As evidenced from the preceding discussion, citrate intoxication is rare. As described by Kleinman and associates,[51] serum K^+ levels may be as high as 19 to 50 mEq/L in blood stored for 21 days. This would be approximately 90 mEq/L units of PRBCs. However, when the loss of K^+ via blood loss is compared with administration of blood, the net gain of K^+ is approximately 10 mEq/L. The change in serum K^+ is usually minor because excess K^+ either moves into the cell or is excreted via the urine. Although hyperkalemia is occasionally reported,[142,143] large amounts of blood must be given. For significant hyperkalemia to occur clinically, bank blood must be given at a rate of 120 mL/minute or more. The fact that such rapid infusion rates of blood are required for the production of hyperkalemia suggests that the K^+ ion must leave the intravascular spaces by diffusion into extravascular spaces, by reuptake into RBCs, or through the kidneys. Although rare, hyperkalemia can occur in patients with severe trauma, impaired renal function, or both[144] (also infants and newborns, see also Chapters 94 and 95).

As with citrate intoxication, hyperkalemia is rare and this also rules against the routine administration of Ca^{2+}. Ca^{2+} may cause cardiac arrhythmias. Ca^{2+} administration should be based on diagnostic signs of hyperkalemia (i.e., peak T wave). Although irritating to veins, 10% calcium chloride provides three times more Ca^{2+} than an equal volume of 10% calcium gluconate because chloride has a molecular mass of 147 and gluconate has a molecular mass of 448. Finally, even though hyperkalemia is rare, it still occurs. Recently, Lee and associates[145] described nine cases of pediatric patients who had cardiac arrest during massive blood transfusions. The mean blood K^+ level was 9.2 ± 1.8 mmol/L. Risk factors were several, including the administration of older (i.e., longer storage) blood.

TEMPERATURE

Administration of unwarmed blood that has been stored at 4° C can decrease the recipient's temperature. If the temperature decreases to less than 30° C, ventricular irritability and even cardiac arrest may occur. This can be prevented by warming the blood to body temperature before transfusion. More subtle reasons exist for warming all blood, even in patients receiving only 1 to 2 units intraoperatively. Because of the cool temperature of the operating room, body temperature often decreases, particularly in patients undergoing extensive abdominal surgery; administration of cold blood further decreases temperature. Maintaining a patient's normal temperature is considered to be increasingly important (see also Chapter 54).

Perhaps the safest and most common method of warming blood is to pass it through plastic coils or plastic cassettes

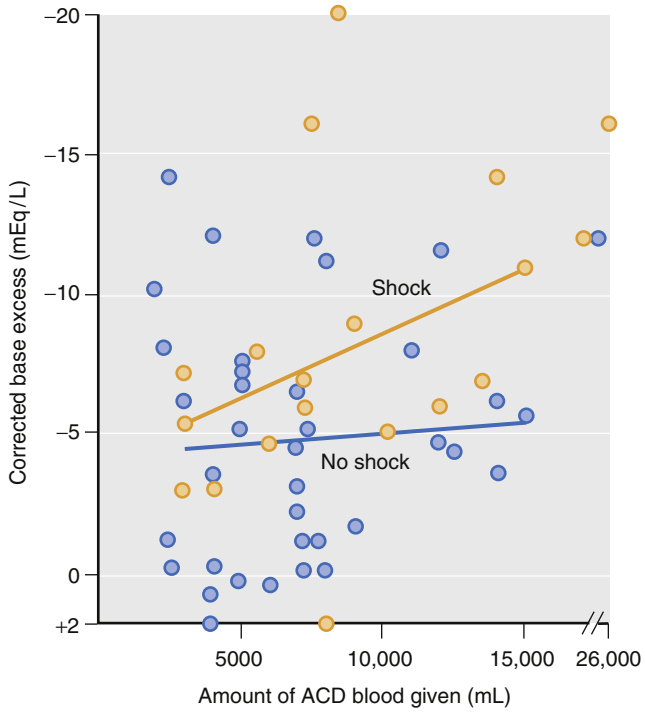

Figure 61-9. Correlation between the amount of blood administered (milliliters) and corrected base excess intraoperatively. *ACD,* Acid citrate dextrose. *(From Miller RD, Tong MJ, Robbins TO: Effects of massive transfusion of blood on acid-base balance,* JAMA *216:1762, 1971.)*

in a warm water (37° to 38° C) bath or warming plates. These heat exchangers should have upper (e.g., 43° C) and lower (e.g., 33° C) temperature limits (see also Chapter 54).

ACID-BASE ABNORMALITIES

The pH of most storage media is very acidotic (e.g., 5.5 for CPD). When this solution is added to a unit of freshly drawn blood, the pH of the blood immediately decreases from 7.0 to 7.1. As a result of accumulation of lactic and pyruvic acids by RBC metabolism and glycolysis, the pH of bank blood continues to decrease to approximately 6.9 after 21 days of storage. A large portion of the acidosis can be accounted for by the P_{CO_2} of 150 to 220 mm Hg. The P_{CO_2} is high mainly because the plastic container of blood does not provide an escape mechanism for carbon dioxide. With adequate ventilation in the recipient, the high P_{CO_2} should be of little consequence. Even when the P_{CO_2} is returned to 40 mm Hg, metabolic acidosis is still present in blood (see Table 61-2). Still, the empirical administration of sodium bicarbonate is not indicated, but it actually may also be unwise without concomitant analysis of arterial blood gases and pHs.[146] Miller and colleagues[147] found that the metabolic acid-base response to blood transfusion was variable (Fig. 61-9). Blood transfusions provide a substrate, namely, citrate, in large quantities for the endogenous generation of bicarbonate, and this accounts for the significant incidence of metabolic alkalosis after blood transfusions.[146] Little logic exists in the empirical administration of bicarbonate for prophylactic treatment of an unpredictable acid-base abnormality.

TRANSFUSION REACTIONS

HEMOLYTIC TRANSFUSION REACTION

From 2008 to 2012, transfusion-related acute lung injury (TRALI) was the common cause of transfusion-related fatalities (Table 61-7).[148] First, a hemolytic transfusion reaction will be discussed because this is frequently the result of the wrong unit of blood being given. A discussion of TRALI will follow. Since 1975, the FDA has required that all fatal reactions occurring in blood recipients or donors be reported within 24 hours by telephone or within 7 days in writing by all FDA-registered transfusion services. From 1976 to 1985, 328 deaths were reported and analyzed.[149] Of these deaths, 159 were acute from hemolytic reactions and 23 from delayed reactions. In 2011, the incidence of an acute hemolytic transfusion reaction resulting from ABO incompatibility was 1:1200 to 1:190,000.[150] (*Anesthesiology News*[151] reported an incidence of 1:606,978). Of the 159 deaths from acute hemolytic reaction, 137 were caused by errors involving ABO incompatibility. More than half of these mistakes occurred after the blood had been issued by the blood bank and were committed by nurses and physicians in the operating room, emergency department, or ward. The incidence of hemolytic transfusion reactions is sufficient enough that The Joint Commission (formerly the Joint Commission on Accreditation of Healthcare Organizations)[152] requires peer-review programs to reduce transfusion errors and complications. Specifically, two patient identifiers are required before a blood product can be given (see discussion on compatibility testing). New technologies are being used to facilitate a decreased incidence of transfusion-related errors. However, when delayed hemolytic reactions (discussed later) are included, the incidence of ABO-incompatible RBC transfusions is more frequent.[153] One of the most catastrophic transfusion reactions is that arising from intravascular hemolysis. Intravascular hemolysis occurs when there is a direct attack on transfused donor cells by recipient antibody and complement. Such a reaction can occur from infusion of as little as 10 mL of blood.[154] If properly treated, death is rare.[152] However, prevention of kidney failure and a coagulopathy (DIC) is crucial. Hemolytic transfusion reactions involving extravascular RBC destruction are generally less serious than those of the intravascular variety. In these cases, recipient antibody coats but does not immediately hemolyze the transfused RBCs. Destruction occurs primarily in the reticuloendothelial system.

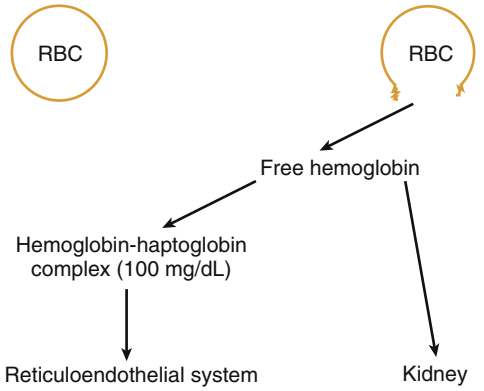

Figure 61-10. Schematic representation of what happens to hemolyzed erythrocytes (*RBC*) as a result of the administration of incompatible blood.

Signs and Symptoms

The clinical consequences of incompatible blood transfusions are very serious but quite variable. Factors include volume of transfused blood, number of antigenic sites on the red cell membrane, and activity of the reticuloendothelial system. The properties of the antibody, including concentration and ability to activate complement, are also important.

