measured by clinicians. We subsequently explain different acid-base abnormalities and the tools used to identify them. These approaches are neither distinct from one another nor scientifically incompatible.

WHAT DETERMINES THE ACIDITY OR ALKALINITY OF A SOLUTION?

Because all acid-base reactions are based on the principles of physical chemistry, three simple rules must be followed[8]:

1. *Electrical neutrality*: In aqueous solutions, in any compartment, the sum of all the positively charged ions must equal the sum of all the negatively charged ions.

2. *Dissociation equilibriums*: The dissociation equilibriums of all incompletely dissociated substances, as derived from the law of mass action, must be satisfied at all times.
3. *Mass conservation*: The amount of a substance in a given compartment remains constant unless it is added, removed, generated, or destroyed. The total concentration of an incompletely dissociated substance is the sum of concentrations of its dissociated and undissociated forms.

To determine the acid-base status of a fluid, all substances to which these rules could be applied must be accounted for. Fundamentally this involves counting up all the charges (and hence hydrogen and hydroxyl ions) delivered by strong cations (bases) and strong anions (acids), weak acid buffers, and CO_2.[9] A discussion of key groups follows.

STRONG IONS

The first group of ions, the strong ions, dissociates completely. The most abundant strong ions in the extracellular space are Na^+ and Cl^-. Other important strong ions include K^+, sulfate (SO_4^{2-}), magnesium (Mg^{2+}), and calcium (Ca^{2+}). In a solution containing strong ions, created, for example, using specified concentrations of NaOH and HCl, the hydrogen ion concentration can be calculated by solving for electric neutrality:

$$([Na^+] - [Cl^-]) + ([H^+] - [OH^-]) = 0$$

This creates two separate simultaneous equations:

$$[H^+] = \sqrt{K_w + ([Na^+] - [Cl^-])^2/4} - ([Na^+] - [Cl^-])/2$$

and

$$[OH^-] = \sqrt{K_w + ([Na^+] - [Cl^-])^2/4} - ([Na^+] - [Cl^-])/2$$

These equations tell us that hydrogen and hydroxyl concentrations are determined by K_w (water dissociation constant), and the difference in charge between Na^+ and Cl^-. Because the former is constant, in this system ($[Na^+] - [Cl^-]$) must determine $[H^+]$ and $[OH^-]$. Given that the concentrations of both Na^+ and Cl^- are known, the net positive charge minus net negative charge can be quantified. It is the strong ion difference (SID).[3] Logically, in any solution, the sum total of the charges imparted by strong cations minus the charges from strong anions will represent the SID. SID independently influences hydrogen ion concentration (Fig. 60-1). SID is always positive in human ECF.

$$SID = \left([Na^+] + [K^+] + [Ca^{2+}] + [Mg^{2+}]\right) - ([Cl^-] + [A^-])$$
$$= 40\text{–}44 \text{mEq/L}$$

Hydroxyl ions almost always exceed hydrogen ions quantitatively in solution. The relationship between SID and $[H^+]$ is nonlinear in these conditions. Any change in SID will change both $[H^+]$ and $[OH^-]$ concentrations. Because of the K_w, this relationship is inverse: as $[H^+]$ increases, $[OH^-]$ decreases (see Fig. 60-1). SID is an independent variable, and $[H^+]$ and $[OH^-]$ are dependent, meaning that the addition of hydrogen ions alone (without strong corresponding anions) cannot influence the pH of the solution.

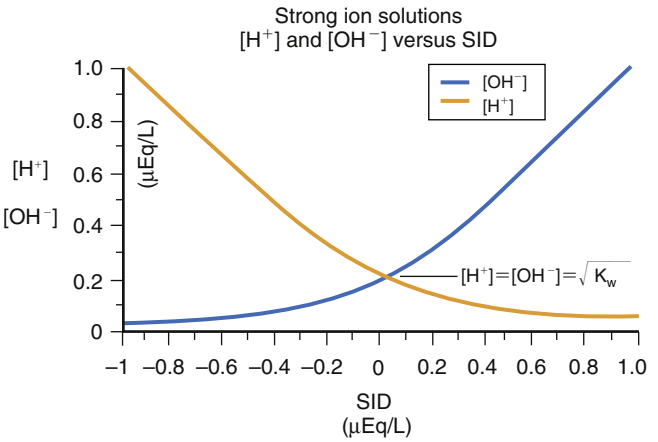

Figure 60-1. Effect of changes in the strong ion gap (SID) on hydrogen and hydroxyl ion concentration. *(Modified from Stewart PA: Modern quantitative acid-base chemistry,* Can J Physiol Pharmacol *61:1444-1461, 1983.)*

WEAK ACID "BUFFER" SOLUTIONS

The degree of water dissociation, and the hydrogen ion concentration, is also influenced by charges derived from weak acids. These acids are partially dissociated compounds whose degree of dissociation is determined by the prevailing temperature and pH. The predominant molecules in this group are albumin and phosphate. Stewart used the term A_{TOT} to represent the total concentration of weak anions or acids that influence acid-base balance.[8]

The acid HA only partly dissociates, represented by the equilibrium:

$$[HA] = K_A [H^+][A^-]$$

K_A is the weak acid dissociation constant. If we assume that HA and A^- play no further part in this reaction (the law of mass conservation), the amount of A^- present in the solution must equal the amount initially present, so:

$$[HA][A^-] = [A_{TOT}]$$

where $[A_{TOT}]$ is the total weak acid concentration.

To calculate the effect of weak acid dissociation on $[H^+]$, we must take into account water dissociation and electrical neutrality:

$$[H^+][OH^-] = K'_w \text{ (water dissociation)}$$
$$[SID] + [H^+] - [A^-] - [OH^-] = 0 \text{ (electrical neutrality)}$$

These four simultaneous equations determine the $[H^+]$ in this solution containing strong ions and weak acids. SID and A_{TOT} are independent variables, whose concentration

was determined during the production of the system. K_w and K_A are constants. Consequently, the other variables [HA], [H^+], [OH^-], and [A^-] must adjust to satisfy the foregoing equations. They are dependent variables.

CARBON DIOXIDE

Along with strong ions and weak bases, ECF contains CO_2. The concentration of CO_2 in ECF is determined by tissue production and alveolar ventilation. CO_2, when in solution, exists in four forms: CO_2 [denoted CO_2(d)], carbonic acid (H_2CO_3), bicarbonate ions (HCO_3^-), and carbonate ions (CO_3^{2-}).

The concentration of CO_2(d) is determined by the solubility coefficient of CO_2 (S_{CO_2}), which depends on body temperature, P_{CO_2}, and other factors. Several equilibrium equations can be derived from the hydration of CO_2:

$$[CO_2\,(d)] = [S_{CO_2}] \times P_{CO_2}$$

The tendency for CO_2 to hydrate to H_2CO_3, and subsequently dissociate to H^+ and HCO_3^-, is reflected by this equation:

$$[CO_2\,(d)] \times [OH^-] = K_1 \times [HCO_3^-]$$

These equations can be combined together and with water equilibrium to the following:

$$[H^+] \times [HCO_3^-] = K_C \times P_{CO_2}$$

HCO_3^- also dissociates to release hydrogen ions and carbonate, the equilibrium reaction for which is represented by this equation:

$$[H^+] \times [CO_3^{2-}] = K_3\,[HCO_3^-]$$

Factors Independently Influencing Water Dissociation

Now that we have looked at the different factors that may influence the concentration of hydrogen ions in a solution, strong ions, weak acids, and CO_2, we can combine the derived equations to solve for [H^+]:

1. Water dissociation equilibrium: $[H^+] \times [OH^-] = K_w$
2. Weak acid dissociation equilibrium: $[H^+] \times [A^-] = K_A \times [HA]$
3. Conservation of mass for weak acids: $[HA] + [A^-] = [A_{TOT}]$
4. HCO_3^- formation equilibrium: $[H^+] \times [HCO_3^-] = K_C \times P_{CO_2}$
5. Carbonate ion formation equilibrium: $[H^+] \times [CO_3^{2-}] = K_3 \times [HCO_3^-]$
6. Electrical neutrality: $[SID] + [H^+] - [HCO_3^-] - [A^-] - [CO_3^{2-}] - [OH^-] = 0$

There are six independent simultaneous equations, and just six unknown, dependent variables determined by them: [HA], [A^-], [HCO_3^-], [CO_3^{2-}], [OH^-], and [H^+]. The three known independent variables are [SID], [A_{TOT}], and P_{CO_2}.

Solving the equations for [H^+]:

$$[SID] + [H^+ - K_C \times P_{CO_2} / [H^+] - K_A \times [A_{TOT}] / (K_A + [H^+]) - K_3 \times K_C P_C / [H^+]^2 - K_w' / [H^+] = 0$$

In other words, [H^+] is a function of SID, A_{TOT}, P_{CO_2}, and several constants. All other variables, most notably [H^+], [OH^-], and [HCO_3^-], are dependent and cannot independently influence acid-base balance.

ACID-BASE ABNORMALITIES

The value of the physical chemistry approach (Stewart approach) is that it allows us to use a simple model for understanding acid-base disturbances because all abnormalities can be explained in terms of SID, A_{TOT}, or P_{CO_2}.[8] Traditionally, acid-base disturbances have been classified as resulting from either alterations in arterial carbon dioxide (Pa_{CO_2}) tension (respiratory acidosis or alkalosis) or alterations in blood chemistry (metabolic acidosis or alkalosis).[10] This classification remains useful, although respiratory or metabolic abnormalities rarely occur independently of one another.

RESPIRATORY ACID-BASE ABNORMALITIES

Respiratory Alkalosis

Respiratory alkalosis occurs when an acute decrease in Pa_{CO_2} results from hyperventilation. The patient presents with symptoms and signs of vasoconstriction: lightheadedness, visual disturbances, dizziness, and perhaps hypocalcemia from increased binding of calcium to albumin. The hypocalcemia is caused by an increase in the available negative charge on albumin in alkaline states. Acute hypocalcemia is associated with parasthesias and tetany.

Respiratory Acidosis

Respiratory acidosis occurs in the presence of an acute increase in Pa_{CO_2}, usually associated with respiratory failure. This may result from problems with the following':

- Central ventilator control—such as toxicity from anesthetic drugs, benzodiazepines, or opioids, stroke, spinal cord injury
- Peripheral ventilator control—such as myasthenia gravis, poliomyelitis, polymyopathy, or neuromuscular blockade
- Ventilation-perfusion mismatch—associated with pneumothorax, pleural effusion, atelectasis, pneumonia, or pulmonary edema

Clinically, patients have signs of CO_2 retention: cyanosis, vasodilatation, and narcosis.

Respiratory acidosis causes a rapid increase in [H^+]. Compensation for hypercarbia is slow, requiring increased urinary excretion of Cl^-,[8] and pH falls rapidly. A concomitant increase in the serum HCO_3^- occurs and reflects a higher total CO_2 load. The acuity of respiratory failure can be deduced by looking at the relative ratio of CO_2 to HCO_3^- (Table 60-1). Many investigators have suggested that respiratory acidosis may not necessarily be harmful. There has been extensive clinical experience

TABLE 60-1 CHANGES IN $Paco_2$ AND $[HCO_3^-]$ IN RESPONSE TO ACUTE AND CHRONIC ACID-BASE DISTURBANCES*

Disturbance	$[HCO_3^-]$ versus $Paco_2$
Acute respiratory acidosis	$\Delta HCO_3^- = 0.2\ \Delta Paco_2$
Acute respiratory alkalosis	$\Delta HCO_3^- = 0.2\ \Delta Paco_2$
Chronic respiratory acidosis	$\Delta HCO_3^- = 0.5\ \Delta Paco_2$
Metabolic acidosis	$\Delta Paco_2 = 1.3\ \Delta HCO_3^-$
Metabolic alkalosis	$\Delta Paco_2 = 0.75\ \Delta HCO_3^-$

Modified from Narins RB, Emmett M: Simple and mixed acid-base disorders: a practical approach, Medicine (Baltimore) *59:161-187, 1980.*

Δ, Change in value; *$[HCO_3^-]$*, concentration of bicarbonate ion; *$Paco_2$*, partial pressure of arterial carbon dioxide.

* HCO_3^- is measured in mEq/L or mmol/L and $Paco_2$ is measured in mm Hg.

with "permissive hypercapnia" for acute respiratory failure, which appears to be well tolerated,[11,12] and it may indeed be beneficial.[13]

METABOLIC ACID-BASE ABNORMALITIES

Metabolic acid-base abnormalities are caused by alterations in the SID or A_{TOT}, or both. An increase in the SID causes alkalemia; a decrease in the SID causes acidemia. The alteration may be caused by a change in the total or relative concentration of strong ions. For example, a decrease in the SID (i.e., more anions relative to cations) causes acidosis; this may occur because of a net increase in anions (e.g., hyperchloremia, lactatemia) or an increase in the volume of distribution of the same quantity of ions (e.g., dilutional acidosis) (Table 60-2).

Metabolic acidosis is of clinical significance for two reasons: disorders arising from the acidosis itself and disorders arising from the cause of the acidosis. Acidosis is associated with alterations in transcellular ion pumps and increased ionized calcium. The results are vasodilation, diminished muscular performance (particularly myocardial), and arrhythmias. The oxyhemoglobin dissociation curve shifts rightward to increase oxygen offload into the tissues (see also Chapter 61). Rapid-onset metabolic acidosis may be associated with profound hypotension, cardiac arrhythmias, and death. The malignancy of the acidosis is strongly related to the underlying disease process; lactic acidosis caused by circulatory shock is more malevolent than is hyperchloremic acidosis resulting from excessive administration of 0.9% saline solution.[13] The body is hyperresponsive to acidosis. Increasing hydrogen ion content in cerebrospinal fluid activates the respiratory center to stimulate respiration. Alveolar ventilation increases, thus reducing both arterial CO_2 content and total-body $[H^+]$. HCO_3^- concentration simultaneously decreases secondary to buffering activity and to the reduction in total CO_2. As a result, the blood pH falls less in metabolic acidosis than in respiratory acidosis.

Metabolic alkalosis rarely occurs as a result of acute illness. Symptoms and signs of metabolic alkalosis include widespread vasoconstriction, lightheadedness, tetany, and paresthesia. The main compensatory mechanism is hypoventilation, which may delay weaning from mechanical ventilation in critically ill patients.

In normal ECF, the SID is 44 mEq, and this positive charge is balanced principally by weak acids. Anything

TABLE 60-2 CLASSIFICATION OF PRIMARY ACID-BASE ABNORMALITIES

Abnormality	Acidosis	Alkalosis
Respiratory	Increased P_{CO_2}	Decreased P_{CO_2}
Metabolic		
Abnormal SID		
Caused by water excess or deficit	Water excess = dilutional ↓ SID + ↓ $[Na^+]$	Water deficit = contraction ↑ SID ↑ $[Na^+]$
Caused by electrolytes	Chloride excess	Chloride deficit
Chloride (measured)	↓ SID ↑ $[Cl^-]$	↑ SID + ↓ $[Cl^-]$
Other (unmeasured) anions, such as lactate and keto acids	↓ SID ↑ $[UMA^-]$	—
Abnormal A_{TOT}		
Albumin [Alb]	↑ [Alb] (rare)	↓ [Alb]
Phosphate [Pi]	↑ [Pi]	

Modified from Fencl V, Jabor A, Kazda A, Figge J: Diagnosis of metabolic acid-base disturbances in critically ill patients, Am J Respir Crit Care Med *162:2246-2251, 2000.*

[Alb], Concentration of serum albumin; *A_{TOT}*, the total concentration of weak ions; *$[Cl^-]$*, concentration of chloride ions; *$[Na^+]$*, concentration of sodium ions; *P_{CO_2}*, partial pressure of carbon dioxide; *[Pi]*, concentration of inorganic phosphate; *SID*, strong ion difference; *$[UMA^-]$*, unmeasured anions; *↑*, increased; *↓*, decreased.

that increases the SID will increase the relative concentration of cations to anions and alkalinize the solution. Anything that decreases the SID will decrease the relative concentration of cations to anions and will acidify the solution. If the extracellular compartment volume is expanded with free water (no electrolytes), the components of the system are diluted, with relatively more dilution of more abundant moieties (Na^+ rather than Cl^-); the results are a reduction in SID and *dilutional acidosis*. This condition rarely occurs in the presence of normally functioning kidneys. Conversely, if free water is removed from the ECF (e.g., from increased evaporative losses), the relative concentration of charged moieties increases, and this concentration affects more abundant ions and compounds (Na^+ rather than Cl^-). The SID increases, and *contraction alkalosis* occurs (see Table 60-2).

In perioperative medicine, "normal saline" (NaCl 0.9%), containing 154 mEq of Na^+ and 154 mEq of Cl^-, is commonly used. The SID of this solution is 0. Functionally, however, each liter of normal saline delivers approximately 50 mmol of hydrochloric acid into ECF. The effects are a net reduction in the relative concentration of Na^+ to Cl^-, a reduction in SID, and *hyperchloremic acidosis*.[14]

Any process that removes Cl^- without Na^+, such as aggressive nasogastric suctioning with a loss of HCl, causes metabolic alkalosis (hypochloremic alkalosis) because of an increase in SID. The alkalosis is caused by Cl^- loss, which obeys the law of conservation of mass (i.e., a finite quantity is available in the ECF), and not by hydrogen ions, whose source, water, is unlimited. Severe diarrhea, which is associated with loss of both K^+ and Na^+, reduces the SID and is associated with metabolic acidosis. Aggressive use of diuretics causes a net loss of free water over Na^+ and Cl^- and leads to contraction alkalosis.

The most significant form of metabolic acidosis is associated with a net gain of "unmeasured" anions (i.e., electrolytes not conventionally measured on serum chemistry analysis) and, consequently, a decreased SID:

1. In dysoxia and states of severe stress, lactate is produced, thus reducing the SID and causing acidosis.
2. In out of control diabetes (ketoacidosis) or during starvation, β-hydroxybutyrate and acetoacetate are produced, thereby reducing the SID and causing acidosis (see also Chapter 39).
3. In severe renal failure, SO_4^{2-} and phosphate (PO_4^{3-}) ("fixed renal acids") are not excreted, with resulting acidosis (see also Chapter 74).

The total weak acid pool, principally serum albumin and phosphate, is also an important determinant of acid-base status. Hyperphosphatemia is associated with the acidosis of renal failure. Hypoalbuminemia is common in critical care (see also Chapter 101). Hypoalbuminemia decreases A_{TOT} and is associated with metabolic alkalosis.[15,16] A strong association exists between hypoalbuminemia and severity of critical illness. Albumin deficits result from four different homeostatic changes: (1) reprioritization of hepatic protein production favoring production of acute phase reactants and limiting albumin synthesis, (2) capillary leak with loss of albumin into the interstitium, (3) breakdown of preexisting albumin so that its constituent amino acids can be used for protein synthesis, and (4) replacement of plasma with protein-free fluids.

The impact of hypoalbuminemia on acid-base balance is important. Stewart's original theory was subsequently modified by Fencl and Figge.[17] The serum albumin concentration is the core negative charge offsetting the net positive charge of the SID.[15] Consequently, the presence of hypoalbuminemia may mask the detection of acidosis[18] that is caused, for example, by unmeasured anions (UMAs), when using conventional tools of acid-base chemistry: pH, HCO_3^-, base deficit, and the anion gap.[19] The presence of hypoalbuminemia has significant implications, not least for its association with adverse outcomes.[20] Hyperalbuminemia is very unusual; in cholera, when associated with hemoconcentration, it is linked with acidosis.[21]

REGULATION OF ACID-BASE BALANCE

Extracellular hydrogen ion concentration appears to be tightly controlled by the body. In all probability this regulation reflects a need to prevent rapid changes in extracellular electrochemical balance from interfering with the function of transcellular ion pumps. To prevent fluctuation, various intracellular and extracellular buffering systems have evolved. A *buffer* is a solution of two or more chemicals that minimizes changes in pH in response to the addition of an acid or base. Ideally, a buffer has a pK_a that is equal to the pH, and an ideal body buffer has a pK_a between 6.8 and 7.2. Most biologically salient buffers are weak acids.

The control of hydrogen ion concentration should be viewed in terms of volatile and metabolic acids. The major source of acid in the body is the volatile acid CO_2, which produces 12,500 mEq of H^+ a day, most excreted by the lungs. In contrast, only 20 to 70 mEq of hydrogen ion–promoting anions are excreted daily through the kidney. Volatile acid is principally buffered by hemoglobin. Deoxygenated hemoglobin is a strong base, and there would be a huge rise in the pH of venous blood if hemoglobin did not bind the hydrogen ions produced in oxidative metabolism.

CO_2 easily passes through cell membranes. Within the erythrocyte, CO_2 combines with H_2O, under the influence of the enzyme carbonic anhydrase, to form H_2CO_3, which ionizes to hydrogen and HCO_3^-. Hydrogen ions bind to histidine residues on deoxyhemoglobin, and HCO_3^- is actively pumped out of the cell. Cl^- moves inward to maintain electroneutrality (the Cl^- shift) and to ensure the continued production of carbonic acid. CO_2 is also buffered directly by hemoglobin (carbaminohemoglobin) and by plasma proteins (carbamino proteins). Venous blood contains 1.68 mmol/L of extra CO_2 over arterial blood: 65% as HCO_3^- and H^+ bound to hemoglobin, 27% as carbaminohemoglobin (CO_2 bound to hemoglobin), and 8% dissolved.

When respiratory failure occurs, the principal CO_2 buffering system, hemoglobin, becomes overwhelmed, leading to the rapid development of acidosis (see also Chapter 103). In response, the kidney excretes an increased Cl^- load, using ammonium (NH_4^+), a weak cation, for electrochemical balance. ECF osmolality is maintained. This process is conventionally referred to as metabolic compensation. Chronic respiratory acidosis increases total-body CO_2 content, reflected principally by an increase in serum HCO_3^-. Hypercapnia increases cerebrospinal fluid HCO_3^-, thus reflecting an overall increase in total CO_2 load. Compensation for this hypercarbia is a reduction in cerebrospinal fluid Cl^-,[22] as well as an increase in cerebrospinal fluid SID.[23-25] This is probably controlled by active transport mechanisms across the blood-brain barrier or at the level of the choroid plexus and can be blocked by furosemide and acetazolamide.[26-29] The result is a rightward shift in the P_{CO_2} response curve: the respiratory center responds to hypercarbia by increasing respiratory drive at a higher P_{CO_2} level than under normal conditions. Mathematically,

$$\Delta HCO_3^- = 0.5\,\Delta Pa_{CO_2} \text{ in mm Hg}$$ [30]

HCO_3^- is a dependent variable that increases or decreases with P_{CO_2}. The rate of conversion of CO_2 to HCO_3^- depends on carbonic anhydrase activity and occurs slowly. It is possible mathematically to determine whether an increase in Pa_{CO_2} is acute or long-standing (see Table 60-1). In acute respiratory acidosis,

$$\Delta HCO_3^- = 0.2\,\Delta Pa_{CO_2}$$

Metabolic acid is buffered principally by increased alveolar ventilation, thus producing respiratory alkalosis, and extracellular weak acids. These weak acids include plasma proteins, phosphate, and HCO_3^-. The HCO_3^- buffering system (92% of plasma buffering and 13% overall) is probably the most important extracellular buffer.

The pK_a of HCO_3^- is relatively low (6.1), but the system derives its importance from the enormous quantity of CO_2 present in the body. The coupling of HCO_3^- and H_2O produces CO_2, which is then excreted through the lungs and increases alveolar ventilation. Physicians must be aware of the importance of this compensatory mechanism. For example, anesthetized or critically ill patients receiving controlled mechanical ventilation lose the capacity to regulate their own P_{CO_2}. Consequently, the combination of acute metabolic and respiratory acidosis can cause a devastating reduction in pH.

The major effect of the kidney on acid-base balance relates to renal handling of Na^+ and Cl^- ions. Because dietary intake of Na^+ and Cl^- is roughly equal, the kidney excretes a net Cl^- load, using NH_4^+, a weak cation, to neutralize urinary chloride electrochemically.[2]

In metabolic acidosis, the kidneys preferentially excrete Cl^-. In metabolic alkalosis, Cl^- is retained, and Na^+ and K^+ are excreted. The presence of HCO_3^- in the urine reflects the need to maintain electrical neutrality. Abnormalities in the renal handling of Cl^- may be responsible for several inherited acid-base disturbances. In renal tubular acidosis, patients are unable to excrete Cl^- in proportion to Na^+.[31] The diagnosis can be made by observing hyperchloremic metabolic acidosis with inappropriately low levels of Cl^- in the urine. The urinary SID is positive. If the urinary SID is negative, the process is not of renal origin. Similarly, pseudohypoaldosteronism appears to result from high reabsorption of chloride.[32] Bartter syndrome is caused by a mutation in the gene encoding the Cl^- channel—*CLCNKB*—that regulates the Na-K-2Cl cotransporter (NKCC2).[33]

The other causes of hyperchloremic metabolic acidosis are gastrointestinal losses (diarrhea, small bowel or pancreatic drainage), parenteral nutrition, excessive administration of saline, and the use of carbonic anhydrase inhibitors.