The classic signs and symptoms (see Table 61-7) of a hemolytic transfusion reaction—chills, fever, chest and flank pain, and nausea—are masked by anesthesia. Under general anesthesia, the only signs may be hemoglobinuria, bleeding diathesis, or hypotension. The presenting sign is usually hemoglobinuria. As little as 50 mL of incompatible blood may exceed the binding capacity of haptoglobin, which is a protein that can bind approximately 100 mg of Hb/100 mL of plasma. When Hb not exceeding this amount is injected or liberated into the bloodstream, the Hb circulates as a complex with haptoglobin, which is cleared by the reticuloendothelial system (Fig. 61-10). A sample of plasma that contains 2 mg/dL of Hb is faintly pink or light brown. When the level of Hb reaches 100 mg/dL, the plasma is red. When the level of plasma Hb reaches 150 mg/dL, hemoglobinuria occurs. In general, the quantity of the free Hb in the plasma correlates with the volume of incompatible blood transfused. Also, complement activation causes release of various substances, including histamines and vasoactive amines. The symptoms can be so alarming that cessation of blood is indicated, even if Hb is not seen in plasma. Laboratory tests that should be performed if hemolytic transfusion reaction is suspected include serum haptoglobin, plasma and urine Hb, bilirubin, and direct antiglobulin determinations. The direct antiglobulin test can confirm the presence of hemolytic transfusion reaction because it shows that antibody is attached to transfused donor RBCs.

Treatment

If a hemolytic reaction is suspected, blood and urine samples should be sent to the laboratory for examination. The blood bank should check all paperwork to ensure that the correct blood component was transfused to the patient. Laboratory tests should be performed to determine the presence of hemoglobinemia: a direct antiglobulin test, repeat compatibility testing, repeat other serologic tests (i.e., ABO and Rh), and analysis of urine for hemoglobinuria.

Although several consequences of intravascular hemolysis are possible, mainly the renal and coagulation systems are affected. The cause of acute renal failure from intravascular hemolysis is likely that Hb in the form of acid hematin precipitates in the distal tubule and causes mechanical tubular blockage. The magnitude of the precipitation probably is inversely related to the volume of urine flow and its pH. The primary emphasis of therapy should be directed toward maintaining urinary output in excess of 75 mL/hr by generous administration of intravenous fluids and diuretics. One approach is summarized in Box 61-1 and includes the administration of crystalloids to maintain the central venous pressure between 10 and 15 cm H_2O while initially administering 12.5 to 50 g of mannitol. If this is ineffective, the dose of mannitol may be increased or the use of more potent diuretics, such as furosemide, which increases blood flow to the renal cortex, may be required to maintain adequate urinary output. Alkalinization of the urine to prevent precipitation of acid hematin in the distal tubules is of questionable value but is easy and therefore recommended. DIC commonly occurs with hemolytic transfusion reactions, probably because RBC stroma is severed, releasing erythrocytin, which activates the intrinsic system of coagulation. This activated coagulation leads to fibrin formation. Subsequently, platelets and factors I, II, V, and VII are consumed. As soon as a hemolytic transfusion reaction is recognized, platelet count, PT, and PTT should be determined to provide baseline values with which subsequent laboratory values can be compared. Hypotension during a hemolytic transfusion reaction may result from activation of the kallikrein system.[155] After a series of reactions, plasma kininogen is converted to bradykinin, a potent vasodilator that can cause hypotension.

Another approach to treatment of a severe hemolytic transfusion reaction has been proposed by Seager and co-workers,[156] who postulated that the kidneys might be spared from exposure to massive amounts of hemolyzed red cells by removing all blood from a patient and replacing it with compatible blood. This was accomplished in a patient who had received 3000 mL of incompatible blood by hemodilution by use of an extracorporeal circuit. Because the patient had rapid recovery of urinary function, this method shows much promise.

In summary, hemoglobinuria or hemolysis should be assumed to be a hemolytic transfusion reaction until proved otherwise. The steps outlined in Box 61-1 should be taken when the diagnosis is suspected or confirmed.

TRANSFUSION-RELATED ACUTE LUNG INJURY

From 2008 to 2012, TRALI was the common cause of transfusion-related fatalities (Table 61-8). ARDS and acute lung injury (ALI) refer to life-threatening respiratory failure from several causes (see also Chapter 101).[157] Sepsis, pneumonia, and blood transfusions are among the most common causes. TRALI is now the leading cause of transfusion-related mortality (see Table 61-7), although it

BOX 61-1 ***Steps in the Treatment of a Hemolytic Transfusion Reaction***

1. STOP THE TRANSFUSION.
2. Maintain the urine output at a minimum of 75 to 100 mL/hr by the following methods:
   a. Generously administer fluids intravenously and possibly mannitol 12.5 to 50 g, given over 5 to 15 minutes.
   b. If intravenously administered fluids and mannitol are ineffective, administer furosemide (20 to 40 mg) intravenously.
3. Alkalinize the urine; because bicarbonate is preferentially excreted in the urine, only 40 to 70 mEq of sodium bicarbonate per 70 kg of body weight is usually required to raise the urine pH to 8, whereupon repeat urine pH determinations indicate the need for additional bicarbonate.
4. Assay urine and plasma hemoglobin concentrations.
5. Determine platelet count, partial thromboplastin time, and serum fibrinogen level.
6. Return unused blood to blood bank for repeat crossmatch.
7. Send patient's blood and urine sample to blood bank for examination.
8. Prevent hypotension to ensure adequate renal blood flow.

TRALI, Transfusion-related acute lung injury.

probably is underdiagnosed and underreported.[158-160] This injury manifests as noncardiogenic pulmonary edema. Specifically, TRALI occurs in the absence of excessive intravascular volume and cardiac failure.[161] Clinically, symptoms and signs appear 1 to 2 hours after transfusion and are in force within 6 hours. Fever, dyspnea, fluid in the endotracheal tube, and severe hypoxia are typical. During anesthesia, a persistent decrease in blood O_2 saturation can be the manifesting sign. Although the chest radiograph is characteristic of pulmonary edema, excessive circulatory volume (i.e., left atrial hypertension) is not present. All blood components, especially FFP, are implicated as caustic factors. The only specific therapy is stopping the transfusion and instituting critical care supportive measures. However, the transfusion should be immediately stopped and the blood bank notified for a different donor and quarantining all units from that donor. All records should be reexamined, and the results of the patient's human leukocyte antigen (HLA) testing should be evaluated if possible. Most patients recover within 96 hours, although TRALI remains the leading cause of transfusion-related death.

Recently, an intense analysis of the risk factors associated with TRALI have been reported.[162] Risk factors include higher interleukin-8 (IL-8) levels, liver surgery, chronic alcohol abuse, shock, higher peak airway pressures while being mechanically ventilated, smoking, and positive fluid-balance. As far as transfusions are concerned, receipt of plasma or whole blood from female donors was identified and subsequently markedly reduced. The decreased use of plasma from female donors reduced the incidence of TRALI. A related finding is that transfusion of PRBCs in the ICU to patients who already have ALI was not associated with 90-day mortality.[18]

DELAYED HEMOLYTIC TRANSFUSION REACTION (IMMUNE EXTRAVASCULAR REACTION)

An immediate hemolytic transfusion reaction often is a dramatic event because the concentration of the antibody is high enough to cause immediate and appreciable RBC destruction. In many cases of hemolytic transfusion reaction, the transfused donor cells may survive well initially, but after a variable delay (2 to 21 days) they are hemolyzed.[163] This type of reaction occurs mainly in recipients sensitized to RBC antigens by previous blood transfusions or pregnancy. As a result, this type of delayed reaction is more common in females who have a known disposition of alloimmunization. These reactions are delayed hemolytic transfusion reactions and are those in which the level of antibody at the time of transfusion is too low to be detected or cause RBC destruction. RBC destruction occurs only when the level of antibody is increased after a secondary stimulus (i.e., anamnestic response). These delayed reactions are often manifested only by a decrease in the posttransfusion Hct value. However, jaundice and hemoglobinuria can occur in these patients and can cause some impairment in renal function, but only rarely do they lead to death. Unlike immediate reactions, antibodies most commonly involved in delayed hemolytic reactions are those in the Rh and Kidd systems rather than the ABO system. Although improved blood-banking procedures have decreased the incidence of immediate hemolytic transfusion reactions, the delayed hemolytic reaction may not be preventable, because pretransfusion testing is unable to detect very low levels of antibody present in potential blood recipients.

Although impairment of renal function is uncommon, the surgical team should include in their differential diagnosis a delayed hemolytic transfusion reaction in any patient who has an unexplained decrease in Hct 2 to 21 days after a transfusion, even without obvious manifestation of hemolysis. This is especially important in a postoperative patient when the decrease in Hct value is thought to be from blood loss and may be an important criterion as to whether additional surgery is necessary.

NONHEMOLYTIC TRANSFUSION REACTIONS

Nonhemolytic reactions to blood transfusions usually are not serious and are febrile or allergic. Specific infectious

causes of febrile reactions are discussed in the section on other options to reduce infectivity. Occasionally, fever may be the first sign of a hemolytic reaction or of bacterial contamination.

The most common adverse reactions to blood transfusions are the less serious febrile reactions. The symptoms consist of chills, fever, headache, myalgia, nausea, and nonproductive cough occurring shortly after blood transfusion, caused by pyrogenic cytokines and intracellular contents released by donor leukocytes. Use of leukoreduced blood lowered the incidence of febrile reactions.[164] Less frequently, the patient may have hypotension, chest pain, vomiting, and dyspnea. Even pulmonary infiltrations with radiographic evidence of prehilar nodule formation and lower lung infiltrates along with overt pulmonary edema have been reported.[164] Because febrile reactions obviously involve fever, they can be easily confused with a hemolytic transfusion reaction. A direct antiglobulin test readily differentiates a hemolytic reaction from a febrile reaction because this test rules out the attachment of an RBC antibody to transfused donor RBCs. More serious complications need to be ruled out (hemolytic and septic reactions), which may also be associated with fever and chills. No clear consensus exists on whether the transfusion should be terminated when a febrile reaction occurs.[165,166]

Allergic reactions can be minor, anaphylactoid, or anaphylactic. An anaphylactoid reaction is clinically similar to anaphylaxis, but it is not mediated by IgE. Most allergic transfusion reactions are minor and caused by the presence of foreign protein in the transfused blood. The most common symptom is urticaria associated with itching. Occasionally, the patient has facial swelling. When these reactions are clearly not a serious hemolytic reaction, the transfusion does not need to be discontinued. Antihistamines are used to relieve the symptoms of the allergic reaction. Infrequently, a more severe form of allergic reaction involving anaphylaxis occurs in which the patient has dyspnea, hypotension, laryngeal edema, chest pain, and shock. These are anaphylactic reactions caused by the transfusion of IgA to patients who are IgA deficient and have formed anti-IgA. This type of reaction does not involve red cell destruction and occurs very rapidly, usually after the transfusion of only a few milliliters of blood or plasma. Patients who experience these anaphylactic reactions can be given transfusions with washed RBCs from which all traces of donor IgA have been removed or with blood lacking the IgA protein. Several investigators have reviewed many other rare transfusion reactions.[149,154,167,168]

OTHER NONINFECTIOUS RISKS OF BLOOD TRANSFUSIONS

Although hemolytic transfusion reactions and TRALI have received an appropriate amount of prime attention in this chapter, the noninfectious risks of blood transfusions are also problematic and of significant concern (Table 61-9). Some of these risks were discussed previously, including febrile, allergic, and anaphylactoid reactions. In fact, the noninfectious hazards or risks have gained attention partly because of the decrease in risk for infectious complications such as hepatitis and human immunodeficiency virus (HIV) infection. In fact, The United Kingdom has a system-wide reporting scheme (SHOT) that requires reporting of transfusion-related adverse outcomes. In the past few years, several review articles have appeared in the literature.[169,170] Their labels were slightly different in that Hendrickson and Hillyer added the word *serious* to their title (i.e., "Noninfectious Serious Hazards of Transfusion"). Nevertheless, they are generally discussing the same risks.

Table 61-9 lists most of the hazards associated with noninfectious risk issues. TRALI and hemolytic transfusion reactions are discussed separately in other sections of this chapter. The term *NISHOT* includes all noninfectious complications. The following are some of the less common risks.

1. Transfusion-associated circulatory overload (TACO): Unlike TRALI, TACO simply refers to an excessive administration of blood. Patients with cardiopulmonary disease, renal failure, and extremes of age (i.e., especially infants; see also Chapter 93) are especially vulnerable. Other than decreasing the rate of infusion, administration of diuretics may be helpful.
2. Transfusion-related immunomodulation (TRIM): Blood transfusions can suppress the immune system because of circulating lymphocytes. The effects of blood transfusion transplant outcomes are consistent with this hypothesis, which confirms the concept of TRIM; the effects on malignancy and infection are not clear (see also the section on transfusion-related immunomodulation).
3. Microchimerism: Chimerism refers to more than one cell line in an individual organism. Specifically, donor lymphocytes may persist in a patient. It is associated with pregnancy, transplant, and trauma. The outcome of patients with microchimerism is not known.
4. Posttransfusion purpura: This refers to recipient alloantibodies attacking donor platelet antigens and is treated with intravenous immunoglobulin.
5. Hypotensive transfusion reactions: Activation of the coagulation pathway activates production of bradykinin and allergic reactions.
6. Transfusion-associated graft-versus-host disease (GVHD): Superficially, this refers to transfusion into an immunocompromised host. This is an extremely serious and often fatal problem (see Reference 22 for more details; see section on transfusion-associated GVHD).
7. Transfusion-related AKI.
8. Alloimmunization: Only 2% to 8% of recipients who are chronically transfused develop RBC alloantibodies (see Hendrickson and Hillyer, reference 22, for more details).
9. HLA alloimmunization and human platelet antigen (HPA) alloimmunization: HLA alloimmunization refers to patients whose platelets become refractory because of antibodies directed against HLA class I antibodies. HPA alloimmunization is platelet refractoriness from antibodies against platelet antigens (HPA antibodies).
10. Undertransfusion and overtransfusion: This complication is listed only for the sake of completeness,

TABLE 61-9 **NONINFECTIOUS HAZARDS OF TRANSFUSION**

Transfusion Reaction	Incidence (per 10^5 Transfusions)	Etiology	Therapy	Prevention
Febrile	All components: 70-6800	Storage-generated proinflammatory cytokines Patient antileukocyte antibodies bind to donor leukocytes	Stop transfusing Give antipyretics Supportive care	Prestorage leukoreduction
TACO	All components: 16.8-8000 Practice-dependent	Circulatory overload Patients with cardiac or renal disease, infants, and the critically ill are at increased risk	Stop transfusing Give diuretics Oxygen	Identify patients at high risk Transfuse slowly
TRALI	Erythrocytes: 10-20 Platelets/plasma: 50-100	Passive transfusion of donor antibodies Storage-generated toxic lipids	Supportive care	Remove high-risk donors from the donor pool
Allergic	All components: 3000 mild, 2 anaphylactic	Mild reactions: Transfusion of soluble antigens in donor plasma Anaphylaxis: IgA deficiency or other recipient protein deficiency	Stop transfusing ASA monitors Large-bore IV access Epinephrine Antihistamines Supportive care	Pretransfusion antihistamine use remains common practice despite limited evidence
Hemolytic	Erythrocytes: 1.1-9.0	Donor antibodies bind to patient erythrocytes Patient antibodies bind to donor erythrocytes	Stop transfusing Repeat matching Supportive care Treat DIC	Standard operating procedures
TRIM	Unknown	The mechanism is unknown but may depend on the presence of donor leukocytes	Treat complications (e.g., infection, malignancy)	Prestorage leukocyte reduction may be beneficial, but this approach is controversial
Microchimerism	All components: 5000-10,000 massive transfusion	Permanent residence of donor cells in recipient	Unknown	Unknown
Posttransfusion purpura	All components: 2	Recipient alloantibodies attack donor platelet antigens	IVIG	Avoid units positive for implicated HPA antigens in patients with a history of PTP
Hypotensive	Unknown	Production of kinins by the activation of the contact system Patients on ACE inhibitors are at increased risk	Stop transfusing ASA monitors Large-bore IV access Supportive care	Avoid the use of negatively charged leukocyte reduction filters
Graft-versus-host	Varies by patient population	Transfusion into immunocompromised host Transfusion of donor cells closely matching HLA type	No consensus exists Consider bone marrow transplant	Gamma irradiation of cellular products

because this topic is adequately reviewed in several previous sections of this chapter.

11. Iron overload: This complication usually does not involve anesthesia because it is the result of chronic transfusion therapy. Iron then begins to deposit into vital organs. In the absence of adequate chelation of iron, fatal liver or heart dysfunction, or both, can occur.

Hendrickson and Hillyer[170] correctly indicated that the list is lengthy. Their recommendations were general and not surprising and included the liberal versus restrictive

TABLE 61-10 PERCENTAGE RISK OF TRANSFUSION-TRANSMITTED INFECTION WITH A UNIT OF SCREENED BLOOD IN THE UNITED STATES*

Infection	Risk	Window Period (Days)
Human immunodeficiency virus-1 and -2	1:1,476,000	5-6
Human T-lymphotropic virus (HTLV-II)	1:2,993,000	51
Cytomegalovirus (CMV)	Infrequent with leukocyte-reduced components

indications for blood transfusion as well as the possible length of storage issue, both of which are extensively covered in this chapter. Gilliss and colleagues[169] stated that evidence-based transfusion should be followed. They also stated that the FDA has provided guidelines rather than mandates; their concern was that a diversity of transfusion medicine would evolve. They conclude that "avoidance of unnecessary transfusions will be the most effective way to reduce complications of blood transfusions." Although their recommendation is inherently obvious, the challenge is defining the word *necessary* or *unnecessary*. No clinician would knowingly administer an unnecessary transfusion. What is the difference between necessary and unnecessary? Accordingly, this chapter (see the section on indications for transfusion) has devoted an entire section to discussion of all of the variables that need to be considered when making a decision to give a unit of blood.