ANALYTIC TOOLS USED IN ACID-BASE CHEMISTRY

Acid-base balance is a core component of the clinical evaluation of acutely and critically ill patients. Arterial blood gas analysis provides immediate information on the status of the patient's respiratory system and ascertains whether or not a state of acidosis or alkalosis is present. By applying a variety of empiric "rules," the information contained in arterial blood gas analysis is often sufficient to identify the presence, cause, and progression of a disease (see also Chapters 44 and 51). The diagnostic sensitivity of arterial blood gas analysis is augmented when a serum chemistry panel, glucose and lactate determinations, and urinary ketone measurements are added.

Several different approaches to acid-base balance are in widespread use.[34] These can be described as follows: descriptive, based on changes in the Henderson-Hasselbalch equation; semiquantitative, based on calculations and nomograms; or quantitative, based on physical chemistry. The descriptive approach uses the interrelationship between P_{CO_2} and $[HCO_3^-]$ to detect and diagnose acid-base abnormalities. An extension of this is the anion gap. The semiquantitative approach includes the buffer-base concept, the standardized base deficit-excess, and the base-deficit gap. The quantitative approach uses SID and A_{TOT} and is quantified using the strong ion gap (SIG).

DESCRIPTIVE APPROACH: CARBON DIOXIDE–BICARBONATE (BOSTON APPROACH)

Schwartz and colleagues at Tufts University in Boston developed a descriptive approach to acid-base chemistry. Their formulation uses acid-base maps and the mathematic relationship between CO_2 tension and serum HCO_3^- (or total CO_2), derived from the Henderson-Hasselbalch equation to classify acid-base disturbances in terms of two independent variables: P_{aCO_2} and $[HCO_3^-]$.[35,36] To validate this approach, patients with known acid-base disturbances, at steady states of compensation, were evaluated. The degree of compensation, relative to what was considered normal, was measured for each disease state. The investigators described six primary states of acid-base imbalance by using linear equations or maps, relating hydrogen ion concentration to P_{CO_2} for respiratory disturbances, and P_{CO_2} to HCO_3^- concentration for metabolic disturbances (Fig. 60-2). For any given acid-base disturbance, an expected HCO_3^- concentration was determined. These maps and equations were then compiled into a series of mathematic rules (Box 60-1). For most simple disturbances, this is a reasonable approach. For example, in acute respiratory acidosis, the $[HCO_3^-]$ will increase by 1 mEq/L for every 10 mm Hg elevation in P_{aCO_2} greater than 40 mm Hg. In chronic respiratory acidosis, the $[HCO_3^-]$ will increase by 4 mEq/L for every

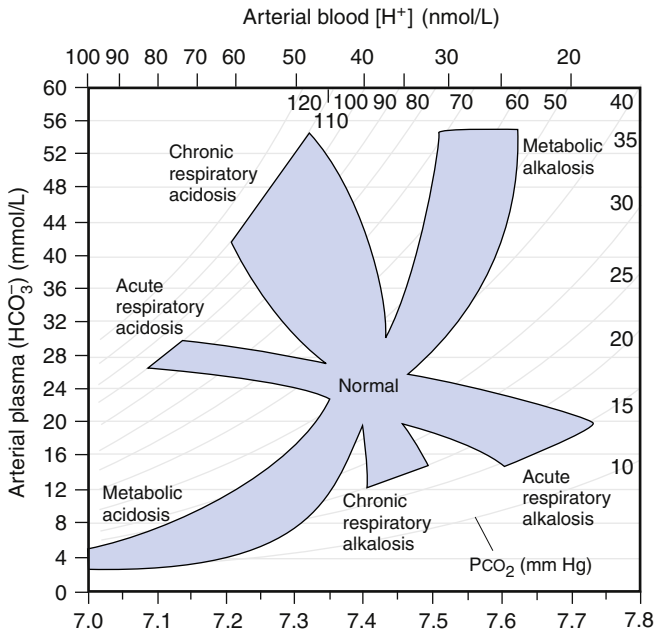

Figure 60-2. Acid-base nomogram using the Boston approach. Different acid-base disturbances can be distinguished based on the relative values of P_{CO_2} and HCO_3^-. *(Modified from Brenner BM, Rector FC:* The kidney, *ed 3. Philadelphia, 1986, Saunders, p 473.)*

BOX 60-1 ***The Descriptive (CO_2-HCO_3^-) Approach to Acid-Base Disorders***

RESPIRATORY DISORDERS

Acute Respiratory Acidosis

$$\text{Expected } [HCO_3^-] = 24 + [(\text{Measured } Paco_2 - 40)/10]$$

Chronic Respiratory Acidosis

$$\text{Expected } [HCO_3^-] = 24 + 4\ [(\text{Measured } Paco_2 - 40)/10]$$

Acute Respiratory Alkalosis

$$\text{Expected } [HCO_3^-] = 24 - 2\ [(40 - \text{Measured } Paco_2)/10]$$

Chronic Respiratory Alkalosis

$$\text{Expected } [HCO_3^-] = 24 - 5\ [(40 - \text{Measured } Paco_2)/10]\ (\text{range: } \pm 2)$$

METABOLIC DISORDERS

Metabolic Acidosis

$$\text{Expected } Paco_2 = 1.5 \times [HCO_3^-] + 8\ (\text{range: } \pm 2)$$

Metabolic Alkalosis

$$\text{Expected } Paco_2 = 0.7 \times [HCO_3^-] + 20\ (\text{range: } \pm 5)$$

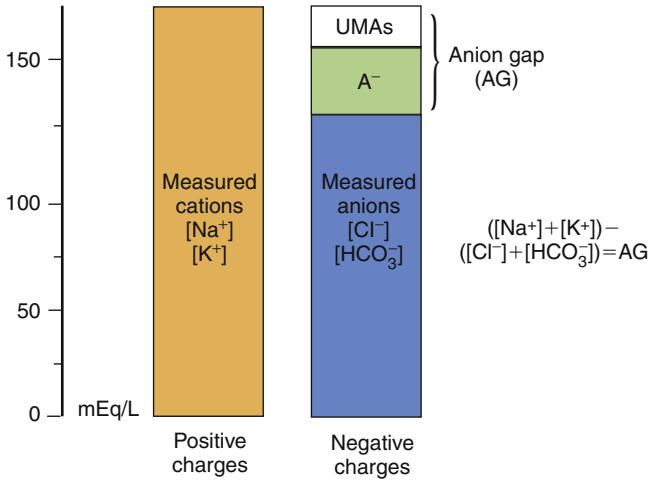

Figure 60-3. The anion gap. The anion gap represents the difference in charge between measured cations and measured anions. The missing negative charge is made up of weak acids (A^-), such as albumin and phosphate, and strong unmeasured anions (UMAs), such as lactate.

10 mm Hg elevation in $Paco_2$ greater than 40 mm Hg. In acute metabolic acidosis, the $Paco_2$ follows the 1.5 × $[HCO_3^-]$ plus 8 rule. In metabolic alkalosis, the expected $Paco_2$ follows the 0.7 × $[HCO_3^-]$ plus 20 rule.

Using these maps and equations and rules, physicians can determine the nature of most respiratory and metabolic acid-base disturbances and in a manner that is usually accurate. Although a mathematic relationship is in place, alterations in $[H^+]$ and $[HCO_3^-]$ do not reflect cause and effect. For example, chronic hypoventilation is associated with an increase in Pco_2 and $[HCO_3^-]$. Many physicians have incorrectly assigned the increase in $[HCO_3^-]$ as compensation for raised Pco_2. It is not. The increased HCO_3^- concentration reflects increased total CO_2 in the body.

Although the Pco_2-HCO_3^- approach is relatively accurate for most disturbances and is particularly useful for respiratory problems, it has several inherent pitfalls, particularly in relation to the metabolic component. First, the approach is not as simple as it seems. It requires the clinician to refer to confusing maps or to learn formulas and perform mental arithmetic. Second, the system neither explains nor accounts for many of the complex acid-base abnormalities seen in perioperative and critically ill patients, such as patients with acute acidosis in the setting of hypoalbuminemia, hyperchloremic acidosis, or dilutional acidosis or patients with lactic acidosis in the setting of chronic respiratory acidosis.

ANION GAP APPROACH

The most widely used tool for investigating metabolic acidosis is the anion gap, developed by Emmet and Narins in 1975.[37] It is based on the law of electrical neutrality. It is entirely consistent with the physical chemistry approach, described later, and is usually used alongside the Boston approach to acid-base balance. The system is based on data that were not easily available or known at the time of publication: the contribution to electrical neutrality ascribed to weak acids (phosphate and albumin) and UMAs. The sum of the difference in charge of the common extracellular ions reveals an unaccounted for "gap" of –10 to –12 mEq/L. Three variants of the anion gap are widely used (Fig. 60-3), and they depend on whether or not K^+ and lactate are included:

$$\text{Anion gap (simple)} = \left([Na^+] - ([Cl^-] + [HCO_3^-])\right)$$
$$= 12 \text{ to } 14 \text{ mEq/L}$$

$$\text{Anion gap (conventional)} = \left([Na^+] + [K^+] - ([Cl^-] + [HCO_3^-])\right)$$
$$= 14 \text{ to } 18 \text{ mEq/L}$$

$$\text{Anion gap (modern)} = \left([Na^+] + [K^+] - ([Cl^-] + [HCO_3^-] + [\text{Lactate}^-])\right)$$
$$= 14 \text{ to } 18 \text{ mEq/L}$$

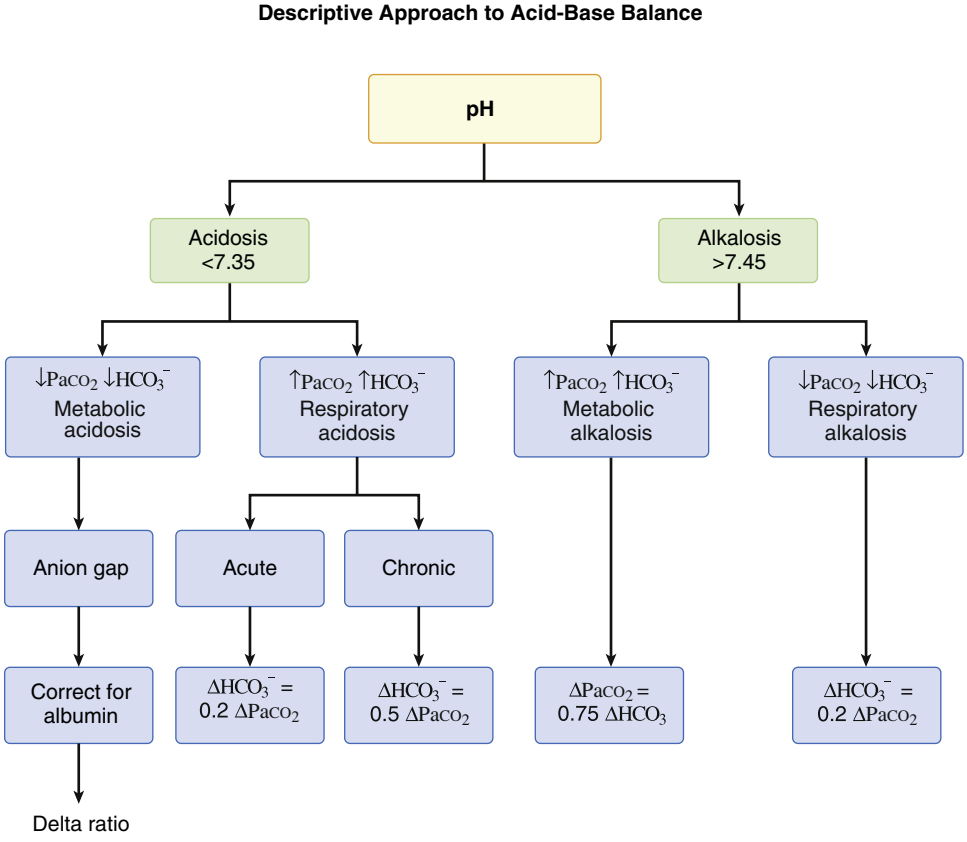
If the patient develops metabolic acidosis, and the gap "widens" to, for example, more than 20 mEq/L, then the acidosis is caused by UMAs: renal acids or ketones. If the gap does not widen, then the anions are being measured, and the acidosis has been caused by hyperchloremia (HCO_3^- cannot independently influence acid-base status) or lactate (if used). Although this is a useful tool, it is weakened by the assumption of what is or is not a "normal gap."[38] The anion gap frequently underestimates the extent of the metabolic disturbance.[18] Most critically ill patients are hypoalbuminemic, and many are also hypophosphatemic.[39] Consequently, the gap may be normal in the presence of UMAs. This was extensively studied by Fencl and Figge, who provided a variant known as the corrected anion gap[19]:

$$\text{Anion gap corrected (for albumin)} = \text{Calculated anion gap} + 2.5 \times (\text{Normal albumin g/dL} - \text{Observed albumin g/dL})$$

In this corrected form, the anion gap accurately quantifies metabolic acidosis, and it is useful for discriminating acidosis caused by UMAs from acidosis reflecting hyperchloremia in a previously healthy patient (e.g., in acute trauma). Moviat and colleagues demonstrated that the anion gap corrected for albumin accurately detects complex acid-base abnormalities in intensive care.[40]

Another version of the anion gap is the delta anion gap (Box 60-2), an approach that has successfully predicted adverse outcomes in critical illness.[41] Simply, if the anion gap is normal, or unchanged, and the HCO_3^- level falls, then the delta ratio will be less than 0.4, and hyperchloremic acidosis is present. A delta ratio between 1 and 2 is what one would expect from metabolic acidosis caused by UMAs or lactate. If the ratio is greater than 2, mixed acid-base abnormalities are present. Although, on the surface, this process is relatively simple, it assumes that the clinician knows the normal anion gap and HCO_3^- for that particular patient. In addition, it does not result in a clear diagnosis other than hyperchloremia. Figure 60-4 is a decision tree that uses this descriptive approach to acid-base balance.

BOX 60-2 *The Delta Anion Gap (Delta Ratio)*



$$\text{Delta ratio} = \Delta \text{ Anion gap} / \Delta [HCO_3^-] \text{ or } \uparrow \text{Anion gap} / \downarrow [HCO_3^-]$$

$$= \frac{\text{Measured anion gap} - \text{Normal anion gap}}{\text{Normal } [HCO_3^-] - \text{Measured } [HCO_3^-]}$$

$$= \frac{(\text{Anion gap} - 12)}{(24 - [HCO_3^-])}$$

SEMIQUANTITATIVE APPROACH: BASE DEFICIT OR EXCESS (COPENHAGEN)

In metabolic acidosis, the addition of routinely UMAs to the ECF results in a net gain of one hydrogen ion for each anion. This is "buffered" principally by HCO_3^-, such that each anion gained results in a fall in the HCO_3^-

Delta ratio	Clinical assessment
<0.4	Hyperchloremic normal AG acidosis
<1	High AG and normal AG acidosis
1 to 2	Pure anion gap acidosis Lactic acidosis: average value 1.6 DKA more likely to have a ratio closer to 1 because of urine ketone loss
>2	High AG acidosis and concurrent metabolic alkalosis or preexisting compensated respiratory acidosis

Figure 60-4. The descriptive ("Boston") approach to acid-base balance. *AG,* Anion gap; *DKA,* diabetic ketoacidosis.

concentration. The change in the HCO_3^- concentration from baseline should reflect the total quantity of net anions gained. Adherents to the descriptive approach to acid-base balance refer to this as the "delta" HCO_3^-. However, this is problematic because it does not separate the effect of CO_2 metabolism on the $[HCO_3^-]$.

In 1948, Singer and Hastings proposed that changes in the whole-blood buffer base could be used to quantify the metabolic component independent of the Henderson-Hasselbalch equation.[42] The buffer base represented the sum of the HCO_3^- and the nonvolatile buffer ions (essentially the serum albumin, phosphate, and hemoglobin). Applying the law of electrical neutrality, the buffer base was forced to equal the electrical charge difference between strong (fully dissociated) ions. Normally buffer base = $[Na^+] + [K^+] - [Cl^-]$. Alterations in buffer base represented changes in strong ion concentrations (which could not be easily measured in 1948). The buffer base increases in metabolic alkalosis and decreases in metabolic acidosis. The major drawback of buffer base measurements is the potential for changes in buffering capacity associated with alterations in hemoglobin concentration.

In 1957, Astrup and colleagues developed the standard HCO_3^-—the HCO_3^- concentration at 37° C and at a $Paco_2$ of 40 mm Hg. Building on this work, Astrup and Siggard-Andersen recognized that Pco_2 and $[HCO_3^-]$ were not independent variables.[43] As a result, they derived the base deficit excess (BDE) approach as a measure that could differentiate respiratory from metabolic acid-base disturbances. As defined, the BDE is the amount of strong acid or base required to return the pH to 7.4, assuming that Pco_2 is constant at 40 mm Hg and that the temperature is 37° C. As in the Boston group, the Siggard-Andersen data were derived from observations on a large population of patients. The investigators carefully titrated known amounts of acid or base to blood maintained by tonometry at various $Paco_2$ values and a wide range of hemoglobin concentration at 37° C. These studies led to the development of an alignment nomogram (Fig. 60-5 and Table 60-3), which allowed for the determination of BDE from a single measurement of pH, $Paco_2$, and hemoglobin concentration at 37° C. Current algorithms for computing the BDE are derived from the Van Slyke equation published in 1977.[44]

$$BDE = (HCO_3 - 24.4 + [2.3 \times Hb + 7.7] \times [pH - 7.4]) \times (1 - 0.023 \times Hb)$$

A very high level of agreement exists between this calculation and the empiric data that were used to construct the original nomogram. The calculation is accurate in vitro, but not in vivo, because of the dynamic buffering activity of hemoglobin within the acid-base paradigm of gas and electrolyte exchange. This approach was modified to use only anemic blood (hemoglobin 5 g/dL), which more accurately reflects whole-body base excess in vivo: the calculation became the *standard* base excess (SBE):

$$SBE = 0.93 \times (HCO_3 - 24.4 + 14.83] \times [pH - 7.4]$$

The BDE approach to acid-base chemistry was successfully validated by Schlichtig[45] and Morgan.[46] The major weakness of this equation is the assumption of a normal quantity of weak acids (A_{TOT}), which is rarely the case in critical illness. Wooten corrected SBE for weak acids (albumin and phosphate) and produced an accurate multicompartment model (SBEc)[47]:

$$SBEc = (HCO_3 - 24.4) + ([8.3 \times Albumin\ g/dL \times 0.15] + [0.29 \times Phosphate\ mg/dL \times 0.32] \times [pH - 7.4]$$

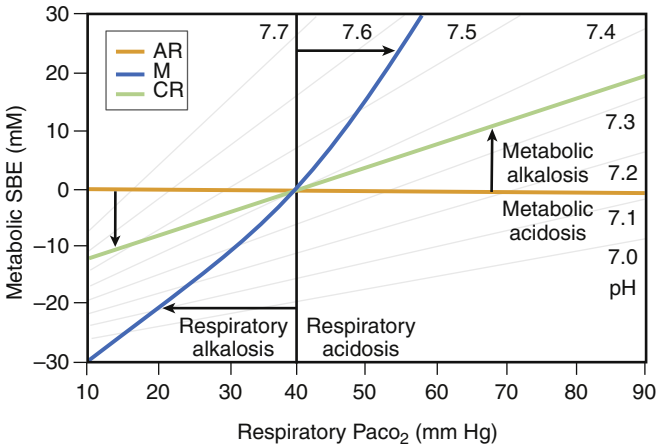


Figure 60-5. Acid-base nomogram using the Copenhagen approach as revised by Schlichtig. The various acid-base disturbances can be distinguished based on Pco_2 and base deficit or excess, here referred to as standard base excess (SBE). *Arrows* represent changes as the body compensates for acute acidosis or alkalosis. *AR,* Acute respiratory acidosis or alkalosis; *CR,* chronic respiratory acidosis or alkalosis; *M,* metabolic acidosis or alkalosis. *(From Schlichtig R, Grogono AW, Severinghaus JW: Human $Paco_2$ and standard base excess compensation for acid-base imbalance,* Crit Care Med *26:1173-1179, 1998.).*

TABLE 60-3 CHANGES IN STANDARD BASE DEFICIT OR EXCESS IN RESPONSE TO ACUTE AND CHRONIC ACID-BASE DISTURBANCES

Disturbance	SBDE versus $Paco_2$
Acute respiratory acidosis	$\Delta BDE = 0$
Acute respiratory alkalosis	$\Delta BDE = 0$
Chronic respiratory acidosis	$\Delta BDE = 0.4\ \Delta Paco_2$
Metabolic acidosis	$\Delta Paco_2 = \Delta BDE$
Metabolic alkalosis	$\Delta Paco_2 = 0.6\ \Delta BDE$

BOX 60-3 ***Calculation of Base Deficit or Excess of Sodium, Chloride, and Free Water and Albumin****

$$BDE_{NaCl} = ([Na^+] - [Cl^-]) - 38$$

$$BDE_{Alb} = 0.25\ (42 - Albumin\ g/L)$$

$$BDE_{NaCl} - BDE_{Alb} = BDE_{calc}$$

$$BDE - BDE_{calc} = BDE\ gap = The\ effect\ of\ unmeasured\ anions\ or\ cations$$

* This approach involves calculating the base deficit or excess (BDE) for sodium, chloride, and free water (BDE_{NaCl}) and that for albumin (BDE_{Alb}). The result is the calculated BDE (BDE_{calc}). This is subtracted from the measured BDE to find the BDE gap.

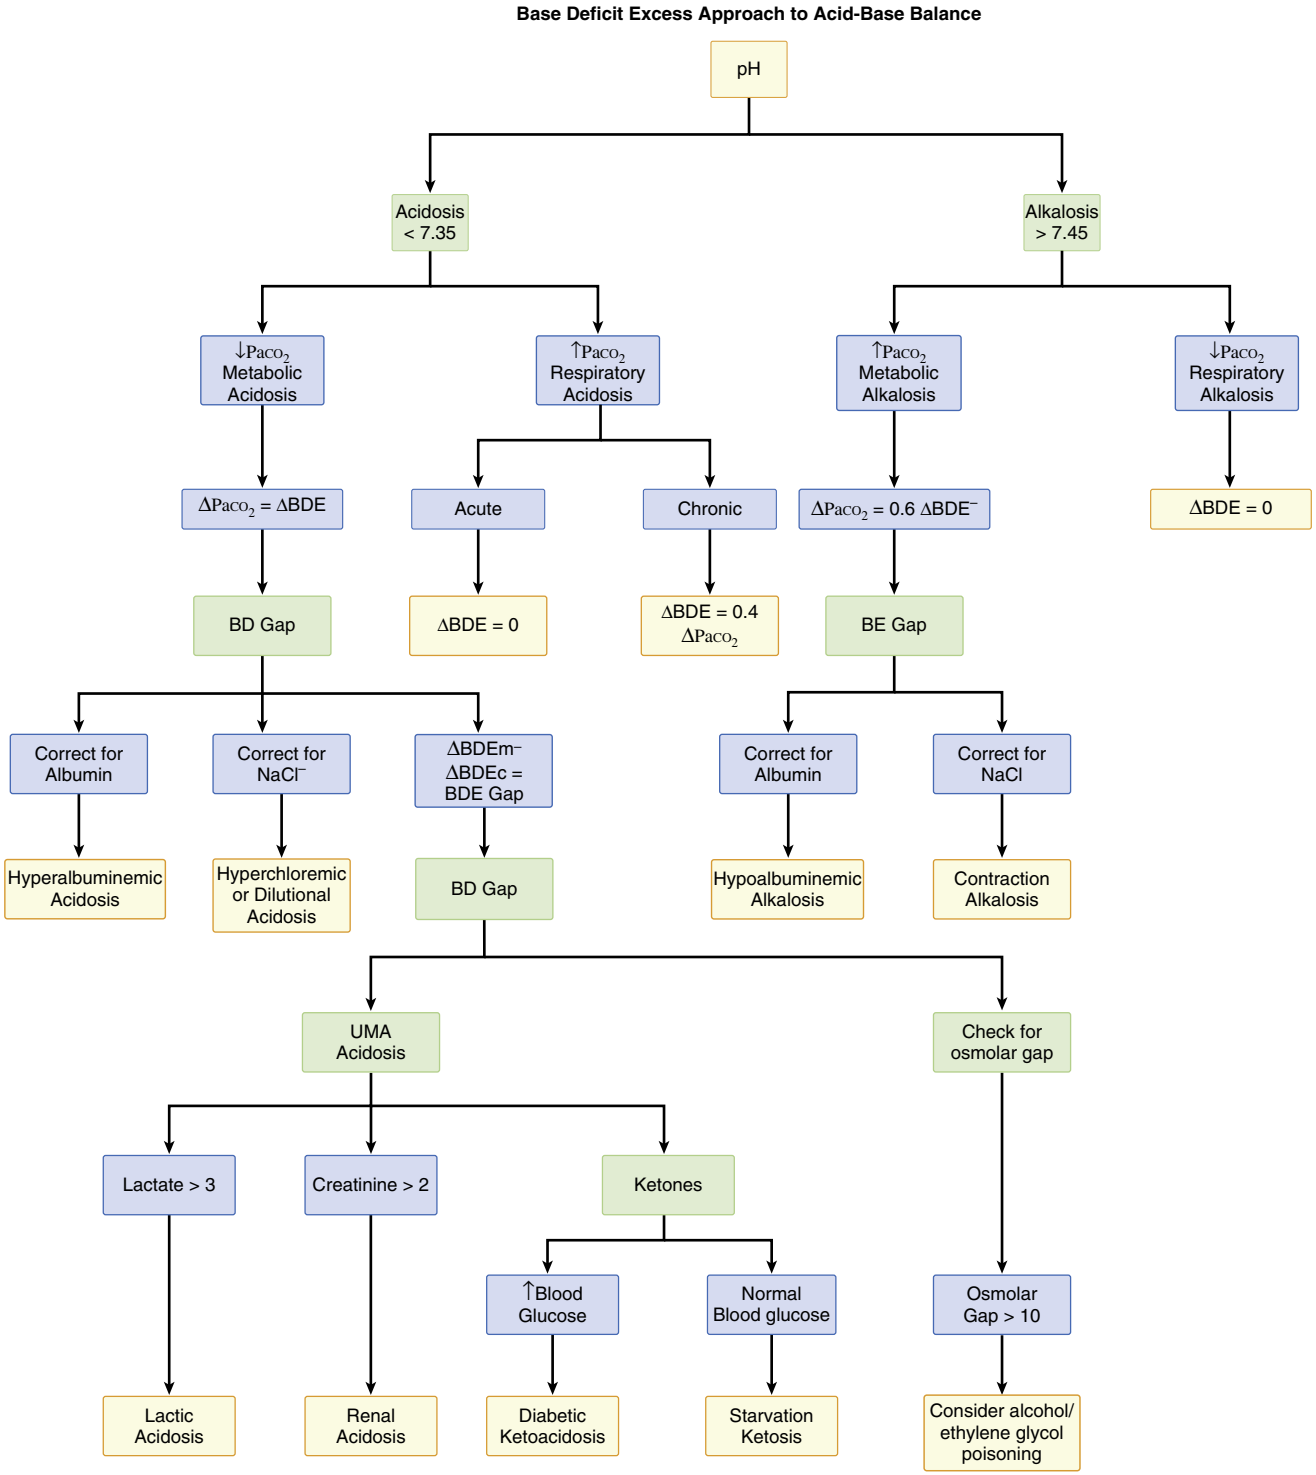

Figure 60-6. The semiquantitative ("Copenhagen") approach to acid-base balance. *BD,* Base deficit; *BE,* base excess; *BDEm,* measured base deficit or excess; *BDEc,* base deficit or excess corrected for albumin, sodium, chloride, and free water (see Box 60-3); *UMA,* unmeasured anion; lactate in mmol/L, creatinine in mg/dL, osmolar gap in mOsm.

Using Wooten's multicompartment model,[47] it can be seen that the SBE is the quantity of strong anion or strong cation required to bring SID back to normal, with the pH corrected to 7.4 and the P_{CO_2} at 40 mm Hg.

Application of simple mathematic rules allows for use of the BDE in each of the common acid-base disturbances (Box 60-3 and Fig. 60-6). For example, in acute respiratory acidosis or alkalosis, BDE does not change. Conversely, in acute metabolic acidosis, the magnitude of change of the P_{CO_2} (in millimeters of mercury) is the same as that of the BDE (in milliequivalents per liter).

Considerable discussion has arisen since the 1980s about the merits and demerits of the BDE, as compared with the CO_2-HCO_3^- system. In reality, little difference

exists between the two; both equations and nomograms were derived from patient data and abstracted backward. Calculations use HCO_3^- as measured on a blood gas analyzer. Consequently, for most patients, either approach is relatively accurate, but calculations may be misleading because they do not allow the clinician to distinguish between, for example, acidosis caused by lactate or Cl^- and alkalosis resulting from dehydration or hypoalbuminemia. These measures may miss the presence of an acid-base disturbance entirely; for example a hypoalbuminemic (metabolic alkalosis) critically ill patient with lactic acidosis (metabolic acidosis) may have a pH, HCO_3^-, and base excess in the normal range. This lack of precision may lead to inappropriate or inadequate therapy.

A complementary approach, used by Gilfix and colleagues,[48] and subsequently by Balasubramanyan and associates[49] and Story and associates,[50] is to calculate the BDE gap. This allows recalculation of BDE using strong ions, free water, and albumin. The resulting BDE gap should mirror the SIG, and the anion gap should be corrected.

We find the simplified calculation of Story and associates to be most useful (see Box 60-3).[50] These investigators used two equations to calculate the BDE for Na^+, Cl^-, and free water (BDE_{NaCl}) and for albumin (see Box 60-3).

STEWART-FENCL APPROACH

A more accurate reflection of true acid-base status can be derived using the Stewart-Fencl or physical chemistry approach.[1,3] This approach is based on the concept of electrical neutrality, a small advance from the anion gap. Plasma has an apparent SIDa $[(Na + Mg^{2+} + Ca^{2+} + K^+) - (Cl^- + A^-)]$ of 40 to 44 mEq/L, balanced by the negative charge on HCO_3^- and A_{TOT} (the buffer base, effective SID [SIDe]). A small difference between SIDa and buffer base (SIDe) represents a SIG and quantifies the amount of UMA present (Fig. 60-7).

$$SIDa = \left([Na^+] + [K^+] + [Mg^{2+}] + [Ca^{2+}]\right) - [Cl^-]$$

$$SIDe = [HCO_3^-] + [\text{Charge on albumin}] + [\text{Charge on Pi}] \quad (\text{in mmol/L})$$

The degree of ionization of weak acids is pH dependent, so one must calculate for this:

$$[Alb^-] = [\text{Alb g/L}] \times (0.123 \times pH - 0.631)$$
$$[Pi] \quad (\text{in mg/dL}) = [Pi]/10 \times pH - 0.47$$
$$SIG = SIDa - SIDe$$

Unfortunately, the SIG may not represent unmeasured strong anions, but only all anions that are unmeasured. For example, if resuscitated with gelatin, a patient's SIG will increase. Further, SID changes quantitatively in absolute and relative terms when changes in plasma water concentration occur. Fencl and Leith addressed this by correcting the Cl^- concentration for free water (Cl^-corr) with the following equation[1]:

$$[Cl^-]\,corr = [Cl^-]\,\text{observed} \times ([Na^+]\,\text{normal}/[Na^+]\,\text{observed})$$

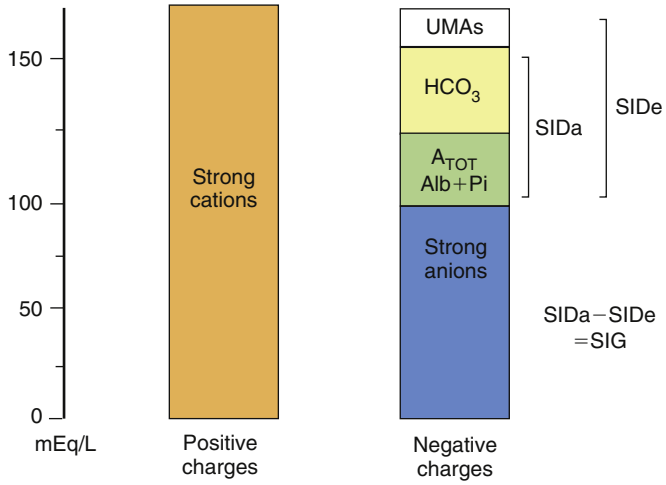

Figure 60-7. The strong ion gap (SIG). SID apparent (SIDa) is the sum of total concentration of weak acids (A_{TOT}) plus concentration of bicarbonate ion (HCO_3^-). SID effective (SIDe) is the real SID. The difference between the two is made up of unmeasured anions (UMAs). *Alb,* Albumin; *Pi,* phosphate.

This corrected Cl^- concentration may then be inserted into the SIDa equation. Similarly, the derived value for UMAs can also be corrected for free water by substituting UMAs for Cl^- in the previous equation.[18] In a series of nine normal subjects, Fencl and colleagues estimated the "normal" SIG as 8 ± 2 mEq/L.[18]

Calculation of SIG is cumbersome. The data required are more extensive and expensive than other approaches, and much confusion exists about the normal range of SIG. It is unclear, in standard clinical practice, that SIG has any advantage over the corrected anion gap (which is SIG without calcium, magnesium, and phosphate—which usually cancel out each other's charges).

No single number can make sense of complex acid-base disturbances. Fencl and associates suggested that anion gap or BDE should be replaced by viewing each blood gas in terms of all alkalinizing and acidifying effects: respiratory acidosis or alkalosis, the presence or absence of abnormal SID (from water excess or deficit, measured electrolytes or unmeasured electrolytes), and abnormal A_{TOT}.[18] Consider the following patient, described by Fencl and colleagues[18] (data in mEq/L unless otherwise stated):

Na, 117; Cl, 92; Ca, 3.0; albumin, 6.0 g/L; K, 3.9; Mg, 1.4; Pi, 0.6 mmol/L; arterial blood gases: pH, 7.33; P_{CO_2}, 30 mm Hg; HCO_3^-,15

Derived values would be as follows:

Anion gap, 13; corrected anion gap, 23; BE, −10; SID, 18; corrected Cl, 112; corrected UMA, 18

Using traditional methods, one would describe this as nongap metabolic acidosis and look for causes of HCO_3^- wasting, such as renal tubular acidosis or gastrointestinal losses. The degree of respiratory alkalosis is appropriate for the degree of acidosis ($\Delta BD = \Delta P_{CO_2}$). The Fencl-Stewart approach reveals a much more complex situation. SID is reduced to 18 mEq/L—caused by free water excess, UMAs, and surprisingly, hyperchloremia (see the corrected Cl^-). The degree of acidosis does not mirror the metabolic disturbance because of the alkalinizing force of hypoalbuminemia. The corrected anion gap mirrors the change in

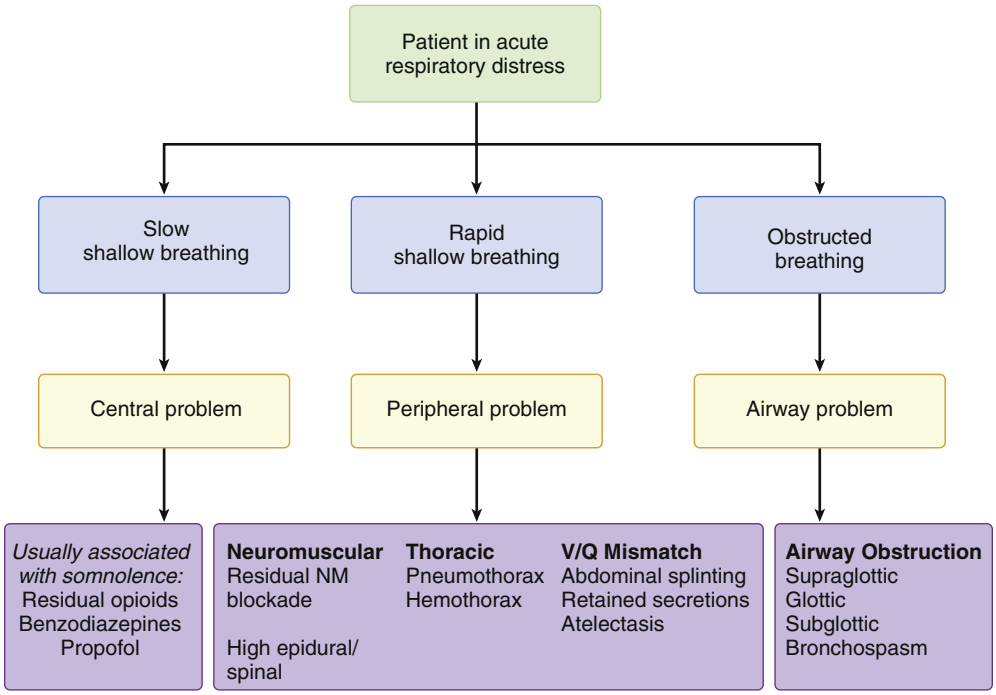

Figure 60-8. Using the breathing pattern to determine the cause of acute respiratory distress and respiratory acidosis. *NM,* Neuromuscular; *V/Q,* ventilation-perfusion.

SID, but this alteration is grossly underestimated by the base deficit. This patient has dilutional acidosis, hyperchloremic acidosis, and lactic acidosis.

In conclusion, for most patients presenting to the emergency room or operating suite who have been previously healthy, the use of tools such as the base deficit or anion gap to assess metabolic disturbances remains reasonable, particularly if it is corrected for albumin. For critically ill patients, the most effective method of interpreting acid-base conundrums involves unraveling simultaneous acidifying and alkalinizing processes and using calculations to distinguish among the various forces at play. Unfortunately, a clinician's ability to interpret such information depends on the amount of available data. A simple blood gas analysis alone may camouflage a significant acid-base disturbance.

In the next section, we look at the causes of many commonly seen acid-base disturbances in different clinical settings.

ACID-BASE PROBLEMS IN DIFFERENT CLINICAL SETTINGS

ACID-BASE DISTURBANCES IN THE EMERGENCY SETTING

Acid-base disturbances are an important part of laboratory investigation of acutely ill patients (see also Chapter 101). The most common disturbances are acute respiratory acidosis or alkalosis and acute metabolic acidosis. Acute metabolic alkalosis is unusual. Mixed respiratory and metabolic acidosis is seen in the severely injured or infected patient.

Acute respiratory acidosis results from hypoventilation or increased dead space ventilation. Assessment begins with an examination of the patient's breathing pattern (Fig. 60-8): slow, shallow breathing indicates impaired respiratory drive; rapid, shallow breathing suggests chest wall or lung disease; and obstructed breathing signifies airway obstruction.

Respiratory acidosis complicates a wide variety of pathologic processes. These include neurologic injury (stroke, spinal cord injury, botulism, tetanus), toxic suppression of the respiratory center (opioids, barbiturates, benzodiazepines), neuromuscular disorders (Guillain-Barré syndrome, myasthenia gravis), abdominal hypertension, flail chest, hydrohemopneumothorax, pulmonary edema, and pneumonia. It also complicates anesthesia with excessive sedation, partial neuromuscular blockade, and intraoperative hypoventilation. Frequently, mechanical ventilation is required to reverse the acidosis.

Acute respiratory alkalosis is caused by hyperventilation, in response to anxiety or pain, central respiratory stimulation (as occurs early in salicylate poisoning), or excessive artificial ventilation. Acute respiratory alkalosis usually accompanies acute metabolic acidosis, in which case the reduction in P_{CO_2} from baseline (usually 40 mm Hg) is equal to the magnitude of the base deficit (see Table 60-3). For example, in a patient with lactic acidosis whose lactate concentration is 10 mEq/L, the base deficit should be –10 and the P_{CO_2} 30 mm Hg. If the P_{CO_2} is higher than expected, then a concomitant problem exists with the respiratory apparatus. An example is the multitrauma patient in whom massive blood loss leads to lactic acidosis and a flail chest causes respiratory acidosis.

Acute metabolic acidosis is caused by an alteration in SID or A_{TOT}. SID is changed by an alteration in the relative quantity of strong anions to strong cations. Anions can be gained, as occurs with lactic acidosis, renal acidosis, ketoacidosis, and hyperchloremic acidosis, or cations can be lost, as occurs with severe diarrhea or renal tubular

BOX 60-4 ***Evaluation of a Patient With Metabolic Acidosis***

1. Is acidosis being caused by measured or unmeasured anions (i.e., chloride)?

Look at blood chemistry
- Calculate anion gap: Na + K – Cl = 10-12
- If gap is normal, too much chloride is present because of excessive administration, excess loss of sodium (diarrhea, ileostomy), or renal tubular acidosis
- If gap is wide (>16), other unmeasured anions are present, causing acidosis

Check serum lactate—if >2, probably lactic acidosis
- If high lactate is explained by circulatory insufficiency (shock, hypovolemia, oliguria, underresuscitation, anemia, carbon monoxide poisoning, seizures), then "type A" lactic acidosis
- If not, think about "type B (rare)" causes—biguanides, fructose, sorbitol, nitroprusside, ethylene glycol, cancer, liver disease

Look at creatinine and urine output
- If patient is in acute renal failure, these may be renal acids

Look at blood glucose and urinary ketones
- If patient is hyperglycemic and ketotic, this is diabetic ketoacidosis
- If patient is ketotic (unmeasured anion) and normoglycemic, this is either alcoholic (check blood alcohol) or starvation ketosis
- Check for presence of chronic alcohol abuse—high mean corpuscular volume, increased γ-glutamyl transferase on liver panel

2. If all these test results are negative, think of intoxication
- Send toxicology laboratory tests (particularly salicylates) and serum osmolality, and calculate osmolality using the formula: 2(Na + K) + Glucose / 18 + BUN / 2.8
- Look for unmeasured source of osmoles: if gap between measured and calculated serum osmolality >12, think of alcohol, particularly ethylene glycol, isopropyl alcohol, and methanol

acidosis. Acidosis also can result from an increase in free water relative to strong ions—the dilutional acidosis that accompanies excessive hypotonic fluid intake and certain poisonings with alcohol such as methanol, ethylene glycol, or isopropyl alcohol.

To investigate acute metabolic acidosis in previously healthy patients, simple observational and mathematic tools, such as the anion gap and base deficit, are useful (see Fig. 60-4; Box 60-4). The base deficit merely demonstrates the presence of an acid-base anomaly. The anion gap differentiates acidosis caused by hyperchloremia (renal tubular acidosis or excessive administration of "normal saline") or lactate from that caused by UMAs (ketones or renal acids) and dilution. When a patient presents with acute metabolic upset, such as trauma, exsanguination, loss of consciousness, or tachypnea, the tests needed to evaluate the patient completely include blood gas analysis, an electrolyte panel, serum osmolality testing, and urinalysis.

In acute metabolic acidosis, three diagnoses should be immediately investigated: (1) lactic acidosis (send for a serum lactate determination—it should mirror the magnitude of base deficit); (2) ketoacidosis secondary to diabetes (the patient should be hyperglycemic and have positive urinary ketones); or (3) starvation and acute renal failure, as demonstrated by high serum urea and creatinine levels and low total CO_2. Starvation and renal failure are diagnoses of exclusion. The presence of a low serum Na^+ concentration (<135 mEq/dL) or a very wide anion/base deficit/SIG should alert the clinician to the unusual possibility of dilutional acidosis, such as that caused by alcohol poisoning. Alcohols such as ethanol, methanol, isopropyl alcohol, and ethylene glycol are osmotically active molecules that expand extracellular water. Alcohol poisoning should be suspected in the patient with an osmolar gap: a difference between the measured and calculated serum osmolality of greater than 12 mOsm demonstrates the presence of unmeasured osmoles. Toxicology analysis can reveal the presence of various alcohols.

Renal acidosis is caused by accumulation of strong ion products of metabolism excreted exclusively by the kidney. Examples include sulfate and formate. In addition, accumulation of phosphate, a weak acid, is caused by relative deficiency of vitamin D. Diabetic ketoacidosis is treated with volume resuscitation and insulin. Starvation ketosis is treated by administration of glucose and then protein. Renal acidosis is treated with dialysis.

The use of $NaHCO_3$ boluses or infusions to treat metabolic acidosis is controversial. Little evidence supports the use of this agent in lactic acidosis or ketoacidosis. $NaHCO_3$ will indeed reverse the acidosis by increasing SID, but in general the acidosis is a reflection of a greater underlying problem. Nevertheless, $NaHCO_3$ (8.4%) is a hypertonic solution and should have a plasma-expanding effect similar to that of hypertonic saline, albeit at the cost of increasing $Paco_2$. This property likely explains the perceived hemodynamic benefit in shock. $NaHCO_3$ infusions have been used to increase SID to reduce patients' symptoms and prevent hyperkalemia in patients awaiting dialysis.

Methanol is metabolized to formaldehyde and formate by alcohol dehydrogenase. These metabolites are highly toxic, causing blindness, cardiovascular instability, and death. Treatment strategies include the use of ethanol to compete for binding on alcohol dehydrogenase and fomepizole to inhibit the enzyme. Ethylene glycol poisoning causes central nervous system depression, lactic acidosis, and formation of calcium oxalate urinary crystals. The resultant hypocalcemia can lead to renal failure, cardiovascular depression, and death. Treatment includes administration of fomepizole with or without hemodialysis.

Lactic Acidosis

Lactic acidosis occurs when the production of lactate in the body is greater than the liver's capacity to clear it. The problem is overproduction or inadequate clearance.

Lactic acid is produced physiologically as a degradation product of glucose metabolism. Its formation from pyruvate is catalyzed by lactate dehydrogenase. Under normal conditions, the ratio of lactate to pyruvate is less than 20:1. In anaerobic conditions, for example following vigorous exercise, lactate levels increase dramatically. In addition, lactate can be produced under aerobic conditions. Activation of β-adrenergic receptors in skeletal muscle by stress (increased circulating catecholamines) or exogenous infusion (epinephrine or norepinephrine

infusions) increases lactate, with resulting aerobic glycolysis. Lactate can be converted to CO_2 and H_2O by the liver; the lactate in Ringer lactate solution is functionally HCO_3^-.

Serum lactate and arterial pH should be measured early in any critically ill patient. A lactate concentration of more than 2 mEq/L is clinically significant, and a level of 5 mEq/L in the presence of metabolic acidosis is severe.[51] Isolated hyperlactatemia in the absence of acidosis is of unclear clinical significance.[52]

Two types of lactic acidosis are recognized. Type A (global inadequate oxygen delivery) is seen in hypovolemic or hemorrhagic shock, whereas type B occurs despite normal global oxygen delivery and tissue perfusion. Lactic acidosis may also develop in situations of significant regional hypoperfusion. Examples include bowel ischemia, in which lactate is produced in large quantity as a result of glycolysis despite global oxygen delivery that is normal. Type B lactic acidosis is associated with any state characterized by excess circulating catecholamines (endogenous or exogenous). Examples include simple exercise and the hyperinflammatory state of trauma or sepsis. Type B lactic acidosis may also be seen in cyanide poisoning (associated with sodium nitroprusside), with biguanides (metformin), and in hypercatabolic diseases, such as lymphoma, leukemia, acquired immunodeficiency syndrome (AIDS), or diabetic ketoacidosis (also see Chapter 39).

Lactic acidosis is a sensitive marker of disease severity,[53] and failure to clear the acidosis is a strong predictor of adverse outcomes.[54-56] The presence of a low mixed venous oxygen saturation (SvO_2) with a high lactate concentration, coupled with an elevated lactate-to-pyruvate ratio (>20:1), is indicative of type A (hypoxia associated) acidosis (Fig. 60-9).

The presence of normal systemic indices of perfusion does not exclude significant regional hypoperfusion or mitochondrial failure.[57,58] Clinicians frequently misinterpret high serum lactate levels as indicative of tissue hypoperfusion and as a result may institute inappropriate therapy.[58,59] Dynamic measurements of lactate over time are better predictors of outcome than are static measures.[60] Lactate clearance has been proposed as an end point of resuscitation in sepsis,[61,62] because lactate concentration should decrease with adequate resuscitation.[62] Rapid clearance of lactate has been associated with improved outcomes.[63,64] A failure of lactate clearance in response to resuscitation suggests that global perfusion is not the underlying problem and should prompt a search for a more sinister etiology (see also Chapter 108).