The use of more sensitive screening tests and changes in transfusion medicine practices has made these infectious risks quite rare. Historically, the FDA has published a table on the risks for infectivity, as displayed in Table 61-10 for the year 2011. Because the rates of infectivity are so infrequent, the FDA may not publish such tables in the future. Finally, rarely, anaphylaxis can occur.

Non–donor-transmitted issues have become dominant concerns (see the section on transfusion reactions; see Table 61-7). The summary of Fiebig and Busch[171] provides definitive information on this topic.

Several blood-safety changes made from 1982 to 2008 have made the risk for disease transmission by allogenic blood so small that even the demand for autologous blood has decreased because of the safety of allogeneic blood. Perhaps the West Nile virus story illustrates how rapidly our blood banks can respond. In 2002, West Nile virus caused the largest outbreak of arboviral encephalitis ever recorded in the United States (i.e., ~4200 patients). Twenty-three cases of transfusion-transmitted infections resulted in seven deaths. In 2003, testing was available that now makes that infection very rare (see Table 61-10).

Yet many questions arise—for example, regarding variant Creutzfeldt-Jakob disease. Three probable transfusion-transmitted cases occurred in Great Britain. How strict should testing be? As described recently,[172] "the sheer number of potential pathogens that have threatened the blood supply[173,174] since 1995 renders it impractical to keep adding expensive safety measures" for each new agent. Surveillance needs to be added to all these tests as a safety measure.

The changes in blood transfusion testing can be appreciated when comparing tests used in 1998 (Box 61-2) with those used in 2008 (Table 61-11). The use of nucleic acid technology has decreased the window of infectivity (i.e., time from being infected to a positive test result), which is a major reason for the decrease in infectivity with hepatitis, HIV, and West Nile virus.

HEPATITIS B

When blood transfusions became a reality in the 1940s, viral hepatitis was recognized as a major complication. The concern is mainly with hepatitis B, C, and, rarely, D, which are parenterally transmitted viruses. Before 1985, the overall incidence of posttransfusion hepatitis ranged from a low of 3% to a high of 19%, depending on the institution and the location (e.g., donors from large cities have a more frequent incidence of the hepatitis virus). In most areas, the incidence of hepatitis has ranged from 3% to 10%. Ninety percent of posttransfusion hepatitis is caused by the hepatitis C virus. Fewer than a third of these patients develop jaundice.[175] To determine their ultimate fate, Tong and colleagues[175] monitored 131 patients with chronic posttransfusion hepatitis C for several years and

Malaria	<1 million in the United States
Chagas disease	<1 million
Severe acute respiratory syndrome (SARS)	?
Variant Creutzfeldt-Jakob disease	Three cases (?) in the United Kingdom

found the following incidence of signs, symptoms, and conditions:

- Fatigue (67%)
- Hepatomegaly (67%)
- Chronic hepatitis (23%)
- Chronic active hepatitis (51%)
- Hepatocellular carcinoma (11%)

It was found that 20 patients had died of the following:

- Complications of cirrhosis (8 patients)
- Hepatocellular carcinoma (11 patients)
- Chronic active hepatitis-pneumonia (1 patient)

Even in 2013, patients are having ramifications from hepatitis C, from which they apparently recovered in the late 1960s and early 1970s. Several decades later, they can get carcinoma of the liver. Although I do not know the incidence, I have had three close friends who have had this outcome. The Centers for Disease Control and Prevention (CDC) reports that of every 100 people infected with the hepatitis C virus, about 75 to 85 will develop chronic hepatitis C virus infection; of those, 60 to 70 will go on to develop chronic liver disease, 5 to 20 will develop cirrhosis over a period of 20 to 30 years, and 1 to 5 people will die from cirrhosis or liver cancer. (Centers for Disease Control, Hepatitis C FAQs for the Public. Available at http://www.cdc.gov/hepatitis/c/cfaq.htm. Accessed July 8, 2014.)

CYTOMEGALOVIRUS

Asymptomatic chronic infection with cytomegalovirus (CMV) is so common in healthy adults that this agent can almost be viewed as normal flora. CMV survives best within cells and is thought to exist in latent form in the monocytes of many people with antibodies indicative of earlier infection. Fortunately, the primary concern is recipients who are at risk because of pregnancy (multiple), immaturity, or immunosuppression. CMV seroconversion usually occurs in subsets of patients receiving multiple transfusions. CMV causes a heterophil antibody-negative response that closely resembles infectious mononucleosis in many respects. An infectious mononucleosis–like syndrome that can occur 1 to 2 months after open-heart surgery is known as the postperfusion syndrome or posttransfusion mononucleosis.[176]

The evidence for transmission of CMV is most convincing when the recipient changes from a seronegative state before transfusion to a seropositive state accompanied by the mononucleosis-like illness several weeks after transfusion.

Transfusion-transmitted CMV can cause significant clinical problems in certain patient populations, such as premature neonates, allograft recipients, and patients who have had their spleen removed.[177] To prevent infection in high-risk populations, use of leukocyte-depleted blood, use of frozen deglycerolized RBCs, and screening of donors for the absence of antibody to CMV have been sometimes recommended (see the section on leukoreduction and irradiation of blood transfusions). The risk for seroconversion is approximately 0.14% overall, or 0.38% per unit of seropositive donor blood. Wilhelm and associates[178] concluded that it is not necessary to provide blood products from CMV-seronegative donors for most patients who receive blood transfusions. They continue to use CMV-seronegative blood to prevent CMV infection in preterm and newborn infants.

Plasma components, such as FFP and cryoprecipitate, components from seronegative donors, and leukoreduced components are considered to be CMV safe.

OTHER TRANSFUSION-ASSOCIATED INFECTIOUS DISEASES

Although many other infectious diseases can theoretically be transmitted by blood transfusion, only a few are of real concern. They include *Yersinia enterocolitica* infection, syphilis, malaria, Chagas disease, variant Creutzfeldt-Jakob disease, parvovirus B19, and severe acute respiratory syndrome (SARS) (Table 61-12).

During the late 1980s, Tripple and colleagues[179] described seven cases of fatal transfusion-associated *Y. enterocolitica* sepsis. These investigators also reviewed the literature and found 26 cases of gram-negative bacterial sepsis with whole blood or PRBCs. *Y. enterocolitica* is a bacterium that can cause mostly mild gastrointestinal problems. However, in severe cases, sepsis and death can occur. Unfortunately, storage of blood at 4° C in phosphate buffer enhances its growth.

Posttransfusion syphilis is unlikely because the infective agent cannot survive during storage at 1° to 6° C. The only blood products that have the potential to transmit syphilis are those stored at room temperature. Platelet concentrates are the blood component most likely to be implicated because they commonly are stored at room temperature.

TABLE 61-13 **COMPARISON OF WHOLE BLOOD AND PACKED RED BLOOD CELLS**

Value	Whole Blood	Packed Red Blood Cells
Volume (mL)	517	300
Erythrocyte mass (mL)	200	200
Hematocrit (%)	40	70
Albumin (g)	12.5	4
Globulin (g)	6.25	2
Total protein (g)	48.8	36
Plasma sodium (mEq)	45	15
Plasma potassium (mEq)	15	4
Plasma acid (citric-lactic)	80	25 (mEq)
Donor-to-recipient ratio	1 unit per patient	1 unit per 4-6 patients

From Landers DF, Hill GE, Wong KC, et al: Blood transfusion-induced immunomodulation. Anesth Analg *82:187, 1996.*

Posttransfusion malaria has never been a significant cause of blood recipient morbidity. Nevertheless, malaria can occur, especially if blood donors at risk for harboring parasites are not excluded. Consequently, blood banks thoroughly question donors for history of travel or migration from areas where malaria is endemic.

Several other diseases have been reported to be transmitted by blood transfusion, including herpesvirus infections, infectious mononucleosis (i.e., Epstein-Barr virus), toxoplasmosis, trypanosomiasis, leishmaniasis, brucellosis, typhus, filariasis, measles, salmonellosis, and Colorado tick fever.

Like malaria, several infectious agents are feared as possibly transmitting disease to patients through blood transfusions for which there are no blood testing methods (Table 61-13). Without a specific test, donor screening with increasingly restrictive criteria are used. For example, in 2003 in the United States, donors with suspected SARS or who traveled to certain countries in Southeast Asia would not be accepted. Even though there are no cases of variant Creutzfeldt-Jakob disease from blood transfusions, the virus can be transmitted by blood in animal models and stringent donor policies based on travel and residence in England or other countries in Europe are in place. Do these increasingly restrictive donor policies increase the risk for an inadequate blood supply[180] (see the section on synthetic O_2-carrying substances).