PERIOPERATIVE ACID-BASE DISTURBANCES

In addition to the acid-base disturbances seen in emergency situations, several acid-base conundrums are peculiar to the perioperative and critically ill patient (Table 60-4; see also Chapters 81, 82, and 101). These include the respiratory acidosis and alkalosis associated with mechanical ventilation, acidosis secondary to hyperchloremia or contraction, and alkalosis resulting from Na^+ gain or Cl^- loss.

Perioperative respiratory acidosis is most often the result of a poor mechanical ventilation strategy, narcosis, or incomplete reversal of neuromuscular blockade. Respiratory alkalosis is likely caused by hyperventilation from secondary pain or anxiety.

Metabolic acid-base disturbances are relatively common perioperatively. Pathologic causes involve lactic acidosis, ketoacidosis, and renal acidosis, as previously described. Iatrogenic causes reflect manipulation of SID by administration of electrolyte or osmotically imbalanced solutions.

Hyperchloremic acidosis is frequently seen in the perioperative period. This abnormality usually follows administration of large volumes of 0.9% (normal) saline solution, which contains 154 mEq of both Na^+ and Cl^- and has an SID of 0. Each liter of normal saline is associated with a reduction in the ECF SID, and it produces hyperchloremic acidosis.

Is hyperchloremic acidosis clinically significant? As a cause of acidosis, hyperchloremia is less sinister than other causes: in a study of critically ill patients with various acid-base disorders, mortality was highest for lactic acidosis (56%); for SIG acidosis it was 39%, and for hyperchloremic acidosis it was 29% ($P < .001$),[65] findings consistent with other data.[66,67] Nevertheless, hyperchloremia may result in clinically significant organ dysfunction. An observational study of 31,000 surgical patients[68] comparing intravenous saline with intravenous balanced salt solutions demonstrated significant outcome differences favoring balanced salt solutions. Complications enhanced by the use of normal saline included postoperative infections, blood transfusions, and kidney injury requiring dialysis. Patients with perioperative metabolic acidosis have a prolonged duration of hospital stay.[69]

A hyperchloremic state may be associated with nephrotoxicity: saline infusion has been associated with reduced renal blood flow,[70] renal vasoconstricton,[71,72] reduced glomerular filtration,[73] splanchnic hypoperfusion,[74] and perhaps an increased risk of contrast nephropathy.[74,75] Critically ill patients with sepsis frequently develop hyperchloremic acidosis that appears to be associated with worse outcomes.[76] In a relatively large before and after cohort study of patients treated in an Australian intensive care unit, the use of Cl^--rich fluids was associated with a 3.7% absolute increase in the risk for need of renal replacement therapy relative to balanced salt solution.[77]

The presence of a significant base deficit and low pH in a patient with diabetic ketoacidosis or lactic acidosis usually prompts continued fluid resuscitation. However, this strategy may be inappropriate if the cause of acidosis is hyperchloremia (see Table 60-4). International guidelines recommending the use of 0.9% $NaHCO_3$ (normal saline) for fluid resuscitation in diabetic ketoacidosis are based on scant evidence. This practice developed as a result of concern that the K^+ content of balanced salt solutions could become problematic if renal insufficiency was the underlying cause of acidosis. However, a study of anephric patients undergoing renal transplantation demonstrated that patients treated with normal saline were more acidotic and hyperkalemic than were patients treated with lactated Ringer solution.[78] Further, a small study that compared normal saline with Plasma-Lyte 148 (a balanced salt solution) reported that patients receiving the balanced salt solution instead of normal saline

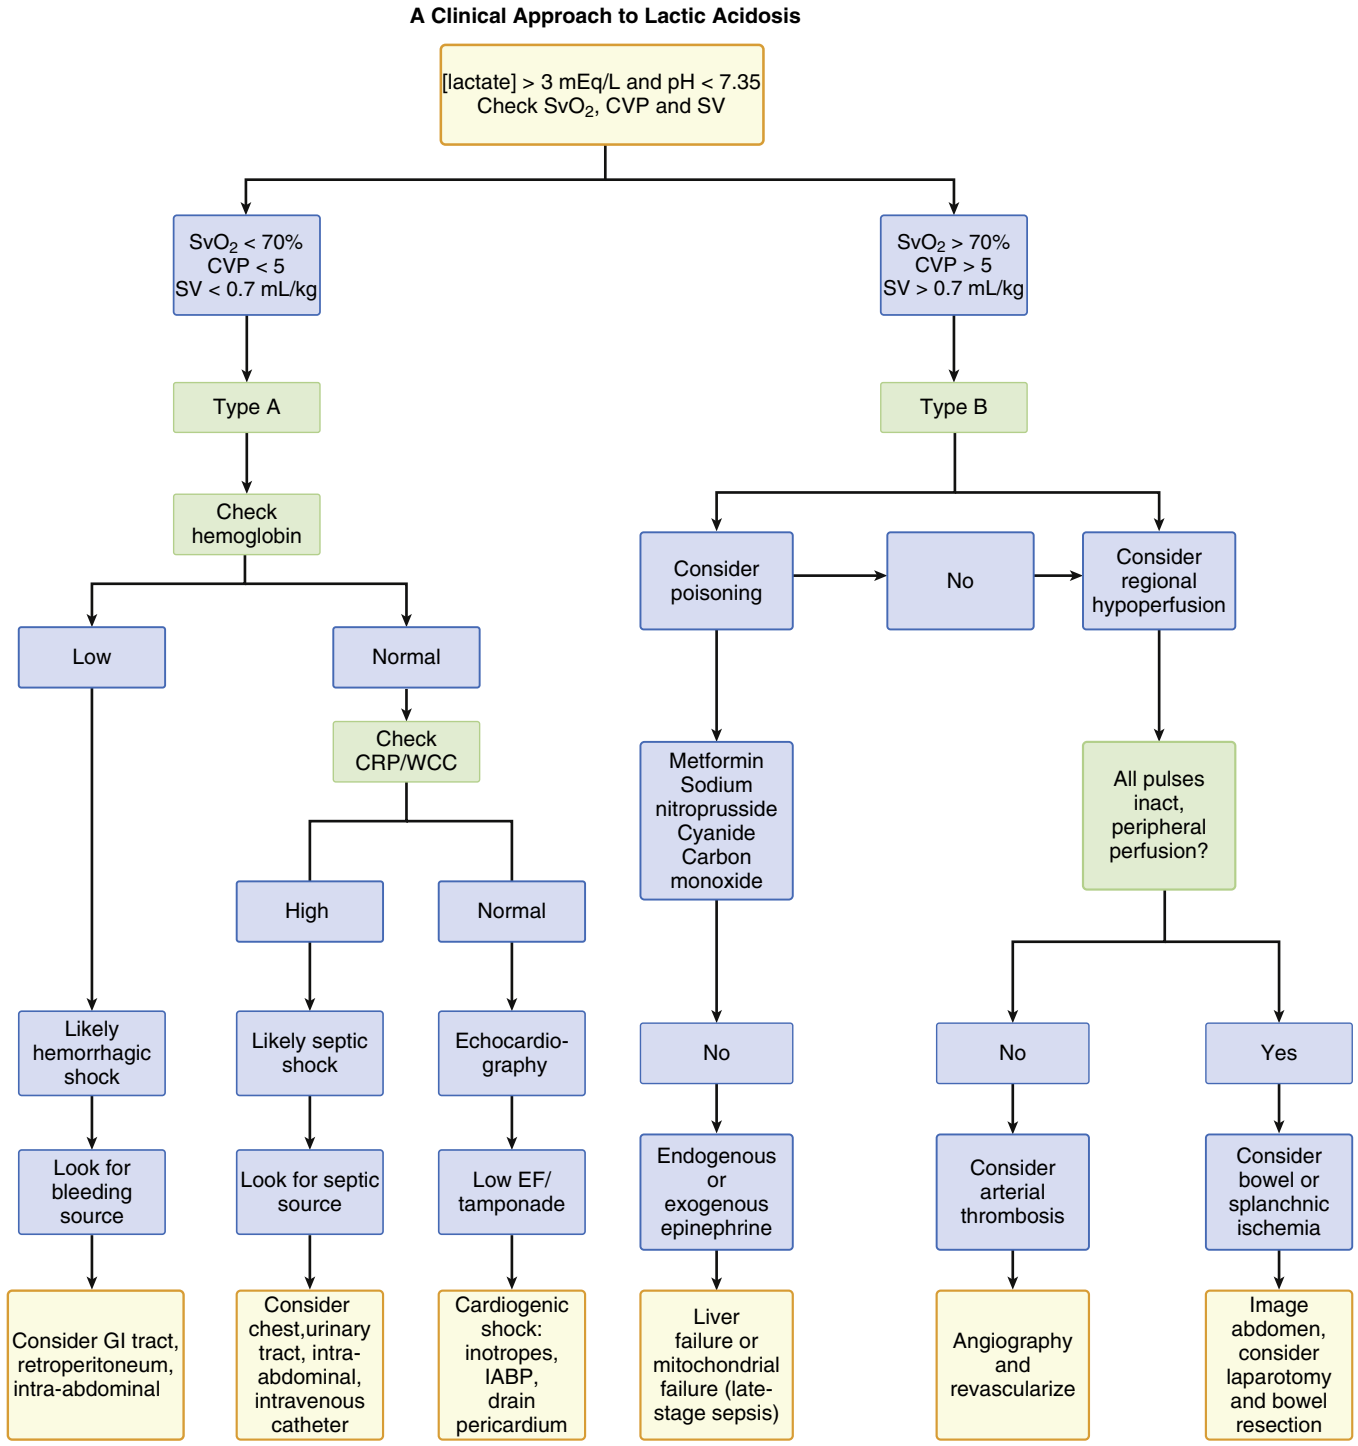

Figure 60-9. Evaluation of a patient with lactic acidosis. *CRP,* C-reactive protein; *CVP,* central venous pressure; *EF,* ejection fraction; *GI,* gastrointestinal; *IABP,* intraaortic balloon counterpulsation; *SV,* stroke volume; *SvO_2,* mixed venous oxygen saturation; *WCC,* white cell count.

had more rapid resolution of metabolic acidosis, less hyperchloremia, an improved blood pressure profile, and greater urinary output.[79]

Mahler and colleagues conducted a study comparing normal saline with lactated Ringer solution in diabetic ketoacidosis: hyperchloremic acidosis was significantly more common in the group receiving normal saline.[80] A similar study comparing normal saline with lactated Ringer solution failed to demonstrate a benefit with lactated Ringer solution; the time to normalization of blood glucose was longer with lactated Ringer solution than with normal saline.[81]

Until more data are available, 0.9% $NaHCO_3$ is not the resuscitation fluid of choice in critically ill patients, in particular those at risk for development of acute kidney injury (see also Chapter 108).

Perioperative metabolic alkalosis is usually of iatrogenic origin. Overventilation of patients with chronic

respiratory failure results in acute metabolic alkalosis because the presence of chronic compensatory alkalosis associated with Cl^- loss in urine has not been taken into account (Fig. 60-10). More frequently, metabolic alkalosis is associated with increased SID secondary to Na^+ gain. This abnormality results from the administration of fluids in which Na^+ is "buffered" by weak ions, such as citrate (in blood products), acetate (in parenteral nutrition), and HCO_3^-. Buffer ions such as citrate, acetate, gluconate, and lactate, under normal conditions, are rapidly cleared by the liver and do not contribute to acid-base balance. Na^+ and Cl^- obey the law of conservation of mass. Na^+ gain is Cl^--sensitive alkalosis, treated by administration of net loads of Cl^-—0.9% $NaHCO_3$, KCl, CaCl, and, occasionally HCl. It is important to correct Cl^--sensitive alkalosis because the normal compensatory measure is hypoventilation, thus increasing $Paco_2$, which may lead to CO_2 narcosis and failure to liberate from mechanical ventilation.

Another cause of metabolic alkalosis in perioperative patients stems from the loss of Cl^--rich fluids from the gastrointestinal tract. Gastric juice contains HCl, which, when lost as a result of continuous suctioning or vomiting, obeys the law of conservation of mass and leads to alkalosis. The loss of hydrogen ions is not the cause of the alkalosis because the ability to produce hydrogen ion is virtually unlimited.

It is important to understand the effects of fluids on acid-base disturbances. For patients receiving 1 or 2 L of fluid perioperatively, little difference exists among the choices of fluids. If larger-volume crystalloid resuscitation is expected, then balanced buffered solutions, which mirror the electrolyte content of ECF, such as lactated Ringer solution, Normosol, or Plasma-Lyte, are recommended. If the patient has been undergoing continuous nasogastric suctioning, then normal saline should be administered intravenously until the base deficit returns to 0; balanced buffered solutions should be used thereafter. Similarly, if large volumes of blood or plasma are administered intravenously, then normal saline should be given. Care must be taken to avoid hypokalemia, hypocalcemia, hypomagnesemia, and hypophosphatemia. Patients who have received purgatives for bowel surgery should be treated with balanced salt solutions.

TABLE 60-4 ACID-BASE DISTURBANCES COMMONLY SEEN PERIOPERATIVELY

Disorder	Cause
Respiratory acidosis	Hypoventilation: narcosis, incomplete reversal of neuromuscular blockade
Respiratory alkalosis	Hyperventilation: anxiety, pain
Metabolic acidosis from unmeasured anions (widened gap acidosis)	Hypoperfusion—lactic acidosis; diabetic ketoacidosis; renal failure
Metabolic acidosis from measured anions (nongap hyperchloremic acidosis)	Hyperchloremia—"normal" saline and saline containing fluids; renal tubular acidosis; bladder reconstructions
Metabolic acidosis from free water excess (hyponatremia, dilution acidosis)	Hypotonic fluid administration; sodium loss—diarrhea; administration of hyperosmolar fluids—mannitol, alcohol: hyperproteinemia
Metabolic alkalosis	Hyperventilation of patient with a history of CO_2 retention (COPD); sodium gain (sodium bicarbonate, massive blood transfusion); chloride loss—nasogastric suctioning

COPD, Chronic obstructive pulmonary disease.

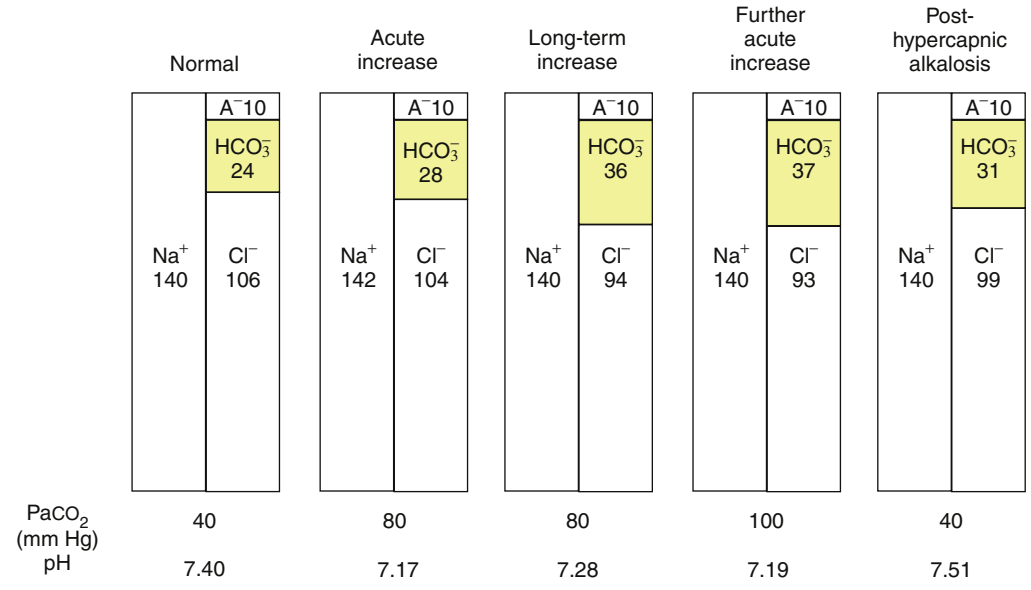

Figure 60-10. Changes in acid-base and electrolyte composition in patients with respiratory acidosis. *Left to right,* the panels depict normal acid-base status; adaptation to an acute rise in the partial pressure of arterial carbon dioxide ($Paco_2$) to 80 mm Hg; adaptation to a long-term rise in $Paco_2$ to 80 mm Hg; superimposition of an acute further increment in $Paco_2$ (to a level of 100 mm Hg) in the same patient; and posthypercapnic alkalosis resulting from an abrupt reduction in $Paco_2$ to the level of 40 mm Hg in the same patient. A^- denotes unmeasured plasma anions, and the numbers within the bars give ion concentrations in millimoles per liter. *(Modified from Androgue H, Madias N: Management of life-threatening acid-base disorders: first of two parts,* N Engl J Med *338:26–34, 1998.)*

ACID-BASE DISTURBANCES IN CRITICAL ILLNESS

Critically ill patients may have many confounding acid-base disturbances that are not evident when only a single quantitative measure, such as base deficit, is employed (see also Chapter 101). Patients frequently have perturbations of P_{CO_2}, SID, and A_{TOT}, and significant disturbances may be overlooked because of apparently normal blood gas results.[82]

The most common single disturbance in acid-base chemistry in critically ill patients is hypoalbuminemia.[17] This abnormality is ubiquitous and causes metabolic alkalosis of unpredictable magnitude. Hypoalbuminemia may mask significant alterations in SID, such as lactic acidosis. Therefore, when the anion gap is used in critically ill patients, it should be corrected for albumin.[19] Similarly, the use of base deficit to predict lactate is unreliable in critical illness, particularly in patients undergoing secondary deterioration.[18] Prolonged respiratory failure, with associated hypercarbia, leads to additional metabolic alkalosis resulting from Cl^- loss in urine.[83] Kidney injury is associated with accumulation of metabolic by-products, phosphate, renal anions, Cl^-, and other UMAs. Polyuric renal failure may be associated with significant contraction alkalosis in response to loss of Na^+, K^+, and free water.

Critically ill patients are vulnerable to significant changes in SID and free water. Nasogastric suctioning causes Cl^- loss, and diarrhea leads to Na^+ and K^+ deficits. Surgical drains placed in tissue beds may remove fluids with varying electrolyte concentrations (e.g., the pancreatic bed secretes fluid rich in Na^+). Fever, sweating, evaporation from denuded tissue, and inadequately humidified ventilator circuits all can lead to large volume insensible loss and contraction alkalosis.

Infusions administered to patients may be responsible for unrecognized alterations in serum chemistry. Many antibiotics, such as piperacillin-tazobactam, are diluted in Na^+-rich solutions. Others, such as vancomycin, are administered in large volumes of free water (5% dextrose). Lorazepam is diluted in propylene glycol, large volumes of which will cause metabolic acidosis similar to that seen with ethylene glycol.[84]

Continuous renal replacement therapy is used in critical illness for hemofiltration and hemodialysis in patients who are hemodynamically unstable. Rocktaeschel and colleagues demonstrated that continuous renal replacement therapy resolved the acidosis of acute renal failure by removing strong ions and phosphate.[85,86] However, in the presence of hypoalbuminemia, use of dialysis to correct metabolic acidosis may unmask metabolic alkalosis caused by hypoalbuminemia. Continuous renal replacement therapy is not an effective treatment for either type A or type B lactic acidosis.

Other, seemingly innocuous therapies may cause significant disturbances to acid-base balance. Loop diuretics, such as furosemide, are often administered to critically ill patients. These agents preferentially excrete water over electrolytes and provoke contraction alkalosis. Carbonic anhydrase inhibitors, such as acetazolamide, may be used to treat patients with hypochloremic metabolic alkalosis or respiratory alkalosis by decreasing the serum SID. This effect is completely explained by the increased renal excretion ratio of Na^+ to Cl^- that results in an elevation in serum chloride.[87] No treatment for hypoalbuminemic metabolic alkalosis exists except recovery. Contraction alkalosis is treated by correcting the free water deficit using the following formula:

$$\text{Free water deficit} = 0.6 \times \text{Patient's weight in kilograms} \times (\text{Patient's } Na^+/140 - 1)$$

Hypochloremic alkalosis should be treated by correcting the Cl^- deficit with normal saline.

Neurosurgical patients are vulnerable to a variety of acid-base disturbances as a result of osmotherapy or from disturbances caused by brain injury (see also Chapter 70). Mannitol is administered to reduce intracranial pressure and causes brief dilutional acidosis. Moreover, these patients are routinely treated with normal saline solution, which causes acidosis. Diabetes insipidus is a frequent complication of severe head injury, particularly when the patient is progressing toward brain death. Diabetes insipidus is caused by damage to the pituitary and/or the hypothalamus and results in a loss of antidiuretic hormone (ADH) secretion. Absent ADH, the kidney is unable to concentrate the urine, and massive diuresis follows. The disorder is characterized by an increase in plasma osmolality in the presence of low urinary osmolality. Diabetes insipidus typically manifests as contraction alkalosis. The treatment is hormonal replacement with either vasopressin or desmopressin.

TREATING ACID-BASE DISTURBANCES

Therapeutic treatment of acid-base disturbances is controversial. Many experts regard it as "window dressing," rather than addressing the cause. This refers particularly to the use of $NaHCO_3$ in the treatment of lactic acidosis.[88] Therapeutic use of $NaHCO_3$ has three effects: (1) intravascular volume expansion because the 7.5% solution is hypertonic (hence the often marked improvement in cardiovascular performance), (2) increased SID resulting from the administration of Na^+ without accompanying strong anion,[89] and (3) increased CO_2 generation. No evidence indicates that $NaHCO_3$ administration improves outcomes in circulatory shock.[88] Much discussion has focused on induction of intracellular acidosis by HCO_3^-,[90] but this is probably clinically insignificant.[88,91] Lactic acidosis is treated with intravascular volume resuscitation and source control. Diabetic ketoacidosis is treated with intravascular volume resuscitation and insulin.

Hyperchloremic or dilutional acidosis is treated by increasing the SID of infused fluids (e.g., by infusing Na^+ without Cl^-). Although no such fluid is available commercially, such a fluid can be constructed by using $NaHCO_3$ or sodium acetate.

Renal acidosis is treated with dialysis, which removes fixed acids. However, alteration in SID with $NaHCO_3$ or sodium acetate can be used, for the patient's comfort, as a bridge to dialysis.

Significant interest in hypercapnic acidosis has been shown since the 1990s, following the introduction of "permissive hypercapnia" in patients with acute respiratory distress syndrome (ARDS), to prevent ventilator-associated lung injury[11] (see also Chapter 101). Accumulating evidence indicates that hypercapnia has a lung-protective effect and that reversing the acidosis may have adverse effects.[92] Nevertheless, in patients with hypercapnic acidosis and associated cardiovascular instability, we recommend the use of *t*ris-*h*ydroxymethyl-*a*mino-*m*ethane (THAM).[93] THAM titrates hydrogen ions (e.g., lactic acid or CO_2) according to the following reaction:

$$R-NH_2 + HA \leftrightarrow R-NH_3^+ + A^-$$

THAM is a proton acceptor that generates NH_3^+/HCO_3^- without generating CO_2, and the protonated R-NH_3^+ is eliminated by the kidneys, along with Cl^-. THAM has the significant advantage of buffering acidosis without increasing serum Na^+ or generating more CO_2.

SUMMARY

Much of the confusion regarding acid-base chemistry relates to the attempt to apply observational approaches, such as that of Henderson-Hasselbalch and Schwartz and Brackett, to the entire spectrum of pathophysiologic processes. The use of physical chemistry principles has permitted an easier explanation of acid-base balance and provides tools to apply to a wide variety of clinical situations. This does not suggest that the "traditional" approach is incorrect, merely that it looks at a mirror image of that proposed by Stewart, Fencl, and others. All acid-base disorders can be explained in terms of SID, A_{TOT}, and P_{CO_2}. This is important to anesthesiologists, who may significantly affect acid-base balance with our choice of fluids and mechanical ventilation strategy.