OTHER ADVERSE EFFECTS OF BLOOD TRANSFUSION

TRANSFUSION-ASSOCIATED GRAFT-VERSUS-HOST DISEASE

Transfusion-associated GVHD is caused by engraftment of donor lymphocytes from transfused blood products, initiating an immune reaction against recipient tissues. Severely immunocompromised patients are at risk. Also, directed donations from first- or second-degree relatives are at risk because transfused lymphocytes with shared HLA haplotypes cannot be recognized and eliminated.[181] A generalized rash, leukopenia, and thrombocytopenia occur. Sepsis and death usually result. Irradiation of blood can prevent transfusion-associated GVHD from occurring, although one case reported it occurring despite leukocyte filtering.[182]

ADVERSE OCULAR REACTION

In 1997, 112 cases of bilateral conjunctival erythema occurred within 24 hours of transfusion. The Centers for Disease Control and Prevention studied 49 other cases in 1997 and 1998 and concluded that they were toxic reactions to a chemical or material used in the blood collection filtration system, most likely a leukocyte-reducing filter system.[183]

TRANSFUSION-RELATED IMMUNOMODULATION

Homologous (allogeneic) blood transfusion exerts a nonspecific immunosuppressive action on the recipient. More than 150 clinical studies have tried to relate allogeneic blood transfusions to recurrence of resected cancers, postoperative infections, and virus activation, with the conclusion that adverse effects may be caused by TRIM. Although the conclusions of these studies are contradictory and inconclusive, universal leukocyte reduction of RBCs is moving forward (see the following section).[184]

LEUKOREDUCTION AND IRRADIATION OF BLOOD TRANSFUSIONS

GENERAL CONSIDERATIONS

Several complications of PRBCs are likely due to leukocytes. These include HLA alloimmunization against class I antigens, febrile reactions, and transfusion-transmitted CMV infections. The universal use of leukoreduced PRBCs internationally includes Western Europe, the United Kingdom, and Canada. Most of the PRBCs given in the United States are leukoreduced. What is the logic on which the use of leukoreduced blood is based?

Clear indications exist for leukoreduced blood. The chances of a febrile reaction can be reduced, especially in patients who are already alloimmunized from pregnancy. The risk for HLA alloimmunization from blood transfusions can be reduced, which would be especially helpful in minimizing refractoriness to platelet transfusions, and the risk for CMV can be reduced by using leukoreduced blood. More specifically, these include chronically transfused patients, potential transplant recipients, patients with transplants, patients with previous febrile nonhemolytic transfusion reactions, and CMV-seronegative at-risk patients for whom seronegative components are not available. Identification of these specific patients groups is from Kleinman.[51]

Universal leukoreduction has been seriously considered or implemented because of some anticipated benefits, including decreased transmission of variant Creutzfeldt-Jakob disease, leukocyte-induced immunomodulation, and even decreased postoperative mortality. In 2001, the case for and against universal leukoreduction was debated.[185,186] As of 2004, these anticipated benefits were not confirmed, despite numerous studies attempting to do so.[187] As nicely summarized by Corwin

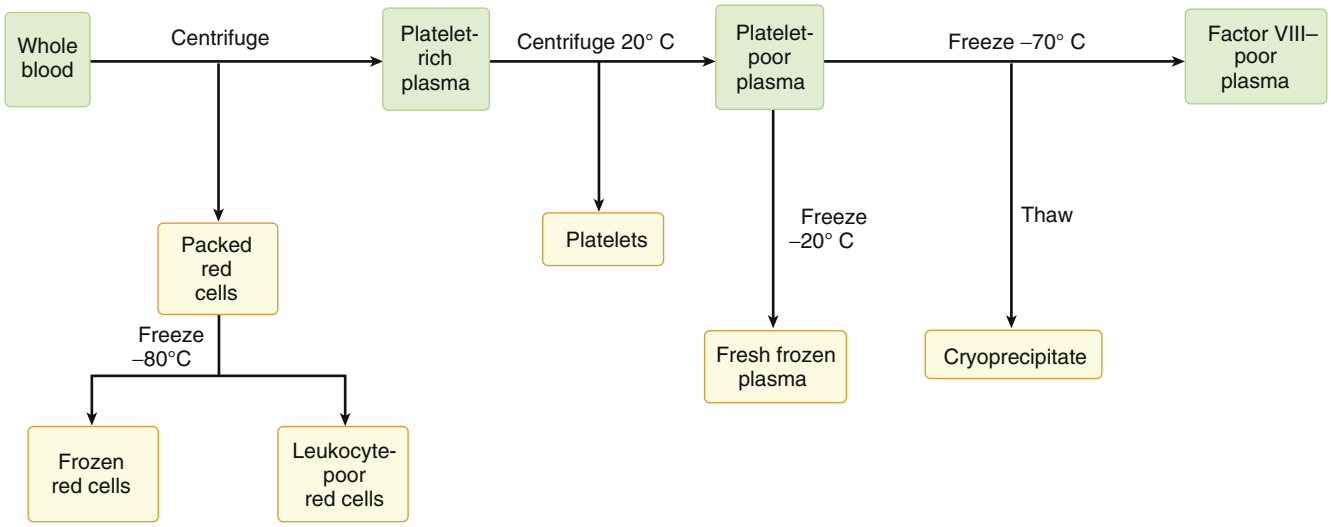

Figure 61-11. Scheme for separation of whole blood for component therapy.

and AuBuchon,[185] a "may help, won't hurt" approach has been used to justify universal leukoreduction. Yet bacterial contamination of platelets, TRALI, and acute hemolytic reactions cause more morbidity and mortality that would not be significantly helped by leukoreduction (see Table 61-7). Nevertheless, universal leukoreduction is the direction in which transfusion medicine has gone.

IRRADIATED BLOOD PRODUCTS

Irradiated blood components include only cellular products (RBCs, platelets, and granulocytes), but not noncellular products (thawed frozen plasma and cryoprecipitate). Indications for irradiation include intrauterine transfusions, neonates younger than 4 months of age, neonates, and pediatric patients undergoing transfusions (for ICU protocols only) (see also Chapters 93 to 95), infants younger than 1 year of age undergoing extracorporeal membrane oxygenation/extracorporeal cardiac life support, adult hematology or oncology patients, and those with immunodeficiency syndrome–directed donations from relatives before release from the blood bank. Irradiation will not be done for patients undergoing routine nonmyeloablative chemotherapy for solid tumors and solid organ transplant patients receiving routine postttransplant immunosuppressive therapy.

BLOOD COMPONENT THERAPY

A major advance in the field of blood banking has been the development of blood component therapy. It is beyond the scope of this chapter to describe the various separation steps in detail, but a superficial outline of the scheme by which various blood components are derived is shown in Figure 61-11. The basic philosophy is based on the concept that patients are best treated by administration of the specific fraction of blood that they lack. This concept has presented problems to the surgical team, who often desire whole blood.

TABLE 61-14 COMPATIBILITY OF BLOOD WITH INTRAVENOUS SOLUTIONS

Blood to Intravenous Solution (1:1 Ratio)	Hemolysis at 30 Minutes	
	Room Temperature	37° C
5% Dextrose in water	1+	4+
Plasmanate*	1+	3+
5% Dextrose in 0.2% saline	0	3+
5% Dextrose in 0.4% saline	0	0
5% Dextrose in 0.9% saline	0	0
0.9% Saline	0	0
Normosol-R, pH 7.4†	0	0
Lactated Ringer solution	0 (clotted)	0 (clotted)

†Abbott Laboratories, Chicago, Ill.

PACKED RED BLOOD CELLS

PRBCs contain the same amount of Hb as whole blood, but much of the plasma has been removed. The Hct value is 40% in whole blood and 70% in packed erythrocytes (see Table 61-13). Philosophically, whole blood provides O_2-carrying capacity and intravascular blood volume expansion. Other than severe hemorrhage, most indications for RBCs can be effectively treated with PRBCs, retaining the plasma and the components thereof for other patients (see Fig. 61-11). Many blood banks have conscientiously followed this principle, and whole blood cannot be obtained in the operating rooms except by special request. In essence, blood bank practice is that except for a rare situation (e.g., hypovolemic shock), whole blood is not necessary.

The administration of PRBCs is facilitated by reconstituting them with a crystalloid or colloid; however, not all crystalloids are suitable. If the solution contains Ca^{2+}, clotting occurs. Lactated Ringer solution is not recommended for use as a diluent for PRBCs (Table 61-14). Conversely, using flow rates and clot formation, Cull and colleagues[188] found lactated Ringer solution and normal saline to be equally acceptable. A more important factor

may be whether the diluent is hypotonic with respect to plasma. If so, the RBCs will swell and eventually lyse. Solutions that cause hemolysis are listed in Table 61-14. Clinicians who fear that the crystalloid-reconstituted RBCs may cause low serum concentrations may be tempted to use a plasma derivative, such as Plasmanate. However, these solutions also can cause hemolysis. The osmolality of Plasmanate is only 180 mOsm/kg. Solutions recommended for reconstituted packed erythrocytes are 5% dextrose in 0.4% saline, 5% dextrose in 0.9% saline, 0.9% saline, and Normosol-R with a pH of 7.4.

PLATELET CONCENTRATES

Platelet concentrates are obtained either as pooled concentrates from 4 to 6 whole-blood donations or as apheresis concentrates obtained from one donor[189] Platelet concentrates are prepared by differential centrifugation from freshly drawn units of blood or from donors who specifically donate large amounts of platelets by plateletpheresis techniques. If platelets are stored at room temperature, they are satisfactory to use 7 days after collection with constant and gentle agitation. Platelet concentrates present unique conflicts in medicine. First, bacterial contamination, mainly from platelet concentrates, is the third leading cause of transfusion-related deaths (see Table 61-7). They are primarily effective at room temperature, which enhances bacterial growth. Furthermore, this has been a problem for more than 20 years. In the report of 10 septic platelet transfusions between 1982 and 1985, half were platelets stored for 5 days or more. A prospective analysis from 1987 to 1990 resulted in seven cases of sepsis in patients receiving platelets for thrombocytopenia secondary to bone marrow failure.[190] Because use of multidonor platelet products stored for 5 days results in an incidence of sepsis five times higher than use of those stored for 4 days, shorter storage times are being emphasized. The incidence of platelet-related sepsis was approximately 1 case in 12,000 people.[191] The estimated incidence of bacterial contamination of platelets was approximately 1 case in 2000.[192]

The increased risk for bacterial overgrowth is related to the storage temperature of 20° to 24° C. For any patient who develops a fever within 6 hours after receiving platelets, sepsis from platelets should be considered. The evaluation of storing platelets for increased efficacy, but yet needing additional testing, actually makes the platelets available to the clinician for only approximately 3 days (Table 61-15). More recently, allowing platelets to be stored for 7 days minus 2 days for testing makes them available for 5 days, which enhances overall use of a valuable product and improves platelet inventory management. At present, platelet concentrates are routinely tested for bacteria and are the only blood product stored at room temperature.[193] The rate of bacteria in platelets was 1/5000 before and 1/50,000 after routine bacteria culturing.[193] Data in 2007 indicated 186 positive cultures in 1,004,206 units, of which 20 were septic reactions. Thirteen of these occurred 5 days after collection and resulted in three fatalities.[194]

Indications for the use of platelets are somewhat difficult to define. In the July 1989 *FDA Drug Bulletin* it was stated that platelets should not be given to patients with immune thrombocytopenic purpura (unless there is life-threatening bleeding), prophylactically with massive blood transfusion, or prophylactically after cardiopulmonary bypass. ASA Task Force[67] provided the following recommendations:

1. Prophylactic platelet transfusion is ineffective and rarely indicated when thrombocytopenia is due to increased platelet destruction (e.g., idiopathic thrombocytic purpura).
2. Prophylactic platelet transfusion is rarely indicated in surgical patients with thrombocytopenia because of decreased platelet production when the platelet count is greater than 100×10^9/L and is usually indicated when the platelet count is less than 50×10^9/L. The determination of whether patients with intermediate platelet counts (50 to 100×10^9/L) require therapy should be based on the patient's risk for bleeding.
3. Surgical and obstetric patients with microvascular bleeding usually require platelet transfusion if the platelet count is less than 50×10^9/L and rarely require therapy if it is greater than 100×10^9/L. With intermediate platelet counts (50 to 100×10^9/L), the determination should be based on the patient's risk for more significant bleeding.
4. Vaginal deliveries or operative procedures ordinarily associated with insignificant blood loss may be undertaken in patients with platelet counts less than 50×10^9/L.
5. Platelet transfusion may be indicated despite an apparently adequate platelet count if there is known platelet dysfunction and microvascular bleeding.

The ASA will be publishing new guidelines in 2015.

Some institutions (e.g., UCSF) have charts that outline the minimum platelet count needed for the categories of (1) prophylaxis, (2) periprocedure, and (3) active bleeding. In the first category, a required platelet count may be 20,000/μL in patients receiving chemotherapy. In the second category, bone marrow biopsy or lumbar puncture should be 20,000 and 30,000/μL. For neurosurgery a platelet count of 100,000/μL may be needed. In the third category, platelet counts as listed before may be at least 100,000/μL. It is likely that all major medical center blood banks have a chart, as superficially described here. A clinician's local blood bank will likely have precise platelet recommendations for most procedures, which should be followed.

TABLE 61-15 **HISTORY OF PLATELET CONCENTRATES SHELF LIFE IN RELATIONSHIP TO KEY EVENTS**

Year	Shelf Life	Practical Shelf Life*
1984-1986	7 days	6-7 days†
1986-1999	5 days	3 days‡
1999-2004	5 days	3 days§
2004-present	5 days	2.5 to 3 days

*Days that platelet concentrates are actually available to clinicians.
†Reports of bacterial contamination.
‡Nucleic acid technology testing, centralized blood donor testing.
§Bacterial detection implemented.

Patients with severe thrombocytopenia (<20,000 cells/mm^3) and clinical signs of bleeding usually require platelet transfusion. However, patients may have very low platelet counts (much less than 20,000 cells/mm^3) and not have clinical bleeding. Patients such as these probably do not need platelet transfusions. Individuals who have undergone trauma or require surgery need higher platelet counts, probably 100,000 cells/mm^3, to maintain adequate hemostasis (see Table 61-5). Laboratory determinations and clinical evaluations must be taken into account before a decision to transfuse platelets is made.

When possible, ABO-compatible platelets should be used. The need to use them, however, is not well documented. Specific testing is difficult. Aggregation, the end point of RBC crossmatch, cannot be used because platelets cause clumping. The platelet membrane has immunoglobulins. Any additional deposit of recipient antibodies is difficult to detect. Despite the fact that platelets can be destroyed by antibodies directed against class I HLA proteins on their membranes and, to a lesser extent, by antibodies against ABO, platelets chosen for transfusion probably will continue to be chosen without regard to antigen systems.[134] ABO-incompatible platelets produce very adequate hemostasis.

The effectiveness of platelet transfusions is difficult to monitor (see also Chapters 62 and 81). Under ideal circumstances, one platelet concentrate usually produces an increase of approximately 7000 to 10,000 platelets/mm^3 at 1 hour after transfusion to the 70-kg adult. Ten units of platelet concentrates are required to increase the platelet count by 100,000 cells/mm^3. However, many factors, including splenomegaly, previous sensitization, fever, sepsis, and active bleeding, may lead to decreased survivals and decreased recovery of transfused platelets.

Various different types of platelet concentrates have been proposed, including apheresis (i.e., collecting more platelets from one donor to avoid pooling of platelets from multiple donors), leukocyte-depleted platelets, and ultraviolet B–irradiated platelets. The use of these products is reviewed by Kruskall.[192]

FRESH FROZEN PLASMA

FFP is the most frequently used plasma product and is prepared at the time blood is obtained from a donor. It contains all the plasma proteins, particularly factors V and VIII, which gradually decline during the storage of blood. The use of FFP carries with it certain inherent risks that are observed with the use of essentially any blood product, such as sensitization to foreign proteins. To increase overall usage of blood products, many variations on the production of FFP exist. For example, variation is seen in how long FFP is viable after thawing from 24 hours to 5 days. Also, plasma frozen 24 hours after phlebotomy (FP24) is comparable to FFP except for an approximately 25% decrease in factor VIII.[195] Of course, plasma is a vital part of the transfusion ratios concept.

The 2006 ASA Task Force concluded that little scientific evidence supports increasing the use of FFP in clinical medicine. A more recent ASA Task Force will publish their summary about FFP and other blood products in 2015. Although FFP is a reliable solution for intravascular volume replacement in cases of acute blood loss, alternative therapies are equally satisfactory and considerably safer. No documentation exists that FFP has a beneficial effect when used as part of transfusion management of patients with massive hemorrhage. Not surprisingly, the risks of FFP administration include TRALI, transfusion-associated circulatory overload, and allergic or anaphylactic reactions. Other uncommon risks exist as well.[196]

In 2012, guidelines for plasma administration were published in an ASA publication.[197] Comparison of the 2006 and 2012 guidelines reflect the changes in thinking of the ASA, as follows:

1. Replacement of inherited single coagulation factor deficiencies for which no virus-safe products exists
2. Replacement of multiple coagulation factor deficiencies with associated bleeding, DIC, or both
3. As a component of plasma exchange in patients with thrombotic thrombocytopenic purpura
4. Reversal of warfarin anticoagulation when severe bleeding is present and prothrombin complex concentrations are not available
5. Prevention of dilutional coagulopathy in patients with major trauma and/or massive hemorrhage

FFP or plasma is often given to critical care patients before insertion of an intravascular catheter. Hall and associates[198] studied 1923 patients admitted to 29 ICUs in the United Kingdom who underwent intravascular catheterization. They compared patients who did and did not receive FFP. Chronic liver disease and more abnormal coagulation tests increased the frequency of patients receiving FFP. Yet the severity of PT alone was not a factor. Whether prophylactic FFP should be given in this situation is not well defined.