Chapter 61

Patient Blood Management: Transfusion Therapy

RONALD D. MILLER

Key Points

- The blood supply is safer now than at any other time in history. Advances in donor screening, improved testing, automated data systems, and changes in transfusion medicine practices account for these increases in safety (see 2012 U.S. Food and Drug Administration Fatalities Report).
- Although the overall condition of the patient is of prime importance, hemoglobin (Hb) values remain a primary component for transfusion decisions with the use of either a restrictive or liberal strategy. Generally, a transfusion trigger of an Hb level of 6 to 8 g/dL or less (restrictive strategy) can be tolerated by relatively healthy, younger patients. Those who are older, critically ill, or have severe cardiorespiratory disease may require a transfusion trigger of 9 to 10 g/dL (liberal strategy).
- Preoperative anemia is an independent risk factor for postoperative morbidity and mortality.
- The term *patient blood management* (see also Chapter 63) has become synonymous with appropriate transfusion strategy, especially with the initial unit of blood given. The indications for more than 1 unit of blood are addressed in this chapter.
- The addition of plasma and sometimes platelets to packed red blood cells (PRBCs) is described by the term *transfusion ratios.* For example, 2 units of plasma with 1 unit of platelets with 1 unit of PRBCs would be 2:1:1.
- Infectivity of blood is no longer a major cause of transfusion-related morbidity and mortality. Transfusion-related acute lung injury is the leading cause of transfusion-related mortality.
- Fresh whole blood has been reemphasized as an excellent choice in patients who are in a dire clinical situation, especially with major blood loss and a related coagulopathy (see also Chapters 62 and 63).
- The quality and effectiveness of blood transfusion is directly related to the length of time blood has been stored. In certain patients in critical clinical situations, blood that has been stored for 14 days or less may be considered.

EVOLUTION AND RECENT HISTORY OF BLOOD TRANSFUSION THERAPY

SOURCE OF DONORS AND HISTORY

Eighty percent of the world's population has access to only 20% of the world's "safe" blood—that is, blood that is properly collected and tested. Only 30% of the world's countries have a nationwide transfusion service and an appropriate donor pool.[1] Another issue in some parts of the world is incentivized donors. The policy of the World Health Organization (WHO) has been that a safe and reliable blood supply should use nonremunerated blood donation. More recently, the WHO suggested that offering economic rewards to donors should be seriously considered.[2] Yet the WHO's Coordinator for Blood Transfusion Safety, Neelam Dhingra, strongly defends the voluntary nonremunerated blood donation as a vehicle to a safer blood supply and increased donor participation.[3] The conclusions presented in this chapter assume the use of contemporary concepts and technology by organized transfusion services with voluntary nonremunerated blood donors.

THE 1960s

Transfusion medicine has undergone enormous changes in the last 50 years and especially since the writing of

this chapter for the 7th edition of *Miller's Anesthesia*. Although many changes have occurred, especially regarding the infectivity of blood, the consensus of whether to use whole blood, its components, or both has vacillated every decade or so. In the l960s, most blood given was in the form of whole blood. Fresh frozen plasma (FFP) was available for the treatment of coagulopathies. In addition, fresh whole blood (usually <24 hours of storage) was given for treatment of severe coagulopathies.[4,5]

THE 1970s THROUGH THE 1980s

Transfusion therapy was characterized in this 10- to 15-year period by "giving the patient only that component of blood that was needed." This philosophy led to component therapy rather than whole blood as the standard of care. For example, if the patient was anemic, only packed red blood cells (PRBCs) would be given instead of whole blood. If thrombocytopenia existed, only platelet concentrates would be given. Overall, caution regarding administration of blood transfusions increased from 1970 to l990 in part because of a major valid concern regarding the infectivity of blood (e.g., hepatitis and immunodeficiency syndrome [AIDS]). These and other health risks appropriately caused clinicians to be extremely cautious when giving blood. Furthermore, individual clinical decisions regarding blood transfusions were and continue to be monitored by local hospital transfusion committees (as required by regulatory agencies of various countries including the United States), which have the responsibility of monitoring the appropriateness of individual and institutional transfusion practices. One outcome of this increased scrutiny was to place prime attention on what the transfusion trigger should be.[6] Specifically, a transfusion trigger defines what the hemoglobin (Hb) value should be to trigger a blood transfusion, as discussed later in this chapter.

1990 TO 2005

In the period from 1990 to 2005, the strategy of specific component therapy was still prominent but not practical for urgent medical and surgical situations. Led by trauma hospitals and the military, the concept of reconstituted whole blood was introduced. Basically, FFP and platelets were added to PRBCs, resulting in the concept of transfusion ratios, which are reviewed in a separate section in this chapter. The addition of plasma and platelets to PRBCs results in a transfusion that is similar to that with whole blood.[7,8] Accordingly, the use of reconstituted whole blood logically rouses the opinion that perhaps we should go back to the previous practice of using whole blood more often instead of PRBCs. Today, even the concept of giving fresh blood has been reintroduced[9] and is emphasized in modern transfusion practice.[10,11]

2005 TO THE PRESENT

The aforesaid issues and the marked decrease in the infectivity of blood transfusions have resulted in multiple transfusion guidelines published by several societies and specialties based on many outcome studies.[12-14] As a result, more fundamental changes in transfusion medicine have occurred in the last 5 years than had taken place since 1970. Also, the term *patient blood management* has become synonymous with appropriate transfusion medicine.[15-17] This term is described as "the appropriate use of blood and blood components with a goal of minimizing their use."[18] Patient blood management tends to emphasize transfusion practice in a nonbleeding state. The clinical importance of preoperative anemia is also receiving significant attention. Clinicians will need to decide whether they wish to practice a liberal versus restrictive transfusion strategy. The anesthesia provider should be an expert on the implications and complications associated with blood transfusions and should be a leader of acute transfusion medicine in the hospital setting. Such experts must understand the changes in transfusion therapy and how patient blood management fits into their clinical situation (see also Chapter 63). Patient blood management in many countries has been facilitated by computerized data systems[19] and supply guidelines.[20] Specifically, transfusion therapy includes all forms and purposes of blood transfusion. Once again, even frozen blood products are being resurrected for use in remote and military locations.[21] A limitation of most of the patient blood management publications is that they describe mostly nonbleeding anemic patients and the initial transfusion. Very little information addresses what guidelines should be used for repetitive transfusions. This chapter focuses on transfusion medicine in the perioperative period, including the indications for both the initial and subsequent blood transfusions.

The decreased incidence of infectivity from blood transfusions has led to the term *noninfectious serious hazards of transfusions (NISHOTs)*.[22] These hazards are numerous and widely based and are described in this chapter.

INDICATIONS FOR TRANSFUSION

ALLOGENEIC (HOMOLOGOUS) BLOOD

Blood transfusions are given to increase oxygen-carrying capacity and intravascular volume. Theoretically, increasing intravascular volume is not an indication for blood transfusion because volume can be augmented with administration of intravascular fluids that are not derived from human blood (e.g., crystalloids or some colloids). For my entire career, Hb values were only one of many variables in a transfusion decision. To add emphasis, it was often stated that an Hb value should not be the sole basis for a transfusion decision; it should be the overall status of the patient. Although the overall status of the patient is of prime importance, I have been surprised at how important the Hb value has become as the basis for many transfusion strategies. In fact, it is the prime criterion for defining restrictive versus liberal transfusion strategies, as described later.

When a patient is hemorrhaging, the goals should be to restore intravascular volume, cardiac output, and

TABLE 61-1 **AMERICAN COLLEGE OF SURGEONS CLASSES OF ACUTE HEMORRHAGE**

Factors	Class I	Class II	Class III	Class IV
Blood loss (mL)	750	750-1500	1500-2000	2000 or more
Blood loss (% blood volume)	15	15-30	30-40	40 or more
Pulse (beats/min)	100	100	120	140 or higher
Blood pressure	Normal	Normal	Decreased	Decreased
Pulse pressure (mm Hg)	Normal or increased	Decreased	Decreased	Decreased
Capillary refill test	Normal	Positive	Positive	Positive
Respirations per minute	14-20	20-30	30-40	35
Urine output (mL/hr)	30	20-30	5-10	Negligible
Central nervous system: Mental status	Slightly anxious	Mildly anxious	Anxious, confused	Confused, lethargic
Fluid replacement (3-1 rule)	Crystalloid	Crystalloid	Crystalloid + blood	Crystalloid + blood

organ perfusion to normal levels. By using crystalloids, colloids, or both to treat hypovolemia, normovolemic dilutional anemia may be created. Increasing cardiac output enhances O_2 delivery to the tissues to a limited extent. In fact, using normovolemic anemia clinically, Mathru and colleagues[23] found inadequate splanchnic and preportal O_2 delivery and consumption when the Hb level decreased to 5.9 g/dL.[23] Although the current patient blood management emphasis is on fewer or even avoidance of blood transfusions, clearly an Hb value exists below which a blood transfusion should be given, as discussed later. Additional O_2 delivery to organs and tissues can only be enhanced by RBCs via whole blood or PRBCs. Thus, increasing O_2-carrying capacity is the only real indication for blood transfusions.

The basis for using the Hb or hematocrit (Hct) value as the initial consideration for defining transfusion requirements followed a 1988 National Institutes of Health (NIH) Consensus Conference[7] that concluded that otherwise healthy patients with Hb value more than 10 g/dL rarely require perioperative blood transfusions, whereas patients with acute anemia (as in intraoperative blood loss) of less than 7 g/dL frequently require blood transfusions. They also recognized that patients with chronic anemia (as in renal failure) might tolerate an Hb concentration of less than 6 to 7 g/L. Amazingly, and despite many studies, publications, and debates, the fundamental guidelines have not changed substantially in the 25 plus years since this conference.

An excellent editorial by Manach and associates[24] outlines key questions that should be considered regarding transfusion triggers, including what we need to learn and the role of databases. Of prime importance is identifying the variables that are predictive for erythrocyte transfusion and the approach that can most accurately estimate the impact of transfusions. Many studies use death rate as their main indicator. Although clearly an important indicator, there are additional obvious factors in between the extremes of life and death, including vital signs, key laboratory values, and other indicators used in critical care units (see also Chapter 101). The ultimate determination of the Hb or Hct value at which blood should be given is a clinical judgment based on many factors, such as cardiovascular status, age, anticipated additional blood loss, arterial oxygenation, mixed venous O_2 tension, cardiac output, and intravascular blood volume (Table 61-1). The O_2 extraction ratio has been recommended as an indicator for transfusions[9]; however, this technique requires invasive monitoring. Even so, the results by this indicator were not dramatic between groups who were or were not transfused.

ADDITIONAL BLOOD TRANSFUSIONS

After the initial administration of blood, what should be the indications for administering additional units of blood? Of major importance is the overall condition of the patient. Generally, most clinical situations should be combined with key information that, at a minimum, should be used to guide the need for additional transfusions. The following key information is required:

1. Overall condition of the patient, including measurement of vital signs
2. Assessment of anticipated blood loss
3. Measurement of blood loss
4. Quantitation of intravenous fluids given overall
5. Determination of Hb concentration

Overall Condition

Of prime importance in effective clinical care is the overall analysis of the patient (see list item 1). Although all five of these variables are clearly important, items 3 and 5 require additional clarification, especially in a chapter focused on blood transfusion.

Measurement of Blood Loss

Measuring blood loss is obviously important when assessing the need for both the initial and subsequent blood transfusions (see Table 61-1). However, the accuracy of these measurements is not uniformly accurate. The overall clinical condition of the patient is explained and illustrated in Table 61-1. With regard to measurement of blood loss, clinical investigators at Duke University emphasized that "interpretation of intermittent measurements of hemoglobin levels is often complicated by fluid shifts, intravenous volume infusions, and actual

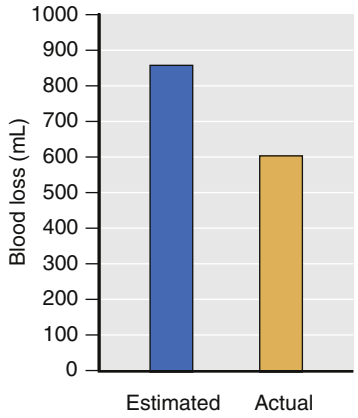

Figure 61-1. Discrepancy between estimated and actual blood loss. *(From Stovener J: Anesthesiologists vastly overstate bleeding,* Anesthesiol News *May 14, 2012.)*

transfusions."[25] A standard approach includes a combination of visualization and gravimetric measurements based on weight differences between dry and blood-soaked gauze pads. A study in patients undergoing spine surgery found that the anesthesiologists' estimate of blood loss was as much as 40% too large (Fig. 61-1). Basically, they collected the blood into heparinized saline to prevent clotting and then measured the volume of blood lost. Their findings were disturbing because overestimation of blood loss could lead to larger amounts of stored blood being given. Another study used an optical scanner for Apple's iPad tablet computer.[26] The scanner tended to underestimate blood loss, compared with the standard gravimetric calculations. Measuring intraoperative blood loss is extremely important and hopefully will be a more frequent topic of investigation.

Quantitation

The indications for administering additional units of blood are clear and logical. However, the five components of the key information (listed earlier) needed for making the decision to give more blood are often not very precise. As indicated previously and in Figure 61-1, intraoperative blood loss is even difficult to adequately quantify. Yet we need to make these decisions.

Determination of Hemoglobin Concentration

Transfusion decisions depend on many clinical factors and the blood Hb value, as indicated earlier. Clearly, these values are critical to decision making regarding blood transfusion and patient blood management decisions. Continuous blood Hb monitoring has become available on a noninvasive basis using spectrophotometric finger technology (Masimo SpHb, Masimo, Irvine, Calif). Numerous studies have been performed in a variety of clinical situations with emphasis on assessment of blood loss and/or the need for transfusions. Although measurement is frequently accurate (i.e., SpHb-Hb < 1.0 to 1.5 g/dL), the appearance of inaccurate values is not uncommon.[27,28]

Accuracy depends on both sensory factors and the physiology of the finger. If blood flow and temperature are increased, so is accuracy. For example, a digital nerve block decreases the number of inaccurate values and increases the number of accurate values.[29] The monitor displays many values, which can be helpful in assessing the accuracy of the SpHb value. Of prime importance is the perfusion index (PI). The accuracy of SpHb can be improved with a PI greater than 4% to 5%. This can be consistently achieved with a bupivacaine digital nerve block for several hours.[30] Although not specifically studied, warming the finger should increase the PI and, therefore, the accuracy of SpHb. This type of thinking was required in the early days of pulse oximetry; perhaps SpHb will evolve into being accurate even when the physiology of the finger is not optimal.

Can SpHb monitoring still be valuable even though its accuracy is not consistent? For example, Giraud and colleagues[31] concluded that SpHb is less invasive and less accurate than other measurements but provides valuable data on a continuous basis. They then concluded that none of the results would have led to transfusion errors as identified by the American Society of Anesthesiologists (ASA) Task Force on Perioperative Blood Transfusion and Adjuvant Therapies' updated practice guidelines published in 2006. Unfortunately, that outline is out of date, and a new one will appear in 2015. Observation of the trend is often recommended. Specifically, if the SpHb value suddenly changes 1 or 2 g/dL, the reasons for this change should be explored even if the absolute value is satisfactory. For example, if the SpHb reading is 11 g/dL, but rapidly decreases to 9.5 g/dL, the clinical situation has changed and needs to be reassessed. Although an attractive concept and possibly accurate, it is largely speculative.

HemoCue (HCue) (AB Leo Diagnostics, Helsinborg, Sweden) can be an accurate point-of-care Hb value. Hb values can be determined at the bedside or operating room in 5 to15 minutes. If the person performing the test is properly trained, both Giraud and colleagues[31] and Miller and colleagues[28] concluded that HCue measurements are extremely accurate. Yet, although HCue is probably more accurate than SpHb, the continuous manner of SpHb may identify some Hb changes more rapidly than HCue. In other words, an Hb value automatically occurs with SpHb whereas with HCue the clinician must make a decision that an Hb value is needed.

My opinion is that SpHb technology will consistently improve, as was the case with pulse oximetry. If so, SpHb could become very valuable with transfusion decision making in the future.

Preoperative Anemia

Preoperative anemia (i.e., low Hb value in women <12 g/dL; in men <13 g/dL) is an independent risk factor for increases in perioperative morbidity and mortality,[17] such as postoperative acute kidney injury (AKI).[32] Ideally, the patient's Hb value is known 2 to 4 weeks preoperatively. This provides sufficient time for the patient to undergo iron therapy, to correct nutritional deficiencies, or both. In a recent review of pharmacologic therapies in patient blood management, Goodnough and Shander[33] emphasized erythropoiesis-stimulating agents, especially intravenously administrated iron therapy, for treatment

of preoperative anemia. The concept of treating anemia preoperatively as a vehicle for decreasing the need for intraoperative transfusions is widely accepted. This concept has been demonstrated in other clinical situations. For example, intravascular iron therapy has eliminated the need for blood transfusions in gynecologic cancer.[34] If limited preoperative time is available, Karkouti and associates[35] seriously suggested that prophylactic erythrocyte transfusion should be used to reduce perioperative anemia. This suggestion met with controversy in the form of editorials and letters to the editor that were written supporting[33] (Karkouti) and condemning[36] such an approach.

Liberal Versus Restrictive Transfusion Strategy

The terminology of liberal versus restrictive has become completely indoctrinated into the transfusion therapy vocabulary. Several medical and surgical organizations have provided documents regarding their own definition of liberal and restrictive approaches. Some of these organizations include the American Association of Blood Banks,[37] International Conference on Transfusion Outcomes Group,[7] and Surgical Hip Fracture Repair (FOCUS).[38,39] Anesthesia providers need to understand exactly what the "strategies" are and their limitations.

Liberal versus restrictive transfusion strategy is based on the Hb value when a transfusion decision is made. A restrictive policy would be giving a blood transfusion only when the Hb value is 7 to 8 g/dL or less. In contrast, a liberal policy would be giving a blood transfusion when the Hb value is 9 to 10 g/dL or greater. Many studies have been performed in multiple clinical situations, with varying patient conditions, and ASA physical status values. One conclusion is that if no clinical advantages are associated with the liberal transfusion policy, perhaps the restrictive approach should be used. Certainly, fewer transfusion reactions would be expected with the restrictive approach.[38] In fact, many of these studies were supported by the NIH, which is an indication of how important this topic is for patient care. As indicated before, I find it amazing how important one laboratory test (Hb) has become regarding transfusion policies and patient blood management. One of many examples is the study by Kotze and colleagues.[40] One of their conclusions is that preoperative Hb values predict markers of hip or knee arthroplasty outcome. Kotze's group is one of many recommending a systemic approach to correcting Hb mass preoperatively. More recently, a meta-analysis was performed on all randomized trials of the liberal versus restrictive transfusion approaches to transfusion medicine.[41] Not surprisingly, they concluded, "restrictive strategies may decrease the incidence of health care–associated infections." Their restrictive Hb values were 6.4 to 9.7 g/dL and liberal 9.0 to 11.3 g/dL (some overlap). Although a meta-analysis contains no original data, Carson[42] provided a cautious editorial regarding Hb values. In my opinion, Hb values are important, but the overall condition of the patient is of prime importance. Accordingly, the American College of Surgeons attempted to categorize patient characteristics and blood loss as a basis for transfusion decisions (see Table 61-1).

The liberal versus restrictive strategy associated with patient blood management has some limitations. This strategy primarily addresses the indications for administering an initial unit of blood.[43] Most of this strategy is directed toward anemia in stable patients who are not actively bleeding. It does not describe what the indications for administration of repetitive units of blood should be. The need for repetitive transfusions in a bleeding patient is not addressed in the liberal versus restrictive discussion. Yet it is a very important topic for anesthesia providers and is discussed later in this chapter. The other considerations include status of the patient, vital signs, and blood loss. The transfusion trigger probably should be different in older patients with coexisting conditions who have abnormal cardiovascular status. Clearly, patients with active bleeding, especially those with cardiovascular disease, should be subjected to a more liberal transfusion strategy.[44]

General Conclusions

The emphasis on Hb levels for transfusion decisions needs some caution. The limitation of such values is based on a potential extreme variability from one patient to another regarding the need for increased O_2-carrying capacity via blood transfusions. For example, young healthy patients with normal cardiorespiratory function may easily compensate for anemia (i.e., chronic or acutely induced by hemorrhage), whereas at an identical Hct value, older patients with cardiac disease may have serious problems with surgery and anesthesia (see also Chapter 80). An individual patient's Hb level may vary markedly in the perioperative period independent of and in addition to transfusions of RBCs. For example, in the process of acute bleeding, Hb values are only slightly decreased initially even if the intravascular volume is markedly depleted.[44] Despite this caution, Hb levels are of principal importance in transfusion decisions.

AUTOLOGOUS BLOOD

Autologous blood (see also Chapter 63) is assumed to be much safer than allogeneic blood, mainly because of the decreased risk for infection. Because of a marked decrease in infectivity from allogeneic blood (see section on infectivity of blood), the difference in safety compared with that with autologous blood is much less. Not surprisingly, the proportion of autologous blood collected has significantly decreased since the peak in 1992. In fact, autologous blood may not be safer than allogeneic blood. Furthermore, autologous blood does have risks. Complications associated with autologous blood transfusions include the following:

- Anemia
- Preoperative myocardial ischemia from anemia induced by preoperative donation
- Autologous units given to the wrong patient
- Need for more frequent blood transfusions

In fact, transfusion-related bacterial sepsis may be more frequent with use of autologous blood because of the underlying medical condition of the donor and less stringent donor selection. Also, autologous blood must be tested the same as allogeneic blood.

TABLE 61-2 **PROPERTIES OF WHOLE BLOOD AND PACKED RED CELL CONCENTRATES STORED IN CPDA-1**

	Days of Storage		
Variable	**0**	**35 (Whole Blood)**	**35 (Packed Cells)**
pH	7.55	6.73	6.71
Plasma hemoglobin (mg/dL)	0.50	46.00	246.00
Plasma potassium (mEq/L)	4.20	17.20	76.00
Plasma sodium (mEq/L)	169.00	153.00	122.00
Blood dextrose (mg/dL)	440.00	282.00	84.00
2,3-Diphosphoglycerate (μM/mL)	13.20	1.00	1.00
Percent survival*	—	79.00	71.00

CPDA-1, Citrate phosphate dextrose adenine-1.
*Percent recovery of O_R-tagged red blood cells at 24 hours.

The testing and screening of blood donors is by no means perfect. Ask yourself a question: If given a choice, would you want your own blood or allogeneic blood?[45]

CHANGES DURING STORAGE OF BLOOD

BIOCHEMICAL CHANGES IN STORED BLOOD

Units of blood collected from donors are usually separated into components, such as RBCs, plasma, cryoprecipitate, and platelets. PRBCs or whole blood can be stored for up to 42 days. The storage bags allow separation of blood into components. Citrate phosphate dextrose adenine-1 (CPDA-1) is an anticoagulant preservative in which blood is stored at 1° to 6° C. Citrate is an anticoagulant, phosphate serves as a buffer, and dextrose is a red cell energy source. The addition of adenine to citrate phosphate dextrose (CPD) solution allows RBCs to resynthesize adenosine triphosphate (ATP), which extends the storage time from 21 to 35 days. As a result, RBCs or whole blood can be stored for 35 days when stored in CPDA-1.[46] The shelf life can be extended to 42 days when AS-1 (Adsol), AS-3 (Nutricel), or AS-5 (Optisol) is used.[47,48] Adsol contains adenine, glucose, mannitol, and sodium chloride. Nutricel contains glucose, adenine, citrate, phosphate, and NaCl. Optisol contains only dextrose, adenine, NaCl, and mannitol. At the University of California, San Francisco (UCSF), 90% of RBCs are stored in AS-1. On a national level, 85% of RBCs are collected in AS-1. The Hct of PRBCs stored in AS-1 is approximately 60%. This duration of storage has been set by U.S. federal regulation and is determined by the requirement that at least 70% of the transfused RBCs remain in circulation for 24 hours after infusion. RBCs that survive 24 hours after transfusion disappear from the circulation at a normal rate. The RBCs that do not survive are subsequently removed from circulation by the blood recipient.

That blood can be stored for 42 days is a mixed blessing. The obvious advantage is the increased availability of blood. However, an increasing number of authors think blood stored for long periods is less effective than fresher blood in critically ill patients, possibly because of a leftward shift in the O_2-dissociation curve (see section on changes in oxygen transport).[49] An increased incidence of postoperative pneumonia in cardiac patients has been associated with the use of older blood.[50]

The citrate ion prevents clotting by binding Ca^{2+}; dextrose allows the RBCs to continue glycolysis and maintain sufficient concentrations of high-energy nucleotides (ATP) to ensure continued RBC metabolism and subsequent viability during storage. Storage at 1° to 6° C assists preservation by slowing the rate of glycolysis approximately 40 times the rate at body temperature. The addition of adenine prolongs storage time by increasing RBC survival, allowing them to resynthesize the ATP needed to fuel metabolic reactions. Without adenine, RBCs gradually lose their ATP and their ability to survive after transfusion.

During storage of whole blood and PRBCs, a series of biochemical reactions occur that alter the biochemical makeup of blood and account for some of the complications that are discussed later. During storage, RBCs metabolize glucose to lactate, hydrogen ions accumulate, and plasma pH decreases. The storage temperatures of 1° to 6° C stimulate the sodium-potassium pump, and RBCs lose K^+ and gain Na. The osmotic fragility of RBCs increases during storage, and some cells undergo lysis, resulting in increased plasma Hb levels. Progressive decreases in RBC concentrations of ATP and 2,3-diphosphoglycerate (2,3-DPG) occur during storage.

PRBCs have a slightly shorter survival time than whole blood (Table 61-2), although values for Hb and K^+ concentrations may appear somewhat high in 35-day stored RBC concentrates. However, the total plasma volume in the concentrates is only 70 mL. Specifically, when CPDA is the anticoagulant used, the Hct is approximately 65%. Because most of the plasma is removed, the resulting volume is approximately 250 mL. When CPDA-1 is used, the storage time is increased from 35 to 42 days. The plasma is removed and 100 mL of storage solution is added, resulting in an Hct of 40% and volume of 310 mL.[51]

CLINICAL IMPLICATIONS: DURATION OF BLOOD STORAGE

Several groups working with patients in intensive care units (ICUs) have attempted to define the point at which blood transfusions should be given by measures of tissue oxygenation and hemodynamics (e.g., increase in O_2 consumption in response to added O_2 content).[52-54] No

specific measure can consistently predict when a patient will benefit from a blood transfusion. However, the quality (e.g., age) of the blood and its increased O_2 capacity (e.g., Hb level > 10 g/dL) may benefit very sick patients. Purdy and colleagues[55] found that patients who received 17-day-old blood (range, 5 to 35 days) versus 25-day-old blood (range, 9 to 36 days) had a more frequent survival rate. In 1999, the length of storage of banked blood was related to the development of postoperative pneumonia after cardiac surgery.[50] (Yet, in contrast, in 2003 prolonged storage of blood was not associated with increased morbidity after cardiac surgery.)[49]

As stated in the 7th edition of this book, "Yet the saga continues," which also applies to this 8th edition. In 2006, Weiskopf and associates[56] performed studies in healthy volunteers who were evaluated by a standard computerized neuropsychological test 2 days and 1 week after acute isovolemic anemia was induced.[56] When correcting the anemia, they concluded that erythrocytes stored for 3 weeks are as efficacious as those stored for 3.5 hours. Spahn[57] wrote an accompanying editorial agreeing with Weiskopf and associates[57] and, furthermore, postulated that 2,3-DPG levels may not be the key factor in determining the delivery of O_2 (i.e., 2,3-DPG levels are reduced in older blood, but the blood still delivers O_2).

Two years later, different conclusions were published. Koch and colleagues[58] concluded that giving erythrocytes (PRBCs) older than 14 days was associated with an increased risk for postoperative complications along with reduced short-term and long-term survival in patients undergoing coronary artery bypass surgery. This article also had an accompanying editorial that concluded, "to the extent possible, newer blood might be used in clinical situations that seem to call for it."[59] Rather than continuing the ongoing saga and debate regarding the influence of the age of blood transfused, all of the available studies that probably relate to the underlying health of the patient and the specific condition that requires blood transfusions need to be analyzed together. Thus, the debate regarding the effectiveness of a blood transfusion and its duration of storage continues. Because the quality of blood decreases with length of storage, an association with morbidity could be expected. Several other studies have sought resolution regarding the impact of storage time on blood.

In 2007, Bennett-Guerrero and associates[60] described the biochemical changes in RBCs in great detail. Yet the most current opinions and data do not answer the questions. A meta-analysis concluded that older stored blood is associated with an increased risk for death.[61] However, Spinella and associates[62] did not arrive at a clear conclusion and recommended more studies. Cata and associates[63] also concluded that no change in outcome occurred in patients undergoing radical prostatectomy and receiving older blood. Saager and colleagues[64] also found no relationship between duration of blood storage and mortality in nearly 7000 patients undergoing noncardiac surgery. This study was a retrospective analysis with mortality as its end point. Yet Frank and associates[65] studied the blood of patients undergoing posterior spinal fusion surgery and found that duration of blood storage was associated with RBC deformity, which was not "readily" reversible after transfusion. They speculated that these deformed cells may be defective in delivering O_2 to the cells. On a broader basis, they concluded that both the "age of blood storage" (i.e., because of the changes in rheology of older blood) and "amount" of blood given should be considered when giving blood.

Although conclusions cannot be definitive, logic dictates that blood less than 14 days of storage should be better than older storage. Yet we still do not have a complete answer for the possible importance of duration of storage on clinical outcomes. Furthermore, the measures of outcome may be insufficiently sensitive to detect clinical outcomes. Many studies use mortality as their outcome measure. Although this is obviously a crucial outcome, it may not be sensitive enough to detect the importance of how long the storage of blood transfused has been. However, other clinical outcomes should be better (e.g., duration of hospitalization, cardiovascular changes). Certainly, many adverse clinical outcomes could occur without a change in mortality per se. Also, many of the studies rely on retrospective analysis, which is significantly dependent on the thoroughness of the database content that records the patient's past clinical course and outcomes. Of course, mortality is a definitive outcome and easily validated, but the less dramatic outcomes need to be analyzed. Two national studies are underway in the United States, including Age of Blood Evaluation (ABLE) and Red Cell Storage Study (RECESS), which will hopefully provide some decisive conclusions regarding the influence of the duration of blood storage.

The development of more sensitive indicators of tissue oxygenation (e.g., intramucosal pH) may provide indicators for transfusion. In the 1990s, several investigative efforts could not relate postoperative Hb levels to specific outcomes. Furthermore, Weiskopf and co-workers[66] found that decreases in Hb concentration to 5.0 g/dL did not produce any evidence of inadequate oxygenation in healthy patients. However, these patients were not subjected to the stresses of recovery from surgery and anesthesia. Still, Weiskopf and co-workers[66] found that these patients compensated for their low Hb levels with increased heart rates and stroke volumes. It is tempting to argue that patients who have a more rapid than expected heart rate or who cannot increase their cardiac output should receive a transfusion at a higher Hb level than 10 g/dL. Unfortunately, precise conclusions cannot be derived from these suggestive data. The following paragraph and list of guidelines was published in the 7th edition of *Miller's Anesthesia* and still applies.

To arrive at some conclusions in the presence of incomplete data, two complementary recommendations are given. The ASA's 2006 updated practice guidelines offer these recommendations[67]:

1. Transfusion is rarely indicated when the Hb concentration is more than 10 g/dL and is almost always indicated when it is less than 6 g/dL, especially when the anemia is acute.
2. The determination of whether intermediate Hb concentrations (6 to 10 g/dL) justify or require RBC transfusion should be based on the patient's risk for complications of inadequate oxygenation.

3. The use of a single Hb trigger for all patients and other approaches that fail to consider all important physiologic and surgical factors affecting oxygenation is not recommended.
4. When appropriate, preoperative autologous blood donation, intraoperative and postoperative blood recovery, acute normovolemic hemodilution, and measures to decrease blood loss (i.e., deliberate hypotension and pharmacologic drugs) may be beneficial. The pharmacologic approach is discussed later in this chapter.
5. The indications for transfusion of autologous RBCs may be more liberal than those for allogeneic RBCs because of less frequent (but still significant) risks associated with the former.

As previously mentioned, the 2006 ASA updated practice guidelines will be updated again in 2015. The following indications were recommended in the 6th edition of *Miller's Anesthesia* and are still useful, with the rule of thumb that administration of 1 unit of PRBCs increases the Hct value by 3% to 5%:

1. Blood loss greater than 20% of blood volume when more than 100 mL
2. Hb level less than 8 g/dL
3. Hb level less than 9 to 10 g/dL with major disease (e.g., emphysema, ischemic heart disease)
4. Hb level of less than 10 g/dL with autologous blood
5. Hb level less than 11 to 12 g/dL and ventilator dependent

Although these recommendations are current, the elusive transfusion trigger remains in a prominent part of the debates in anesthesia specifically and in medicine in general. Both lists of recommendations[67] agree that a transfusion trigger of 8.0 g/dL or less can be tolerated by patients who are not critically ill or do not have severe cardiorespiratory disease. That conclusion is still valid.

How liberal should the transfusion trigger be in critically ill patients? Some critical care physicians have suggested that administration of blood transfusions is related to the incidence of ventilator-assisted pneumonia[68] and nosocomial infections[69]; although this possibility cannot be excluded, these are complicated problems with many variables. Despite the difficulty with identifying a specific transfusion trigger, Ely and Bernard[70] have generally confirmed the conclusions listed earlier in the 6th edition of *Miller's Anesthesia*. Subsequent efforts and editorials lean toward a lower transfusion trigger for even critically ill patients.[71,72] Better outcomes have not consistently occurred with transfusion-induced Hb levels more than 8.0 g/dL (i.e., 9.0 to 10.0 g/dL).[73,74] Yet Vincent and associates,[75] using a multicenter observational study, found that "blood transfusions may no longer be associated with increased mortality rates and may be associated with improved survival." Although these multicenter studies have statistical challenges,[76] a more liberal transfusion trigger is suggested. Perhaps the margin of safety should be increased by increasing the Hb in critically ill patients, including those with cardiorespiratory disease. Some concern even exists about the underuse of blood transfusion therapy.[77] However, blood is a valuable resource that sometimes is in short supply. Perhaps with the availability of erythropoietin and synthetic RBCs, a more liberal Hb concentration can be used. As concluded by Weiskopf,[78] "We merely await advances in technology that will enable us to measure directly the value of concern and thereby free us from arguments over which surrogate (e.g., hemoglobin) to measure and what value indicates the need for augmented oxygen delivery." Although Weiskopf wrote this opinion in l998, surrogate indicators, such as the blood Hb values, are still used for transfusion decisions.

COMPATIBILITY TESTING

GENERAL PRINCIPLES

The ABO-Rh type, crossmatch, and antibody screen are frequently referred to as compatibility tests. These tests were designed to demonstrate harmful antigen-antibody interactions in vitro so that harmful in vivo antigen-antibody interactions could be prevented. Donor blood used for emergency transfusion of group-specific blood must be screened for hemolytic anti-A or anti-B antibodies, or both. All donor blood must be tested for the correct ABO and Rh type and screened for unexpected antibodies. Similarly, recipient blood must also undergo ABO-Rh typing, as well as testing for unexpected antibodies. Once this has been completed, proper selection of donor blood requires a test for compatibility between recipient blood and donor blood; this test is known as a crossmatch (Fig. 61-2).

All approved blood banks have redundant processes in place to ensure that the patient receives the correct unit of blood. For example, in 2012, UCSF's Blood Bank reported 88 incidents of near misses, which infers that some part of the process was not sufficiently precise. Four near misses occurred when the wrong blood was in the tube that was given to the blood bank; five other tubes had wrong patient information on the tube. These incidences emphasize the advantage of and need for a confirmatory specimen drawn at a separate time from the type and screen. At the risk for being redundant, a patient must not receive the wrong unit of blood. A hemolytic blood transfusion reaction usually occurs when the wrong unit of blood is given. This type of reaction is described later in the chapter.

ABO-RH TYPING

Determination of the patient's correct blood type is exceedingly important because the most serious and tragic reactions are usually caused by accidental transfusion of ABO-incompatible blood. These reactions result from naturally occurring antibodies (i.e., anti-A and anti-B), which activate complement and lead to rapid intravenous hemolysis. Anti-A or anti-B antibodies, or both, are formed whenever the individual lacks either or both of the A and B antigens. In essence, antibodies are directed against those antigens that are lacking in the individual's own cells. ABO typing is performed by testing RBCs for the A and B antigens and the serum for the A and B antibodies before transfusion (Table 61-3).

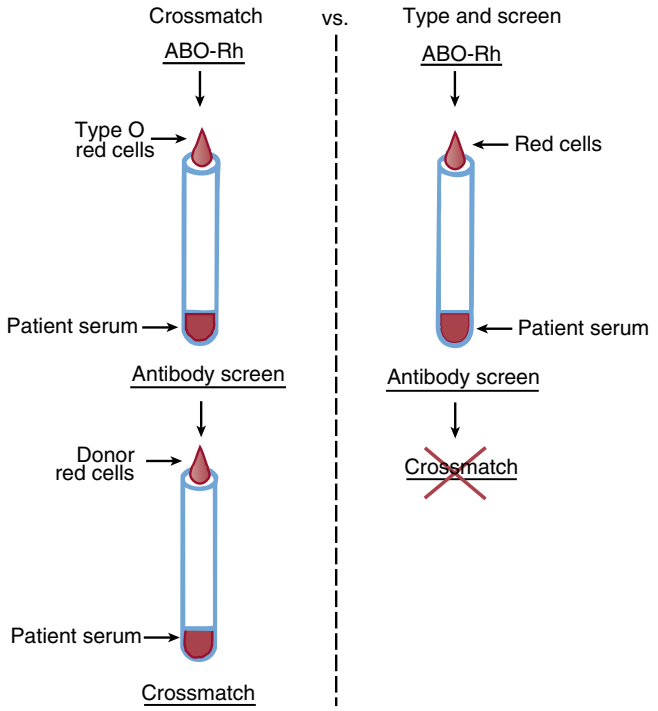

Figure 61-2. Outline of the tests used for a crossmatch. The X over the word *crossmatch* means that the crossmatch is not included in the type and screen.

The only additional required testing is that for the Rh(D) antigen. Antigen D is a very common one and, except for the A and B antigens, the one most likely to produce immunization. Of Rh(D)-negative recipients, 60% to 70% are immunized (produce anti-D) if they are given blood transfusions with Rh(D)-positive blood. Approximately 85% of individuals possess the D antigen and are classified as Rh(D) positive; the remaining 15%, who lack the D antigen, are classified as Rh(D) negative. Because anesthesiologists and surgeons often have difficulty understanding the blood grouping system, Table 61-4 is included to facilitate identification of donor blood groups whose blood patients can receive.

CROSSMATCHING

A crossmatch is essentially a trial transfusion within a test tube in which donor RBCs are mixed with recipient serum to detect a potential for serious transfusion reaction. The crossmatch can be completed in 45 to 60 minutes and is performed in three phases: an immediate phase, an incubation phase, and an antiglobulin phase.

The first, or immediate, phase (RT) is conducted at room temperature and is a check against errors in ABO typing. It detects ABO incompatibilities and those caused by naturally occurring antibodies in the MN, P, and Lewis systems. This takes 1 to 5 minutes to complete.

The second, or incubation, phase involves incubation of the first-phase reactions at 37° C in albumin or low–ionic strength salt solution. The addition of albumin and low–ionic strength salt solution aids in the detection of incomplete antibodies or antibodies able to attach to a specific antigen (i.e., sensitization) but are unable to cause agglutination in a saline suspension of RBCs. This phase primarily detects antibodies in the Rh system. An incubation period of 30 to 45 minutes in albumin and of 10 to 20 minutes in low–ionic strength salt solution in this phase is of sufficient duration to allow antibody uptake sensitization by cells so that incomplete antibodies missed in this phase can be detected in the subsequent antiglobulin phase.

The third, or antiglobulin, phase of the crossmatch, the indirect antiglobulin test, involves the addition of antiglobulin sera to the incubated test tubes. With this addition, antihuman antibodies present in the sera become attached to the antibody globulin on the RBCs, causing agglutination. This antiglobulin phase detects most incomplete antibodies in the blood group systems, including the Rh, Kell, Kidd, and Duffy blood group systems.

Although all three phases of the crossmatch are important, the first two are of prime importance in preventing serious hemolytic transfusion reactions (see section on type and screen). The incubation and antiglobulin phases are especially important because the antibodies appearing in these phases are capable of causing serious hemolytic reactions. Except for hemolytic reactions involving anti-A and anti-B, reactions caused by antibodies appearing in the immediate phase are frequently less severe. This is because many of the antibodies appearing in this phase are naturally occurring antibodies present in a low titer and are not reactive at physiologic temperatures.

ANTIBODY SCREENING

The antibody screen is also carried out in three phases and is similar in length to the crossmatch. The screen, however, is a trial transfusion between the recipient's serum and commercially supplied RBCs that are specifically selected to contain optimal numbers of RBC antigens or antigens that will react with antibodies that are commonly implicated in hemolytic transfusion reactions.

TABLE 61-3 ABO COMPATIBILITY TESTING

	Red Cells Tested With		Serum Tested With	
Blood Group	Anti-A	Anti-B	A Cells	B Cells
A	+	–	–	+
B	–	+	+	–
AB	+	+	–	–
O	–	–	+	+

TABLE 61-4 DONOR BLOOD GROUPS THAT PATIENTS CAN RECEIVE

Donor	Recipient
O	O, A, B, AB
A	A, AB
B	B, AB
AB	AB

The screen for unexpected antibodies is also used on donor serum and is performed shortly after withdrawal of blood from the donor. It is necessary to screen donor serum for unexpected antibodies to prevent their introduction into the recipient serum. This screen is performed primarily to prevent reactions between transfused donor units.

APPROACHES REQUIRING LESS THAN A COMPLETE CROSSMATCH

TYPE AND SCREEN

The term *type and screen* refers to elimination of the crossmatch in which blood is set aside with only the ABO-Rh type having been determined and antibody screening having been performed. The type and screen without crossmatch determines the ABO-Rh of the patient and the presence of the most commonly found unexpected antibodies. Specifically, the patient's serum is screened for the presence of unexpected antibodies by incubating it with selected reagent RBCs (i.e., screen cells).[79] These cells contain all antigens capable of inducing clinically significant RBC antibody reactions.

Complete transfusion testing for compatibility between donor and recipient blood ensures optimal safety and therapeutic effect of transfused blood. In some cases, however, the crossmatch is eliminated and blood can be set aside in which only the ABO-Rh type and antibody screen are performed (i.e., type and screen). For those few patients in whom the antibody screen reveals the presence of unexpected antibody, the antibody is subsequently identified in the blood bank and units of blood lacking the corresponding antigen are set aside for surgery. If an emergency transfusion is required after type and screen alone, an immediate-phase crossmatch is performed before transfusion to eliminate reactions that may result from human errors in ABO-Rh typing. Blood given in this manner is more than 99% effective in preventing incompatible transfusion reactions caused by unexpected antibodies.[80] The type and screen without the complete crossmatch does not protect against reactions caused by antibodies reactive against lower incidence antigens—that is, those not represented on the screening cells but present on the donor RBCs. Generally, antibodies that are not detected in the type and screen are weakly reactive antibodies that do not result in serious hemolytic transfusion reactions. In a study of 13,950 patients, Oberman and associates[81] discovered only eight "clinically significant" antibodies after complete crossmatch that were not detected during the antibody screening. The antibodies were all in lower titer and were believed by Oberman and associates to be unlikely to cause serious hemolytic reactions.

Most recently, Dexter and associates[82] established that using the estimated blood loss located in an anesthesia information system is more efficacious than that based on estimated blood loss and incidences of transfusions. An editorial by Reich and associates[83] emphasizes that this approach to type and screen decisions is an example of medicine's increasing dependence on information systems as described in the Preface of this book.

Type and screen should not be confused with the term *type and hold.* This term refers to a sample of blood from a potential blood recipient received by the blood bank in which the blood type but no crossmatch has been ordered. This term is misleading because it does not denote how long the blood should be held or whether an antibody screen has been performed on the sample. However, in most cases in which a type and hold has been ordered, an antibody screen is performed on that sample. Because of the confusion that has arisen with type and screen, the type and hold terminology and method of ordering blood have been abandoned by most blood banks.

MAXIMAL SURGICAL BLOOD ORDER SCHEDULE

The following paragraph is the same one that appeared in the 7th edition of *Miller's Anesthesia* and still applies in hospitals without contemporary information technology systems in place: Routine preoperative crossmatching of blood for surgical cases means that crossmatched blood is unavailable for others for 24 to 48 hours. During this time, 1 to 2 days is lost and the chance for outdating increases. A second aspect relates to the growing realization that, for certain elective surgical procedures, the number of crossmatched units ordered frequently far exceeds the number actually transfused. To quantify this problem better, the crossmatch-to-transfusion (C/T) ratio has been used. If the C/T ratio is high, the blood bank is burdened with keeping a large blood inventory, using excessive personnel time, and having a high incidence of outdated units. Sarma[84] recommended that for surgical procedures in which the average number of units transfused per case is less than 0.5, determination of the ABO-Rh type and a screen of the patient serum for unexpected antibodies (type and screen) should be used. This would be in lieu of a complete type and crossmatch for patients with negative antibody screens. For those with a positive antibody screen, the blood bank must provide compatible units that lack the corresponding antigen. Blood banks attempt to maintain C/T ratios of 2.1 to 2.7.[84] To increase the rate of use and lower the C/T ratio, blood banks attempt to decrease the emphasis on crossmatching of blood through such means as the type and screen and such programs as the maximal surgical blood order schedule (MSBOS).[85] This schedule consists of a list of surgical procedures and the maximal number of units of blood that the blood bank will crossmatch for each procedure. This schedule is based on the blood transfusion experience for surgical cases in hospitals in which the schedule is employed. Each hospital's MSBOS is developed by the suppliers and the users of blood in that hospital, such as blood bank staffers, anesthesiologists, and surgeons.

In the past several years, many blood banks have implemented information technology systems and revised procedures. Although information systems may vary among some institutions, some common pathways exist. Instead of the blood bank examining the next day's surgical schedule and allocating blood as described in the previous paragraph, now information technology systems have the capability of displaying the surgical schedule along with the MSBOS's recommendation regarding

blood for each surgical procedure. For institutions with information technology systems in place, the process is more as follows. The night before, the blood bank examines the surgical schedule and MSBOS recommendations to see what blood samples are missing and whether blood is needed. A communication to the preoperative team on what samples are needed (e.g., is any type and screen and ABO confirmation missing) and what tests have already been performed is disseminated. Then the preoperative team checks this communication and sends appropriate blood samples. The blood bank uses the MSBOS information to see if additional testing should be performed. If the MSBOS says that a type and screen is not needed, testing will not occur.*

IS THE CROSSMATCH REALLY NEEDED?

In previously transfused or pregnant patients, only approximately 1 patient in 100 may have an irregular antibody other than the anti-A and anti-B antibodies. However, some of these irregular antibodies are reactive only at temperatures below 30° C and therefore are insignificant in most transfusions. Others that are reactive at approximately 30° C can produce serious reactions if the transfused cells contain appropriate antigen. In order of probable significance, anti-Rh(D), Kell, C, E, and Kidd are the most common of clinically significant antibodies. After anti-A and anti-B, anti-Rh(D) is the most common significant antibody. If the correct ABO and Rh blood type is given, the possibility of transfusing incompatible blood is less than 1 chance in 1000. Put in other terms, ABO-Rh typing alone results in a 99.8% chance of a compatible transfusion, the addition of an antibody screen increases the safety to 99.94%, and a crossmatch increases this to 99.95%.[86]

The blood bank can reduce the chance of incompatibility by performing an antibody screen. The chance of this screening test missing an antibody that is potentially dangerous has been estimated to be no more than 1 in 10,000.

EMERGENCY TRANSFUSION

Blood transfusions constitute a part of the overall care of a patient with a serious and urgent clinical situation (see also Chapters 81 to 83). In the past few years, terminology has been added to our clinical vocabulary to characterize these situations. The "lethal triad" consists of hypothermia, acidosis, and a coagulopathy, the combination of which is well known to contribute to morbidity and mortality in severely injured or hemorrhaging patients. These factors add many biochemical and physiologic factors that contribute to persistent hemorrhage and clinical decline in patient welfare. The approach of damage control resuscitation has evolved. This approach includes use of permissive hypotension, damage control surgical techniques, and cautious administration of crystalloids. Topical hemostatic agents may include topical application of hemostatic dressings. There are even "walking blood banks" of prescreened donors available for urgent transfusion needs.[87]

In many situations, urgent need for blood occurs before completion of compatibility testing (ABO-Rh, antibody screen, and crossmatch; see also Chapter 81), which describes transfusion challenges in patients who require surgery and anesthesia after injury from trauma. In essence, for those situations that do not allow time for complete testing, an abbreviated format for testing can be used, such as described in the following paragraphs.

TYPE-SPECIFIC, PARTIALLY CROSSMATCHED BLOOD

When using uncrossmatched blood, it is best to obtain at least an ABO-Rh typing and an immediate-phase crossmatch. This incomplete crossmatch is accomplished by adding the patient's serum to donor RBCs at room temperature, centrifuging it, and then reading it for macroscopic agglutination. This takes 1 to 5 minutes and eliminates serious hemolytic reactions resulting from errors that may occur in ABO typing. Only a few unexpected antibodies outside the ABO systems are detected, such as those directed against antigens in the MN, P, and Lewis systems, most of which are not clinically significant.