In an effort to "expedite" the availability of plasma for patients who require massive transfusions, some trauma centers keep thawed plasma readily available. In one study, patients with severe trauma who had already received 1 unit of RBCs and plasma were then divided into two groups, one of which immediately received 4 units of thawed plasma. The patients who received the plasma had a reduction in overall blood product use and 30-day mortality.[199] To me, the improvement in outcome was impressive. It makes one wonder if any other reasons accounted for improvement in care independent of blood administration.

OTHER PLASMA PRODUCTS

Several plasma products should be briefly described. This topic was well reviewed by Tanaka and Kor[197] in a publication from the ASA. Plasma frozen within 24 hours of collection is labeled PF24. Other products are labeled prothrombin complex concentrates. In Europe, prothrombin complex concentrates are available that are sterile lyophilized concentrates of vitamin K–dependent factors. Other preparations are available. In the United States, three-factor prothrombin complex concentrate products are available. Indications approved by the FDA are very restrictive.

CRYOPRECIPITATE

Cryoprecipitate is prepared in such a way that it contains significant levels of factor VIII and fibrinogen. It also contains von Willebrand factor and fibronectin. All other plasma proteins are present in only trace amounts in cryoprecipitate. The use of cryoprecipitate in the treatment of factor VIII deficiency or hemophilia A has been outlined by Brown and co-workers.[200] Cryoprecipitate contains factor VIII:C (i.e., procoagulant activity), factor VIII:vWF (i.e., von Willebrand factor), fibrinogen, factor XIII, and fibronectin, which is a glycoprotein that may play a role in reticuloendothelial clearance of foreign particles and bacteria from the blood.

Cryoprecipitate is frequently administered as ABO compatible; however, this probably is not very important because the concentration of antibodies in cryoprecipitate is extremely low. Cryoprecipitate may contain RBC fragments, and cryoprecipitate prepared from Rh-positive individuals can possibly sensitize Rh-negative individuals to the Rh O antigen.

Cryoprecipitate should be administered through a filter and as rapidly as possible. The rate of administration should be at least 200 mL/hr and infusion should be completed within 6 hours of thawing.

Commercial concentrates of factor VIII have been the standard therapy for hemophilia. Although heat inactivation of factor VIII concentrate reduces infectivity, such a risk is still present. Recombinant DNA techniques have been used to develop factor VIII, which is free of disease transmission.[201] Mild cases of hemophilia may be treated without blood products by administration of desmopressin. Appropriate therapy is difficult to ascertain for patients who have inhibitors (i.e., alloantibodies) to factor VIII.

Fibrin glue is used occasionally by surgeons to create local hemostasis. It is prepared in a manner similar to that of cryoprecipitate. When FFP is thawed, the precipitate contains large amounts of fibrinogen. When centrifuged, approximately 4 mL of concentrated precipitate results. With added thrombin, it is applied locally, the efficacy of which is difficult to determine.

PROTHROMBIN COMPLEX

Factor IX can be recovered from plasma or plasma fractions by absorption with ion exchanges or inorganic chemicals. These products are all complexes of factors II, VII, IX, and X. Two commercial preparations are Konyne (Cutter Laboratories, Berkeley, Calif) and Proplex (Hyland Division of Travenol Laboratories, Costa Mesa, Calif). Other products include AlphaNine SD (BDI Pharma, Columbia, SC), BeneFix (Wyeth Pharmaceuticals, New York), Mononine (CSL Behring, King of Prussia, Pa), and Profilnine SD (Grifols, Los Angeles, Calif). Bebulin VH (Baxter, Deerfield, Ill) is a vapor-heated concentrate of vitamin K–dependent factors in a much smaller volume than is achievable with FFP.

The main indication for these products is treatment of factor IX deficiency, or hemophilia B (i.e., Christmas disease). This hemorrhagic disorder is distinguishable from hemophilia A only by laboratory tests. Factor IX or prothrombin complex also has been used for the treatment of acquired hypoprothrombinemic bleeding disorders, principally sodium warfarin overdose; however, its use is limited because of the risk for hepatitis.

FIBRINOGEN CONCENTRATES

Fibrinogen concentrate is derived from human plasma and does not contain relevant levels of other coagulation factors. It also does not have the complications associated with blood transfusions. Accordingly, administration of fibrinogen can reduce the required need for allogeneic blood components. Quite often, the efficacy of fibrinogen administration has been clinically documented by fibrin-based ROTEM briefly described in this chapter and Chapter 62.[202] This randomized controlled trial strongly suggested that fibrinogen concentrate could be a first-line therapy to reduce transfusion requirements. In an accompanying editorial, Faraday[203] stated that "The administration of fibrinogen concentrates demonstrates clear potential to improve hemostasis more rapidly and at lower risk for immunologic reactions, infection, and (intravascular) volume overload than conventional allogeneic blood products." Also, Tanaka and colleagues[204] concluded that a single dose of 4 g of fibrinogen would achieve a blood level approximately 200 mg/dL and reduce the incidence of platelet administration and number of donor exposures. Yet a systematic review of five randomized trials and 15 nonrandomized studies concluded that that prothrombin complex and fibrinogen concentrations were not superior to conventional blood components for the treatment of perioperative coagulopathy in bleeding patients.[205]

SINGLE-DONOR PLASMA

Single-donor plasma is plasma that has been removed from stored blood without any effort being made to preserve coagulation factors. Single-donor plasma is very effective as a volume expander. All the precautions outlined for the administration of FFP should be followed when single-donor plasma is administered. It obviously cannot be used to correct deficiencies in coagulation factors.

ALBUMIN AND PLASMA PROTEIN PREPARATIONS

Several commercial products containing albumin are available for use to increase intravascular volume. Albumin is available as a 5% or a 25% solution in isotonic saline. Plasma protein fractions containing albumin and α and β globulins are available. These solutions are prepared commercially from albumin fractions from large pools of plasma reconstituted in isotonic electrolyte solutions. Such solutions can be given without regard to ABO blood type and without crossmatch and should be used primarily as volume expanders. They are very expensive and in short supply. Bacterial sepsis has been associated with albumin administration.[206] For much of 1997, there was a shortage of 5% albumin because of the concern

about contamination with variant Creutzfeldt-Jakob disease. If available, albumin should be administered within 4 hours of initiation of the infusion because of the potential for contamination after opening the bottle. In 2003, Vincent and associates[207] analyzed all adverse reports on the 10 major suppliers of human albumin worldwide from 1998 to 2000. Although cases were possibly underreported, the investigators concluded that adverse events were rare with human albumin administration. It appears to be quite safe, but the indications for its use are controversial.

Administration of the plasma protein fraction of 5% serum albumin solutions should be restricted for the treatment of documented hypoproteinemia or conditions such as burns and peritonitis, in which hypoproteinemia is likely. These solutions expand the vascular space for a longer period than do balanced electrolyte solutions. However, albumin's osmotic ability draws fluid into the vascular space from other extracellular fluid compartments. In most states of hypovolemia and dehydration, the entire extracellular fluid space is already depleted. Fluids such as 0.9% saline or lactated Ringer solution, which expand the entire extracellular fluid space, should be given.

SYNTHETIC COLLOID SOLUTION THERAPY

The crystalloid-versus-colloid conflict has been debated for many years. The University Hospital Consortium developed guidelines for the use of albumin, nonprotein colloid, and colloid solutions.[208] Unfortunately, no anesthesiologists were represented in the consensus exercise. No doubt exists that colloids expand intravascular volume more than crystalloids (i.e., a smaller amount of colloid is required for adequate intravascular resuscitation).[209] However, outcomes (e.g., mortality) do not provide convincing evidence that one fluid replacement strategy is better than others.

SYNTHETIC HYDROXYETHYL STARCH

Various starch preparations have been used to enlarge intravascular volume for many years. An excellent review by Van Der Linden and colleagues[210] stated that the understanding "the pharmacokinetics and pharmacodynamics of the hydroxyethyl starches has evolved so that we now appreciate that both properties vary depending on the starch source and on their chemical composition: degree of substitution, molecular location of the substitution, average molecular weight and molecular weight distribution." The most commonly used preparation was 6% hydroxyethyl starch (HES, Hespan). Although an effective intravascular expander, it has not gained widespread popularity, probably because of its effects on coagulation, particularly with regard to increased bleeding and platelet function. The molecular mass plays some role in the adverse coagulation effects (i.e., smaller molecular mass has less effect on coagulation). Two other HES preparations have been developed to decrease coagulation effects. Hextend has been studied extensively. It is 6% HES but also contains a physiologically balanced medium of electrolytes, glucose, and lactate. It has a pharmacokinetic and pharmacodynamic profile similar to those of other starch preparations with fewer effects on coagulation.[211] Gelatin also has been used, but it has not been as widely studied as HES.[212]

Van Der Linden and associates[211] could not find evidence that tetrastarches signaled any adverse safety issues. However, Zarychanski and co-workers[213] concluded that these starches should not be used because of serious safety concerns, especially increased risk for mortality and AKI. They also took into account research misconduct by one investigator who had published many articles regarding the clinical use of HES-like compounds. In an accompanying editorial,[214] the conclusions with HES-like compounds were outlined, including the extensive unethical research that has been described as data fabrication and scientific misconduct. Accordingly, Antonelli and Sandroni[214] concluded that HES most likely should not be used for acute intravascular volume resuscitation of critically ill patients. It remains to be seen whether more clinical research will be conducted.