TYPE-SPECIFIC, UNCROSSMATCHED BLOOD

For proper use of type-specific blood, the ABO-Rh type must be determined during the patient's hospitalization. Blood types from historical records, relatives, ambulance drivers, and other hospitals are frequently inaccurate. For those who have never been exposed to foreign RBCs, most ABO type-specific transfusions are successful. Caution should be used for patients who have previously received transfusions or have had pregnancies. In my experience in the military, type-specific uncrossmatched blood was frequently used in emergencies with no serious consequence. In the civilian setting, using 1 year's experience with 56 patients, uncrossmatched, type-specific blood for emergency transfusion produced no adverse effects, even though complete serologic testing had not been performed.[88] These investigators concluded that although the use of uncrossmatched blood is usually safe, the potential for serious reaction still exists, and they cautioned against its indiscriminate use. Approximately 1 in 1000 patients has an unexpected antibody detected in crossmatch. For those who have previously been exposed to RBC antigens, transfusion of the ABO-Rh type-specific, uncrossmatched blood may be more hazardous. For every 100 of these individuals, 1 has an antibody detected by the crossmatch.

TYPE O RH-NEGATIVE (UNIVERSAL DONOR), UNCROSSMATCHED BLOOD

Type O blood lacks the A and B antigens and consequently cannot be hemolyzed by anti-A or anti-B antibodies in the recipient's blood (see Tables 61-3 and 61-4). Because of this, people with type O blood have been

*This author acknowledges the help of Morvarid Moayeri, MD, PhD, Associate Director of the UCSF Blood Bank, for his help with this paragraph.

called universal donors and their blood can be used in emergency transfusions when typing or crossmatching is not available. However, some type O donors produce high titers of hemolytic immunoglobulin G (IgG), IgM, anti-A, and anti-B antibodies. High titers of these hemolysins in donor units are capable of causing destruction of A or B RBCs of a non–type O recipient. Type O Rh-negative, uncrossmatched PRBCs should be used in preference to type O Rh-negative whole blood because packed erythrocytes have smaller volumes of plasma and are almost free of hemolytic anti-A and anti-B antibodies. If type O Rh-negative whole blood is to be used, the blood bank must supply type O blood that is free of hemolytic anti-A and anti-B antibodies.

In addition to trauma units, anesthesia and surgical teams often struggle with how much and how the crossmatch process can be attenuated in emergency situations. At the risk for being repetitive, a brief situation is described. Some hospitals have an emergency-release RBC pack, which is uncrossmatched RBCs that are O negative. If clinicians think the situation is urgent, this blood usually can be provided in approximately 5 minutes. Also available in concept in some hospitals is a massive transfusion protocol (MTP), which includes 4 units uncrossmatched O negative RBCs, 4 units thawed AB plasma, and 1 unit of platelet concentrates. A physician must directly order this blood, and that decision is reviewed after analysis of the emergency situation. The complete crossmatch (i.e., electronic, immediate spin, or Coombs or antihuman globulin) is only eliminated in a well-defined emergency and with only O-negative blood.

This process is usually with PRBCs and not whole blood. Although uncrossmatched blood appropriately causes great concern, the risks for complication "appear" to be quite infrequent.[†]

During emergency transfusion of more than 2 units of type O Rh-negative, uncrossmatched whole blood, the patient probably cannot be switched to his or her blood type (A, B, or AB) as soon as the blood bank determines the correct blood type. Switching could cause major intravascular hemolysis of donor RBCs by increasing titers of transfused anti-A and anti-B. Continued use of O Rh-negative whole blood results only in minor hemolysis of recipient RBCs, with hyperbilirubinemia as the only complication. The patient must not be transfused with his or her correct blood type until the blood bank determines that the transfused anti-A and anti-B has decreased to levels that permit safe transfusion of type-specific blood.

FRESH WHOLE BLOOD

The definition of fresh whole blood is based on storage time, which varies from 1 hour to 5 days[89] before it is administered to patients. This definition takes into account that whole blood stored for 1 hour is much different from that stored for 5 days. For example, Kor and associates[90] concluded that there was no difference in pulmonary function or coagulation status when comparing fresh blood with standard-unit blood transfusion. However, this rather liberal definition of fresh blood is based on being stored for less than 5 days. Was this really fresh blood? For example, blood stored for less than 24 hours is much different than that stored for 4 days. The degree to which fresh blood regains its various functions is directly related to the length of storage and whether it has been cooled. The longer blood is stored, the less effective it becomes, especially regarding coagulation. Even 1 unit of whole blood stored for 24 hours at 4° C has less hemostatic effects than 1 unit of fresh blood stored for less than 6 hours because of decreased platelet aggregability.[91] Whole blood that has been typed and crossmatched, but not cooled retains most of the factors in normal in vivo blood. Spinella and colleagues[92] define fresh blood as having a shelf life of 24 hours and that is stored at 1° to 6° C within 8 hours after collection. Some institutions define it as fresh if it has been stored less than 48 hours at 2° to 5° C. The difference between 1 hour and 2 days of storage is tremendous, especially as it relates to platelet activity.

Numerous articles appear in the literature regarding the use of fresh whole blood. Part of the explanation of variability among studies is related to the duration of storage and use of hypothermia during the storage of fresh whole blood. Nevertheless, whole blood has been a component of transfusion for over 70 years, including during World War II.[11] The military and trauma hospitals have promoted and fine-tuned its use. My experience in Vietnam verified that typed and crossmatched warm whole blood was extremely effective in treating the coagulopathy from massive transfusions, especially in the absence of sepsis.[4,5] The use of unrefrigerated fresh whole blood is well known to be clinically very effective.[93] Many different protocols have complicated variations to the concept of simple administration of fresh whole blood as very effective, as described in the next paragraph.

The current literature is not consistent partly because of the variety of clinical situations. Even the ratio concept has been used for platelets. A transfusion ratio of 1:1:1 (RBCs to frozen plasma to platelets) was compared with a standard MTP based on laboratory values.[94] No difference between the two groups was found. However, the fixed ratio was associated with increased plasma wastage. Cotton and colleagues[95] compared whole blood versus component therapy. Unfortunately, each group automatically received platelets, making any conclusions regarding platelets impossible. Not surprisingly, fresh whole blood is effective in treating unresponsive life-threatening hemorrhage. A study of human volunteers who were given fresh and stored autologous blood came to the conclusion that blood stored for more than 21 days is not more injurious than fresh whole blood.[15] Yet using autologous blood is probably not an appropriate model to answer this question.

Basically, administration of older stored blood, colloids, and crystalloids dilute the platelets resulting in dilutional thrombocytopenia. After 15 to 20 units of blood have been given, the thrombocytopenia will cause a coagulopathy on a dilutional basis. If any additional cause of the coagulopathy exists (e.g., sepsis, massive

[†]This author acknowledges the help of Morvarid Moayeri, MD, PhD, Associate Director of the UCSF Blood Bank, with this section.)

consumption), the clinical coagulopathy will appear with fewer than 15 to 20 units of blood given. A more current rule of thumb is to transfuse 1 apheresis pack (6 units) of platelets in anticipation of a platelet count of 50 to 75,000/μL.[96]

One additional consideration is the best source of platelets—fresh blood or apheresis platelets. This question was studied in the armed forces when given to massively transfused military patients. No difference was found in adverse effects and mortality between patient groups receiving platelets.[97] In an atmosphere of limited resources, fresh whole blood is an excellent source of platelets.

SPECIFIC RECOMMENDED PROTOCOLS

In view of the aforementioned considerations, recommended protocols exist for the care of patients who are in urgent clinical situations potentially including hypovolemia and the possible requirement for blood transfusions. Of course, administration of blood products is only one part of a comprehensive approach to such urgent clinical challenges (see also Chapters 81 through 83). The following recommendations are brief and general, with the details of these further discussed in other sections of this chapter or in other chapters of this edition.

1. Infuse colloids, or crystalloids, or both. This topic was addressed by Myberg and associates.[98] Colloids are discussed in this chapter's section on synthetic colloid solution therapy, and the section on crystalloids in Chapter 59. The Myberg article "Resuscitation Fluids" states, "Although albumin has been determined to be safe for use as a resuscitation fluid in most critically ill patients and may have a role in early sepsis, its use is associated with increased mortality among patients with acute brain injury (also see Chapter 70). The use of hydroxyethyl starch (HES) solutions is associated with increased rates of renal-replacement therapy and adverse events among patients in ICUs. There is no evidence to recommend the use of other semisynthetic colloid solutions." In essence, crystalloids and blood (assuming blood loss and/or anemia) are the main fluids for resuscitation in acutely ill patients.
2. Draw a blood sample for typing and crossmatching.
3. If crossmatched blood is not ready to give, use type-specific or type O Rh-negative RBCs or type O-positive RBCs for males or postmenopausal females without a history of transfusions; type-specific, partially crossmatched blood; or type-specific, crossmatched blood.
4. In certain severe cases, the problems of massive transfusion should be anticipated. As indicated in this chapter, fresh whole blood should be considered if available.

Innovative methods of storing blood are being developed. For example, storing blood in an electrostatic field of 500 to 3000 V decreases hemolysis and attenuates the decrease in pH associated with prolonged storage.[99]

COMPLICATIONS

CHANGES IN OXYGEN TRANSPORT

RBCs are transfused primarily to increase transport of O_2 to tissues. An increase in the circulating red cell mass produces an increase in O_2 uptake in the lungs and a corresponding probable increase in O_2 delivery to tissues. The respiratory function of RBCs may be impaired during preservation, making it difficult for them to release O_2 to the tissues immediately after transfusion.

REVIEW OF THE OXYGEN DISSOCIATION CURVE

The O_2 dissociation curve is determined by plotting the partial pressure of O_2 (Po_2) in blood against the percentage of Hb saturated with O_2 (Fig. 61-3). As Hb becomes more saturated, the affinity of Hb for O_2 also increases. This is reflected in the sigmoid shape of the curve, which indicates that a decrease in Pao_2 makes considerably more O_2 available to the tissues. The sigmoid shape of the curve implies greater efficiency of blood transportation of O_2 from the lungs to tissues.

Shifts in the O_2 dissociation curve are quantitated by the P_{50}, which is the partial pressure of O_2 at which Hb is half saturated with O_2 at 37° C and pH 7.4. A low P_{50} indicates a left shift in the O_2-dissociation curve and an increased affinity of Hb for O_2; in other words, the left

shift of the curve indicates that a lower-than-normal O_2 tension saturates Hb in the lung and the subsequent release of O_2 to the tissues occurs at a lower than normal capillary O_2 tension. An increased affinity may be enough to ensure that O_2 is released to the tissues unless the tissue P_{O_2} is in the hypoxic range. The clinical evidence supporting the accuracy of this hypothesis during infusion is discussed in the following section.

CLINICAL EVIDENCE

The clinical evidence is not consistent, reflecting the difficulty of conducting a systematic study of seriously ill patients in varied clinical settings. For 40 years, various clinicians in a variety of clinical settings have tried to establish a firm relationship between the 2,3-DPG levels associated with stored blood and patient welfare (e.g., organ function). In 1993, Marik and Sibbald[100] found that the administration of blood that had been stored for more than 15 days actually decreased intramucosal pH, suggesting that splanchnic ischemia had occurred. In the past 10 years, numerous studies have tried to prove that older blood (and therefore decreased O_2 delivery) is not as beneficial as fresher blood in critically ill patients. Although a definitive conclusion cannot be made, I think that blood with less than 15 days of storage should be used in very ill patients.

COAGULATION IN GENERAL

Unless a patient has a preoperative coagulopathy (e.g., aspirin, antiplatelet drugs, hemophilia), major trauma or blood loss will initiate a cascade of coagulation abnormalities, including a consumptive coagulopathy from tissue hypoperfusion as manifested by increased protein C levels.[101] The addition of a large amount of blood (e.g., 6 to 10 units of PRBCs) only augments this coagulopathy. Various protocols have been developed for approaches to massive blood transfusion administration (Fig. 61-4). This coagulopathy is caused by a combination of factors, of which the most important are the volume of blood given and the duration of hypotension or hypoperfusion. Patients who are well perfused and are not hypotensive for a long period (e.g., 1 hour) can tolerate multiple units of blood without developing a coagulopathy. The patient who is hypotensive and has received many units of blood probably has a coagulopathy from a condition that resembles disseminated intravascular coagulation (DIC) and dilution of coagulation factors from stored bank blood. When such bleeding occurs, the differential diagnosis for a patient who did not have a pretransfusion coagulopathy (e.g., hemophilia) is dilutional thrombocytopenia, low factors V and VIII, a DIC-like syndrome, or hemolytic transfusion reaction. Clinical manifestations include oozing into the surgical field, hematuria, gingival bleeding, petechial bleeding from venipuncture sites, and ecchymosis.

THROMBOCYTOPENIA

Thrombocytopenia is defined as a platelet count less than 150,000/mm^3 or more than 50% over the previous measurement. Clinical bleeding usually does not occur until less than 50,000/mm^3 for surgical bleeding and even less for spontaneous bleeding.[96] Thrombocytopenia can be a cause of a hemorrhagic diathesis in a patient who has received multiple units of bank blood. Independent of whether whole blood or PRBCs are given, few viable platelets exist in a unit of blood stored for more than 24 hours. For whole blood at a storage temperature of 4° C, platelets are damaged sufficiently to be readily trapped and absorbed by the reticuloendothelial system soon after infusion. Even platelets that are not immediately stored have a reduced survival time. Considering survival time and viability, total platelet activity is only 50% to 70% of the original in vivo activity after 6 hours of storage in bank blood at 4° C. After 24 or 48 hours of storage, platelet activity is only approximately 10% or 5% of normal, respectively. Infusion of bank blood stored for longer than 24 hours dilutes the available platelet pool. Platelet counts decreased to less than 100,000/mm^3 when 10 to 15 units of blood were given to acutely wounded, previously healthy soldiers.[101] The platelet count in smaller, older patients may decrease to 100,000/mm^3 after being given fewer units of blood because these patients have a smaller blood volume and possibly a lower preoperative platelet count than soldiers. Over 40 years ago, my colleagues and I defined the importance of the platelet count because when it is approximately 75,000/mm^3 or less, a hemorrhagic diathesis is likely to occur (Table 61-5). One trauma group even suggested that a normal platelet count may not be high enough in severely injured trauma patients.[13] The general principle of using the platelet count as one of the indicators of clinical bleeding still applies even when thromboelastography (TEG) is used as a monitor.[102] Also, as indicated in Chapter 62, TEG and other devices are increasingly being used instead of specific blood levels of coagulation factors (e.g., platelet count, partial thromboplastin time [PTT]).

The preceding paragraph places emphasis on dilutional thrombocytopenia being the major cause of clinical bleeding in patients receiving multiple units of blood. In this situation, the clinician can dependably predict what the platelet count will be.[11] However, a concomitant medical condition can alter these relationships. Other authors emphasize that platelet counts cannot be predicted.[96] Certainly, if the patient has other medical issues (e.g., DIC, sepsis), thrombocytopenia will happen more rapidly. Routine monitoring of coagulation (see later discussion) should be a standard approach when hemorrhage occurs.[96] As discussed earlier in this chapter, the military and trauma hospitals tend not to follow this approach because they give blood in combinations of transfusion ratios.

Although major emphasis had been placed on monitoring the platelet count, several investigators[103,104] have questioned the role of dilutional thrombocytopenia in the coagulopathy of massively transfused patients. They correctly point out that the platelet count rarely decreases to as low a level as would be predicted from dilution alone (Fig. 61-5). This is probably because platelets are released into the circulation from the spleen and bone marrow and because of the presence of nonfunctional platelets. Reed and associates[104] found no benefit to prophylactic

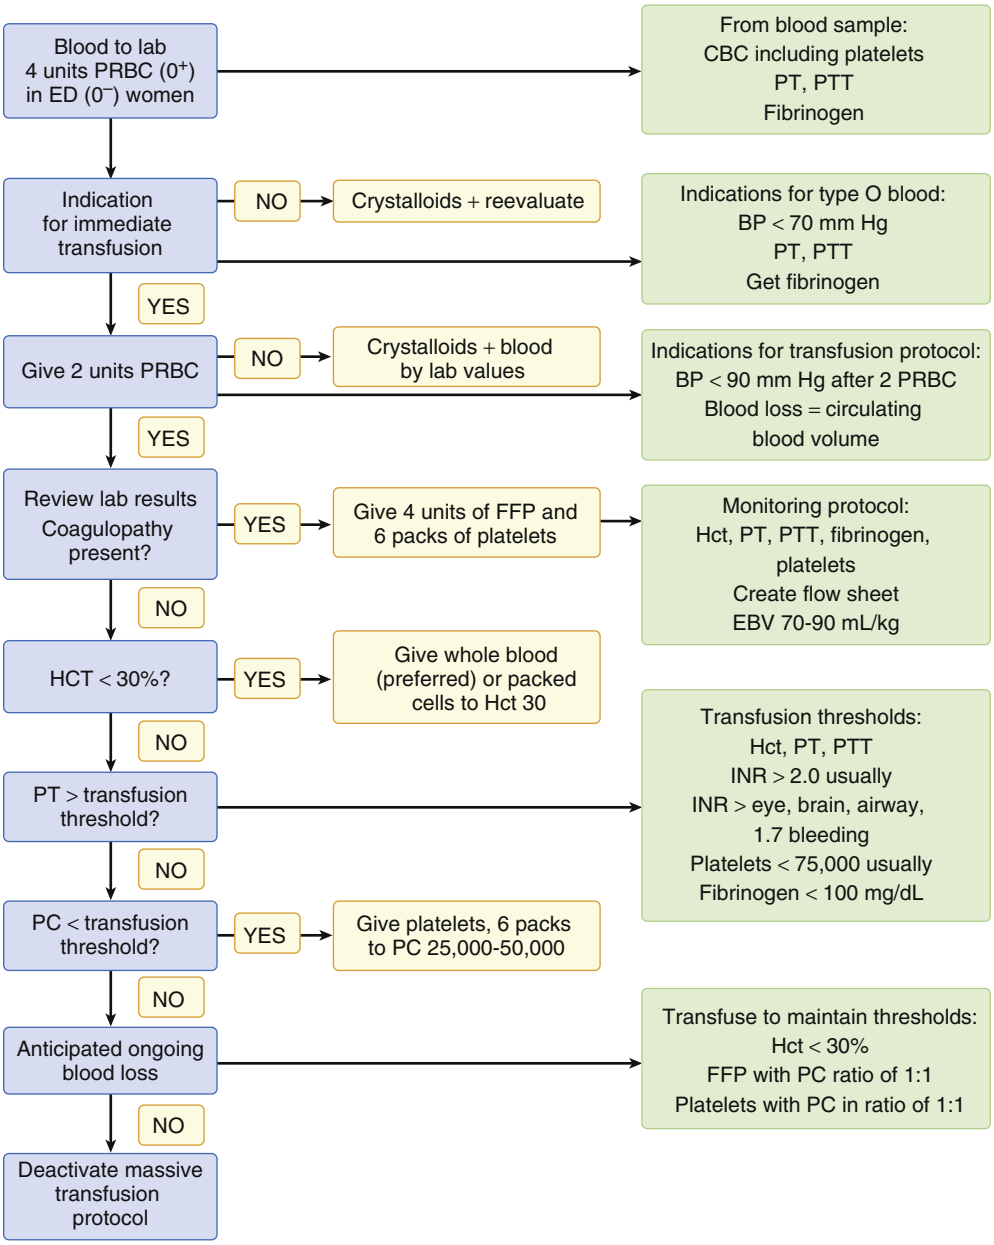

Figure 61-4. This algorithm for diagnosing and treating a massive transfusion was modified from the massive transfusion protocol used at the San Francisco General Hospital. There are many other similar approaches (e.g., Fig. 61-8 provides an algorithm for a pure coagulation). This protocol suggests how to approach a patient with major blood loss but does not include the use of recombinant activated factor VII, which may be possible in the future. platelet administration during massive transfusion. Platelets should not be given to treat laboratory evidence of thrombocytopenia unless clinical coagulopathy is also present. Treating laboratory numbers without correlation with the clinical status is fundamentally contrary to good medical practice; transfusion medicine is no exception. When the platelet count is less than 50,000 to 75,000/mm³, a bleeding problem is likely and is probably a combination of dilutional thrombocytopenia and DIC. Platelet therapy would be appropriate in this situation (see later section on platelet concentrates). Evaluation of

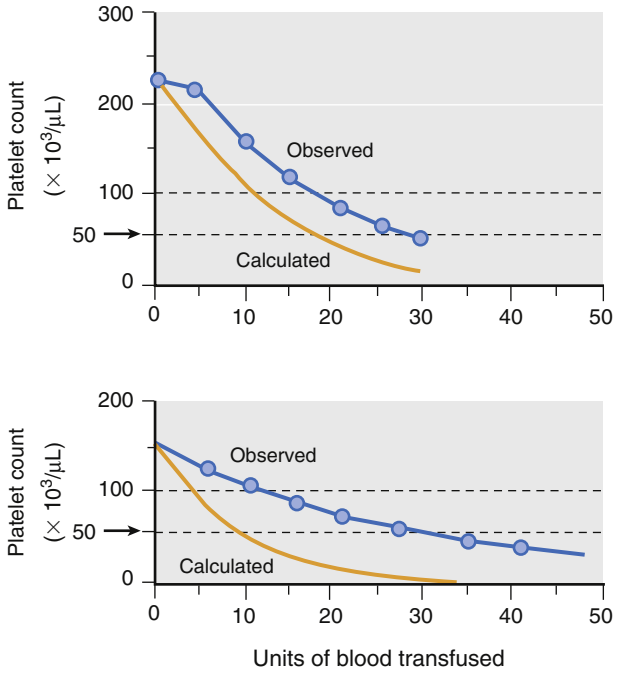

Figure 61-5. Mean platelet counts after massive transfusions in relation to number of units of blood transfused. the literature with regard to the benefit of some blood-related therapy is difficult. Basically, sicker patients often need more blood. Yet, are these patients better off because of the blood? Patients who receive platelets during liver transplantation have an increased mortality rate in one study.[105] The unanswered question is whether the increased mortality rate is because the patients who received platelets were more critically ill before platelets were given. This is just one of the reasons why efficacy of blood product administration is often difficult to assess.

To place such emphasis on the platelet count as a guide is appropriate, as defended previously, with some exceptions. For example, patients with chronic thrombocytopenia or leukemia are commonly known to survive and not have a hemorrhagic diathesis with a platelet count lower than 15,000 cells/mm^3. However, this does not negate the general guideline that patients with a platelet count of less than 75,000 cells/mm^3 are likely to bleed. For unexplained reasons, patients with an acutely induced thrombocytopenia (e.g., from blood transfusions) develop a hemorrhagic diathesis at a much higher platelet count than patients with a chronically induced thrombocytopenia (e.g., idiopathic thrombocytopenic purpura). A higher platelet count is required to maintain adequate hemostasis with a surgical incision or trauma because damaged capillaries require platelets to plug the holes. The chapter on transfusion therapy in the 7th edition of this book resolved that the platelet count was a reasonably accurate guide as to when patients will develop a bleeding problem from dilutional thrombocytopenia (see Table 61-5). Although that conclusion is still correct, increasingly it is not practically useful because of the growing use of point-of-care thromboelastometry (ROTEM) to guide hemostatic therapy.[106]

LOW LEVELS OF FIBRINOGEN AND FACTORS V AND VIII

In the past few years considerable attention has been brought to the decreases in blood fibrinogen concentrations that occur during blood loss and blood replacement, probably because of the availability in some countries of a lyophilized fibrinogen concentrate for clinical use. Previously, fibrinogen supplementation was primarily received from administration of FFP and cryoprecipitate. Levy and colleagues[107] provided an excellent scholarly review of fibrinogen and hemostasis. As indicated earlier, more precise monitoring with thromboelastometry has allowed much more information to become available regarding fibrinogen. Levy and colleagues had two major conclusions. First, "fibrinogen is critical for effective clot formation, and its monitoring and guided supplementation as the treatment of major bleeding increasingly recognized." Second, their last sentence is typical of such reviews: "The prospective study of fibrinogen supplementation in acquired bleeding is needed to accurately assess the range of clinical settings in which this management strategy is appropriate, the most effective method of supplementation, and a comprehensive safety profile of fibrinogen concentrate used for such an approach." Indeed, such studies are beginning to appear. An examination of the Cochrane Database concluded that fibrinogen administration probably does reduce transfusion requirements.[108] Another group concluded that current recommendations for fibrinogen replacement are too conservative.[109] Yet another group[110] amazingly concluded that the clinical effectiveness of FFP was not apparent in trauma patients, but administration of fibrinogen concentrate generally improved outcome. I find the conclusion about FFP unbelievable, but we have an obligation to report the entire literature. However, fibrinogen increased fibrin-based clot firmness after aortic surgery.[111] Furthermore, a dilutional coagulopathy from colloid administration was better treated with a combination of factor XIII concentrates and fibrinogen rather than fibrinogen alone[112]—not a surprising result. Finally, a quote from Weiskopf[113] probably provides the best summary—"clinical trials with fibrinogen offer the exciting possibility of testing our understanding of static coagulation as it applies to the dynamics of surgery."

Historically, factors V and VIII and not fibrinogen have received prime attention.[114] These factors gradually decrease to 15% and 50% of normal, respectively, in whole blood after 21 days of storage. PRBCs even have fewer coagulation factors. Consequently, administration of FFP, which contains all the factors except platelets, has been recommended on a therapeutic or a prophylactic basis. However, this practice is of questionable benefit because only 5% to 20% of factor V and 30% of factor VIII are needed for adequate hemostasis during surgery. In other words, in spite of a patient receiving massive blood transfusion, factors V and VIII rarely decrease below those levels required for hemostasis. My colleagues and I examined this problem by giving 500 to 1000 mL of FFP to

TABLE 61-6 LABORATORY FINDINGS IN VARIOUS PLATELET AND COAGULATION DISORDERS IN THE INTENSIVE CARE UNIT

five patients who had received more than 15 units of bank blood and who had a clinically significant hemorrhagic diathesis. Despite the PTTs (which measure all factors except VII and XIII) and platelets having returned to normal, bleeding persisted in every patient. Only when platelets in the form of fresh blood were administered did bleeding cease. Although low factors I, V, and VIII are likely not the primary cause of bleeding during massive blood transfusion, such deficiencies may intensify bleeding from other causes, usually dilutional thrombocytopenia in the case of blood transfusion.

In 1985, the NIH conducted a consensus conference on this issue.[115] The conference concluded that little or no scientific evidence exists for the administration of FFP as part of the therapy for coagulopathy induced by multiple blood transfusions. Despite the fact that this conference and its recommendations are over 25 years old, the following criteria are still relevant even though they did not have the advantage of ROTEM:

1. Generalized bleeding that cannot be controlled with surgical sutures or cautery
2. PTT time at least 1.5 times normal
3. Platelet count greater than 70,000/mm^3 (to ensure that thrombocytopenia is not the cause of bleeding)

DISSEMINATED INTRAVASCULAR COAGULATION–LIKE SYNDROME

The coagulation system consists of clotting and fibrinolytic mechanisms. The function of the former is to prevent excessive blood loss, and that of the latter is to ensure circulation within the vasculature. With this DIC-like syndrome, the clotting system is deranged and this leads to disseminated fibrin deposition, which renders the fluid blood unclottable. The deposited fibrin may severely alter the microcirculation and lead to ischemic necrosis in various organs, particularly the kidney. The unclottable blood or circulating serum may induce a severe hemorrhagic diathesis. Although Table 61-6 centers around platelet disorders that have an impact on the coagulation system overall, it also displays the interchange between various medical conditions and their impact on various measures of the coagulation system, which is well described in this reference.[116]

The specific reasons for the development of DIC syndrome are usually not apparent. However, hypoxic acidotic tissues with stagnant blood flow probably release tissue thromboplastin directly or through liberation of some toxin as possibly modulated through the protein C pathway.[101] The release of tissue plasminogen activator from damaged tissue may cause fibrinolysis. In sepsis and eventual organ failure, the pathogenesis of this DIC syndrome is more apparent. The extrinsic route of coagulation is activated by tumor necrosis factor and endotoxins. Presumably, tumor necrosis factor induces tissue factor expression on the surface of activated monocytes and possibly by exposure to subendothelially localized tissue factor in blood[117] (see Chapter 62 for more details). Although the intrinsic system does not induce DIC, it may contribute to hypotension. This triggers the coagulation process, resulting in consumption of factors I, II, V, and VIII and platelets. Supposedly, thrombi and fibrin are deposited in the microcirculation of vital organs, interrupting their blood flow.

In an attempt to counteract the hypercoagulable state, the fibrinolytic system is activated to lyse the excessive fibrin almost simultaneously; this is called secondary fibrinolysis (see also Chapter 62). DIC should not be considered a distinct disease entity but rather a sign of another disease. DIC has been associated with almost all life-threatening diseases. Any condition in which tissue

damage is sufficient to release tissue products or toxins into the circulation can be associated with DIC. If enough thromboplastin lodges in the circulating blood, the result is massive focal necrosis or more generalized activation of the coagulation system.

HEMOLYTIC TRANSFUSION REACTION

The appearance of a hemorrhagic diathesis after blood transfusion should signal the possibility of a hemolytic transfusion. This entity is discussed later in this chapter.

DIAGNOSIS AND TREATMENT OF A HEMORRHAGIC DIATHESIS AFTER WHOLE BLOOD TRANSFUSIONS

Although treatment is more likely to be successful when the cause of the bleeding problem has been identified, precise diagnosis is often difficult. In addition to clinical examination of the patient, various coagulation laboratory tests have been used for years. One traditional approach has been to obtain a blood specimen on which the following tests can be performed: platelet count, PTT, and plasma fibrinogen level; observation of a clot for size, stability, and lysis; and observation of the plasma for evidence of hemolysis. Provided the PTT is 1.5 times normal or more and other tests are normal, the bleeding is probably a result of very low levels of factors V and VIII. This can be treated with FFP, which contains all the coagulation factors except platelets, or with cryoprecipitate. Although the preceding situation is a nice textbook description, I have never observed a clinical situation involving blood transfusions in which the PTT was increased without the presence of thrombocytopenia.

Point-of-care diagnosis of perioperative clinical coagulopathies is being increasingly facilitated by TEG and ROTEM, as reviewed by Srivastava and Kelleher.[118] Specifically, point-of-care ROTEM (viscoelastic and rotational) is being used to diagnose intraoperative coagulopathies.[119-123] All varieties of major surgeries and types of patients are being monitored with one of these devices, including liver transplantation[124] and postpartum hemorrhage.[102] Data are available within 10 to 20 minutes and are increasingly used to guide hemostatic therapy in trauma patients and, more recently, in other clinical situations. The theoretic advantages are assessment of clot formation in the context of whole blood, including contributions from platelets and RBCs and analysis of multiple stages of the clotting process from fibrin formation through fibrinolysis‡ (see also Chapter 62 for further details).

Dilutional thrombocytopenia in association with DIC, and hypoperfusion is the most likely cause of bleeding from blood transfusion.[114] When the platelet count is less than 100,000/mm^3, a bleeding problem is likely to develop (see Table 61-5); therefore, platelets are ordered. The rule of thumb is based on the fact that a bleeding diathesis probably will develop after infusion of 20 units of stored blood in healthy patients and after lesser amounts in debilitated or small patients (Fig. 61-6).

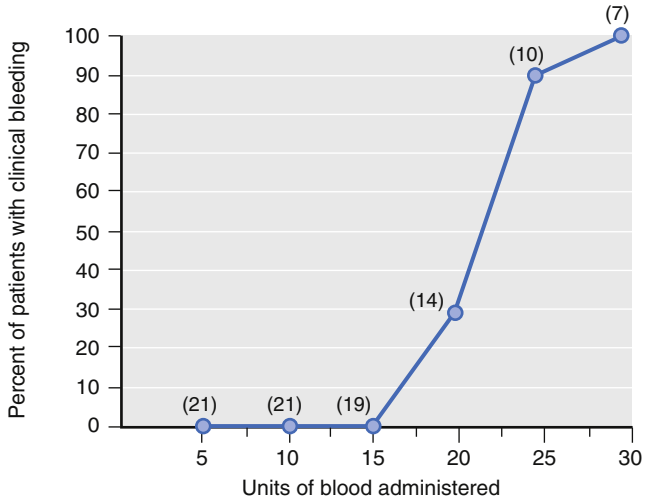

Figure 61-6. Correlation between units of blood administered and percent of patients who had a hemorrhagic diathesis. The numbers in parentheses represent the number of patients at each data point. (*From Miller RD: Transfusion therapy and associated problems,* Reg Refresher Courses Anesthesiol *1:101, 1973.)*

Whether platelets are administered in the form of fresh blood, platelet-rich plasma, or platelet concentrates depends on intravascular volume replacement requirements, personal preference, and availability of laboratory personnel. Fresh blood (<6 hours old) supplies the largest number of platelets per donation. More than 80% of the platelets can be given by platelet-rich plasma, which has half of the volume of a unit of blood. However, because most blood banks advocate giving patients only components that are necessary, platelet concentrates are frequently recommended. The remainder of the unit of blood, such as RBCs, plasma, and albumin, can be saved for other patients. Platelet concentrates are contained in a 50-mL unit and provide approximately 70% of the platelets in a unit of blood. In a 70-kg person, approximately 10 units of platelet concentrates are required to increase the platelet count by 100,000/mm^3.

Although logistically difficult to obtain, fresh blood is extremely effective in treating transfusion-induced coagulopathies. My personal and subjective observations in Vietnam indicated that fresh blood (i.e., ≤6 hours and unrefrigerated blood) had a dramatic effect in patients with extensive hemorrhage. Approximately 20 years later, Lavee and associates[125] found that 1 unit of fresh whole blood was as effective as, if not superior to, 8 to 10 platelet units. In 1996, Erber and colleagues,[93] used fresh unrefrigerated whole blood in surgical patients with ongoing extensive bleeding despite adequate component replacement therapy and adequate surgical hemostasis. An accompanying editorial expressed caution and described the unfortunate problems with conducting a larger trial with fresh blood.[126] I think that fresh blood also contains unidentified factors that make it far more effective than blood components.

Determining the plasma fibrinogen level is useful because this coagulation factor does not decrease in

‡Thank you to Brian M. Gilliss, MD, MS, for his help in facilitating my understanding of this process.

bank blood. If the in vivo plasma fibrinogen level is low (<150 mg/dL), it is not a result of a dilutional coagulopathy and strongly suggests DIC or a DIC-like syndrome. DIC is likely with thrombocytopenia, hypofibrinogenemia, and lysis of a clot within 2 hours.[114] Unfortunately, fibrinogen levels in PRBCs decrease with increasing storage time. As a result, hypofibrinogenemia occurs on a dilutional basis when multiple units of PRBCs are given.[127]

ε-Aminocaproic acid (EACA) inhibits the formation of plasmin and attenuates fibrinolysis. EACA should not be used in the treatment of DIC. Blocking the fibrinolytic system and having the coagulation system activated have resulted in disseminated thrombosis. Because primary fibrinolysis is rare other than in prostatectomy and liver transplantation[128] (see also Chapter 75), EACA should probably not be given unless the preceding diagnosis is clearly established after expert consultation. Despite the previous recommendations, bleeding from a transfusion-associated coagulopathy occasionally persists. A new approach has been described. Administration of recombinant activated coagulation factor VII (rfVIIa, Novo Nordisk Pharmaceuticals, Plantation, Fla) has produced successful treatment of such coagulopathies intraoperatively. Most of these patients also had other conditions, such as necrotizing pancreatitis, cirrhosis, or severe trauma. This exciting product is extremely expensive and should be viewed as a rescue therapy until approval by the U.S. Food and Drug Administration (FDA) is more broadly based[129] (see Chapter 62 for details).

DIAGNOSIS AND TREATMENT OF HEMORRHAGIC DIATHESIS AFTER PACKED RED BLOOD CELL TRANSFUSIONS

With much less plasma, dilution of certain coagulation values may be more profound with the use of PRBCs rather than whole blood. Murray and co-workers[127] specifically examined the question of using PRBCs for major blood loss. In general, the direction of coagulation changes was similar to that seen with whole blood, with one major exception. With use of PRBCs, fibrinogen levels decreased significantly in contrast to use of whole blood, in which fibrinogen levels remained unchanged unless DIC was present (Fig. 61-7). Although all the coagulation factors decreased, the decrease was less than expected from dilution. The researchers thought that factors such as factor VIII are probably stored in endothelial cells and released from the endothelium during surgical stress. When PRBCs are used to replace major blood loss, the clinician may be tempted to give FFP prophylactically. However, Murray and co-workers[127] specifically recommended not following the policy; they stated that FFP was needed only when prothrombin time (PT) and PTT were at least 1.5 times normal and fibrinogen levels were less than 75 mg/dL. These recommendations are similar to those stated in the section on FFP. Leslie and Toy[130] provided more specific guidelines when PRBCs are used for massive transfusions. They believed that when 12 or more units of PRBCs or cell-saver blood had been given, coagulation factors (i.e., FFP) were necessary. Patients who received 20 or more units often required platelet therapy, a finding identical to that of patients given whole blood.

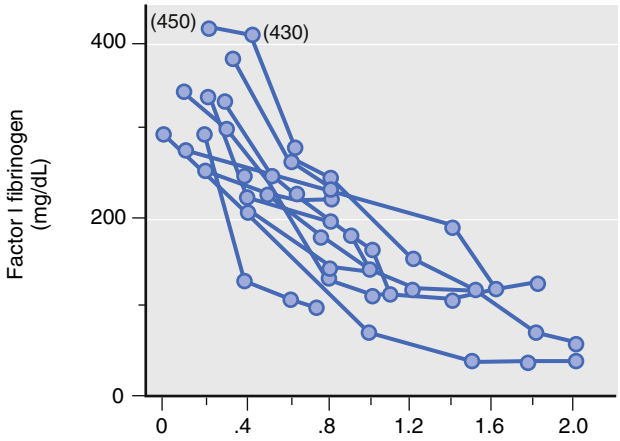

Figure 61-7. Decreases in fibrinogen level as blood volume is replaced with Adsol-packed red blood cells and crystalloid solutions. Each patient is represented by a *solid line. (From Murray DJ, Olson J, Strauss R, et al: Coagulation changes during packed red cell replacement of major blood loss,* Anesthesiology *69:839, 1988.)*

An algorithm for the evaluation and initial therapy of a patient with a suspected coagulopathy is given in Figure 61-8 (see also the section on blood transfusions, pharmacology, and hemostasis).

TRANSFUSION RATIOS

The transition from administration of whole blood to component therapy in the l970s created new challenges in transfusion medicine, especially in patients undergoing trauma or any type of surgery associated with significant blood loss. As indicated previously, administration of whole blood (1960s to mid-l970s) usually did not require FFP. Significant thrombocytopenia usually occurred after 15 to 20 units of blood.[5] The decision to give FFP or platelet concentrates was usually based on laboratory results, such as a platelet count and a PTT.

With the change from whole blood to PRBCs, the incidence of coagulopathies increased, especially with medical units responsible for trauma patients. Rather than basing treatment of transfusion or clinically induced coagulopathies on clinical judgment or laboratory tests, the concept of developing ratios of FFP and/or platelet concentrates with PRBCs evolved. For example, a 1:1:1 ratio would be transfusion of plasma and platelets to RBCs on a one-to-one basis. A 1:1 ratio frequently appears in the literature, which could be the combination of either FFP or platelets with RBCs.

Can an analysis of the literature specifically identify what the ratio should be? The most aggressive recommendation was that both a high-dose FFP (1.5 RBC to 1 FFP) and platelets (1 platelet to 6 RBCs) decreases mortality.[131] Some clinicians give FFP automatically to massively transfused patients even without a demonstrated coagulopathy with improved mortality rates.[132] Holcomb and associates[133] also concluded that increased platelet (i.e., instead of FFP) ratios were associated with improved survival after massive blood transfusions. However, these aggressive uses of FFP, platelets, and other blood products should only be given in response to coagulopathies from massive blood transfusions. For example, aggressive

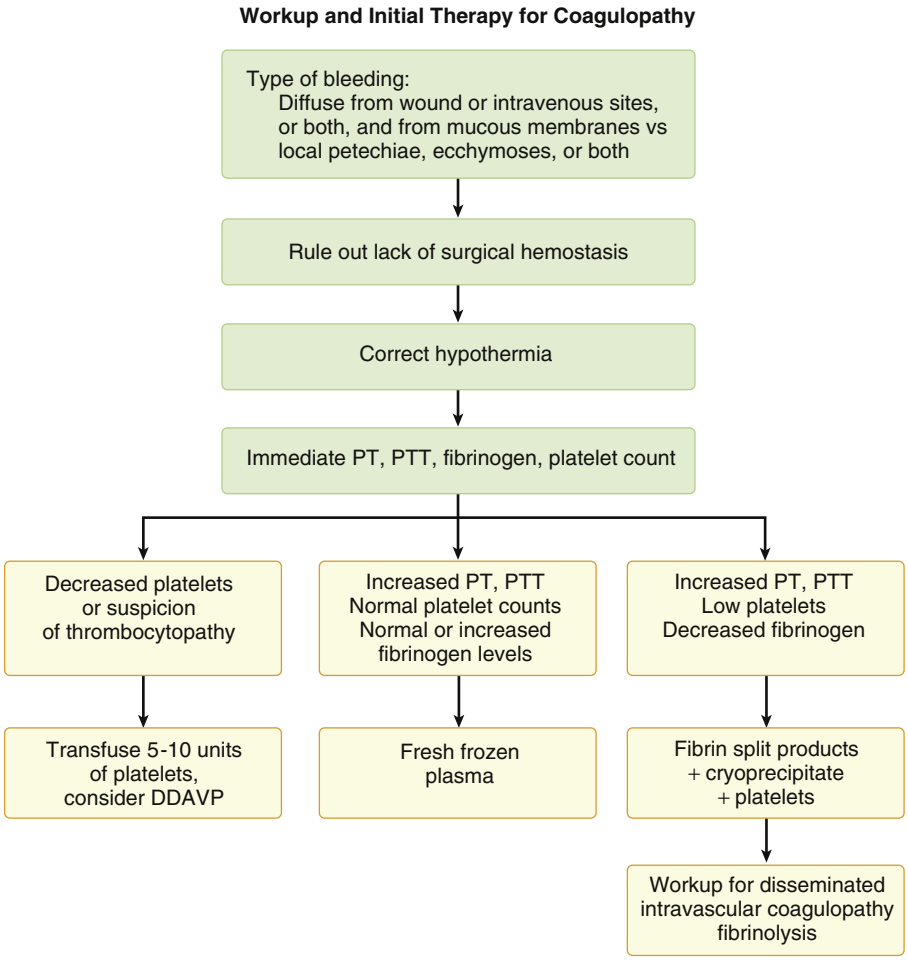

Figure 61-8. Algorithm of the evaluation and initial therapy of a patient with suspected perioperative coagulopathy. The evaluation is based on the clinical scenario and is affected by the type and location of injury, the amount of fluid administered, and the age and body temperature of the patient. *DDAVP,* 1-Deamino-8-D-arginine vasopressin, a vasopressin analogue also known as desmopressin acetate; *PT,* prothrombin time; *PTT,* partial thromboplastin time. *(Modified from Habibi S, Corrsin DB, McDermott JC, et al: Trauma and massive hemorrhage. In Muravchick S, Miller RD, editors:* Atlas of anesthesia: subspecialty care, *New York, 1998, Churchill Livingstone.)*

plasma administration to nonmassively transfused patients was associated with an increased rate of serious complications, including acute respiratory distress syndrome (ARDS) and organ dysfunction.[134]

Mortality was less frequent when patients with traumatic brain injury were given blood products with a high ratio of FFP to PRBCs.[135] A retrospective study showed that a higher FFP/PRBC ratio was associated with the need for advanced interventional procedures in patients with postpartum hemorrhage.[136] Yet an analysis of 26 studies concluded, "Without randomized controlled trials controlling for survivor bias, the current available evidence supporting higher plasma-to-erythrocyte resuscitation is inconclusive." Even more recently, the results of the Prospective Observational Multicenter Major Trauma Transfusion (PROMMTT) study were reported with a commentary by Maier.[137] The sources of the data were 10 U.S. level-I trauma centers. The conclusion of the study[138] was that "higher plasma and platelet ratios early in resuscitation were associated with decreased mortality in patients who received transfusions of at least 3 units of blood products during the first 24 hours after admission.[138] Among survivors at 24 hours, the subsequent risk for death by day 30 was not associated with plasma or platelet ratios." Yet a review by a group in the military divided their data according to the Injury Severity Score. A survival benefit was seen in ratios with high plasma to RBC resuscitation. However, no additional benefit of 1:1 over 1:2 ratios was identified.[139]

To me, an interesting philosophic problem has evolved. Approximately 30 to 40 years ago, whole blood was primarily given. Then in the 1970s, the concept of giving patients only the specific blood component they needed was the basis for dividing blood into separate components. However, in the last 10 years, military and trauma units have been using a concept they described as "reconstruction of deconstructed blood for trauma"—that is, components are added to PRBCs to make it more like whole blood, but it is called reconstituted whole blood. In summary, we had primarily whole blood 30 to 40 years ago and returned to that concept by approximately 2005. This is a rather strange and ironic pathway for blood transfusion medicine to follow.

BLOOD TRANSFUSIONS, PHARMACOLOGY, AND HEMOSTASIS

An extensive review of pharmacologic therapies in patient blood management has been made by Goodnough and Shander.[33] Iron therapy and erythropoiesis-stimulating agents are described earlier in this chapter. Drugs used for hemostasis are categorized into three groups: (1) antifibrinolytics, (2) serine protease inhibitors, and (3) analogues of the antidiuretic hormone.

The first group, antifibrinolytics, includes EACA and tranexamic acid, which are plasminogen inhibitors. Two studies found a decreased blood loss from total knee arthroplasty. Presumably, release of the pneumatic tourniquet releases fibrinolytic material, which is inhibited by tranexamic acid.

The second group is the serine protease inhibitors, including aprotinin, nafamostat, and ecallantide. Aprotinin inhibits fibrinolysis and improves platelet function. It has been used to decrease blood loss in multiple surgical procedures, including cardiopulmonary bypass. However, its ultimate place in the treatment of coagulopathies has not been established.

The third group is synthetic analogues of the antidiuretic hormone vasopressin. Three other drugs (i.e., desmopressin, recombinant factor VIIa, and prothrombin complex concentrates) have been recommended for perioperative coagulation problems.[140] Two of those drugs have received special attention. The first is desmopressin (1-deamino-8-D-arginine vasopressin [DDAVP]), a synthetic analogue of the antidiuretic hormone vasopressin and a procoagulant drug. It increases the levels of factor VIII and von Willebrand factor and is a well-established therapy for hemophilia and von Willebrand disease. It also reduces blood loss and transfusion requirements in patients with normal preoperative coagulation status who are undergoing spinal or cardiac surgery. However, the ultimate role of desmopressin remains to be determined.[140] It can cause hypotension, hyponatremia, and increased platelet adhesion. As indicated before, recombinant factor VIIa and prothrombin complex concentrates are also in this category.

Other vehicles for producing hemostasis include fibrin sealant, collagen, thrombin, and gelatin sponges. A large meta-analysis using perioperative blood transfusion as the outcome in cardiac surgery concluded that aprotinin and tranexamic acid, but not desmopressin, decreased the exposure of patients to allogeneic blood transfusion perioperatively.[141] The ultimate use of these drugs is evolving.

CITRATE INTOXICATION AND HYPERKALEMIA

Citrate intoxication is not caused by the citrate ion per se; it occurs because citrate binds Ca^{2+}. The signs of citrate intoxication are those of hypocalcemia—hypotension, narrow pulse pressure, and increased intraventricular enddiastolic pressure and central venous pressure. However, citrate intoxication is very rare. Having hypothermia, liver disease, liver transplantation, or hyperventilation or being a pediatric patient[142] increases the possibility of citrate intoxication. The appearance of severe hypocalcemia during liver transplantation is well documented (see also Chapter 74). The combination of infusion of large amounts of citrate (i.e., through blood transfusions) and of reduced metabolism from absent or reduced liver blood flow (i.e., in the anhepatic phases of liver transplantation) leads to citrate intoxication. As a result, Ca^{2+} infusions are common during liver transplantation. The rate of citrate metabolism is decreased by 50% when body temperature is decreased from 37° to 31° C. Excluding these conditions, infusion of more than 1 unit of blood every 10 minutes is necessary for ionized Ca^{2+} levels to begin to decrease. Even at these rates of infusion, ionized Ca^{2+} levels do not decrease enough to cause bleeding. As indicated previously, if a hemorrhagic diathesis starts after administration of blood, low Ca^{2+} levels are not part of the differential diagnosis.