In 2013, the FDA Safety Information and Adverse Event Reporting Program published via their MedWatch program a "Boxed Warning on Increased Mortality and Severe Renal Injury and Risk of Bleeding." Specifically, they recommended that HES solutions not be administered to patients with sepsis who are in the ICU, those with preexisting renal function issues, and those undergoing cardiopulmonary bypass. Also if HES is being given, it should be stopped at the first sign of a coagulopathy and/or renal dysfunction.

Since 2012, various forms of caution regarding the use of HES have been steadily appearing, which puts the future of colloids for clinical care in question. Yet in late 2013, an editorial by Seymour and Angus[215] states that whether patients with hypovolemic shock should be resuscitated with colloids or crystalloids (i.e., normal saline or lactated Ringer solution) is one of the oldest debates in medicine. Their editorial was in response to another study[216] regarding colloids versus crystalloids in patients with hypovolemic shock. Although there was a slightly better outcome with colloids regarding 90-day mortality, the overall conclusion leaned toward no difference between the use of colloids versus crystalloids (the Colloids versus Crystalloids for the Resuscitation of the Critically Ill [CRISTAL] trial). They point out that numerous clinical trials have been conducted, including Saline versus Albumin Fluid Evaluation (SAFE), Efficacy of Volume Substitution and Insulin Therapy in Severe Sepsis (VISEP), Scandinavian Starch for Severe Sepsis/Septic Shock (6S), Crystalloid versus Hydroxyethyl Starch Trial (CHEST), and the aforementioned CRISTAL trials. The conclusion is that there may be no definitive answer to the question of whether patients with hypovolemic shock should preferentially receive colloids or crystalloids.

The preceding paragraph indicates that the colloid versus crystalloids topic has been extensively studied, with no definitive answer. Nearly all of these groups have conducted their studies in acutely ill patients, frequently located in ICUs, except for one report. HES may be more effective for treating anaphylaxis associated with anesthesia.[217] Yet although many of the conclusions can

apply to intraoperative care, none of the studies were conducted during surgery and anesthesia. In summary, the justification and benefit for the use of colloids (which are expensive) (i.e., instead of crystalloids) are often not clear. Although many studies have been conducted, they frequently conclude that further study is required. My opinion is different. If the use of colloids is similar to that of crystalloids, perhaps the correct answer is that little or no difference exists, not that more studies are needed. If colloids (especially HES) are used, the anesthesia provider should be able to justify this decision based on the most recent available clinical evidence. Moral and associates[218] ask the question as to whether tetrastarch solutions are definitely dead? The editorial by Nolan and colleagues[219] goes further to say, "hydroxyethyl starch: here today, gone tomorrow."

DEXTRANS

Dextran 70 (Macrodex), with a molecular mass of approximately 70,000 Daltons, is an effective volume expander. However, after infusion of more than 20 mL/kg in 24 hours, dextran 70 may interfere with normal blood clotting, causing a deficiency with crossmatching procedures and possibly a bleeding diathesis. These clotting defects reflect reduced platelet adhesiveness resulting from an antithrombin effect. The incidence of severe anaphylactoid or anaphylactic reactions is a concern. These reactions are mediated by dextran-reactive antibodies that are IgG immunoglobulins. Dextran-reactive antibodies are formed in response to dextran polysaccharides. This process can be prevented if the potentially reactive sites on the dextran-reactive antibody are blocked before the antibody is given. By prior administration of a hapten, a substance capable of combining with immunoglobulins but not producing a reaction, the reactive sites are occupied and unable to react to the antigen. Prior administration of dextran I (Promit, molecular mass of 1000 D) proved effective as a hapten and decreases, but does not eliminate, the incidence of severe reactions.[220] Dextran 70 exerts a higher colloid osmotic pressure than blood. Dextran 70 and albumin may deplete the extracellular fluid space of water, as does albumin.

Dextran 40 (Rheomacrodex), with a molecular mass of 40,000 Daltons, has been used primarily to reduce blood viscosity and cellular aggregation and improve microcirculation during low-flow states. It is often given prophylactically to decrease the incidence of postoperative thromboembolism. Blood viscosity may be increased by trauma, blood loss, burns, and endotoxin shock. Although viscosity can be decreased by dextran 40, the presumed improvement in flow through the microcirculation has not been well documented.

HYPERTONIC SALINE, POSSIBLY WITH DEXTRAN

The Na concentration of hypertonic saline solutions is 250 to 1200 mEq/L. The theoretical advantage is that the greater the Na concentration, the less total volume is required for adequate resuscitation. The lower infusion volume probably reflects the osmotically related movement of intracellular water into the extracellular space. Other mechanisms include a direct inotropic effect on the myocardium and a direct peripheral vasodilator effect. The main problem is severe hypernatremia, which can cause brain dehydration and can be fatal.

Various hyperosmotic-hyperoncotic solutions have been used for resuscitation of hypovolemic patients. The most common combination is hypertonic saline and 6% dextran 70. In animals, these fluids restore gut and kidney microcirculation more effectively than normal saline.[221,222] The addition of dextran increases the intravascular volume effect of hypertonic saline but does not extend the duration of effect in a clinically significant manner.[221] Clinical practice will be required to ascertain the ultimate role, if any, of these fluids.

SYNTHETIC OXYGEN-CARRYING SUBSTANCES

OTHER THAN HUMAN RED BLOOD CELLS (BLOOD)

Various other substances that carry or facilitate the transport of O_2 have been made. Two attempts have been made using the concept of synthetic blood. The first approach uses linear binding kinetics, unlike the nonlinear binding of Hb. The most notable is the perfluorochemical emulsion called Fluosol-DA. However, it had little use because it carries O_2 (i.e., a small amount) only when the Pa_{O_2} is more than 300 mm Hg.[222] A newer perfluoro compound, perfluorooctyl bromide, carries three to four times more O_2 and has a longer half-life and presumably fewer problems than are associated with Fluosol-DA. Other related products are Oxygent (Alliance), Oxycyte (synthetic blood), and several other perfluorocarbon emulsions.

The remaining synthetic blood (a term this author uses but not one officially accepted by industry and the FDA) or O_2 therapeutics are labeled as Hb-based O_2 carriers (HBOCs). These products modify the Hb molecule from humans, animals, or recombinant technology. Original efforts required Hb to be stroma free to prevent nephrotoxicity. The stroma-free Hb needed to be modified to have a favorable O_2 affinity and to extend its relatively short intravascular half-life. Only three products have been undergoing clinical trials. Two products are from outdated human RBCs and the third from bovine RBCs. However, these solutions are not without complications. The most serious are kidney toxicity, an increase in affinity for O_2 (i.e., left shift in the O_2 dissociation curve), and arteriolar vasoconstriction from nitric oxide scavenged by the infused Hb. As described at the end of this section, this vasoconstriction may prove to be their ultimate downfall. A variety of approaches are being used, including crosslinking, pyridoxylation and polymerization, and conjugation and encapsulation, to decrease O_2 affinity, to increase deposition in the reticuloendothelial system, and to increase half-life.

Genetic engineering has provided hope for blood products. Initially, recombinant erythropoietin was developed for treatment of anemias and facilitation of autologous blood donation (see also Chapter 63). In 1992, a human

TABLE 61-16 COMPARISON OF SYNTHETIC BLOOD IN GENERAL WITH ALLOGENEIC BLOOD

Parameter	Synthetic	Allogeneic
Oxygen delivery	Rapid and consistent	Dependent on 2,3-DPG
Risk for disease transmission	None	See Table 61-11
Storage	Room temperature Stable efficacy	Refrigeration Loss of efficacy
Shelf life	1-3 yr	42 days
Preparation	Ready to use	Crossmatch
Compatibility	Universal	Type specific
Duration of action	1-3 days	60-90 days

2,3-DPG, 2,3-Diphosphoglycerate.

recombinant Hb (rHb 1.1) was designed as a blood substitute.[223] With the use of genetic engineering techniques, it was made from *Escherichia coli*. It functions as normal Hb in terms of O_2-carrying capacity, but it does not require crossmatching, transmit disease, or become rapidly outdated. How much recombinant material can be tolerated by humans remains to be determined. Unfortunately, this caused arteriolar vasoconstriction from NO scavenging. Although arterial blood pressure was sustained, it was at the expense of severe vasoconstriction of microvascular structures, which is not beneficial for organ perfusion. Recently, rHbg 2.0, which minimizes NO scavenging, caused little arteriolar vasoconstriction when compared with rHbg 1.1 and diaspirin crosslinked Hb.[224,225] It is hoped that studies of these newer Hb solutions will lead to new synthetic blood products in humans.

An example of a product that appears to be the initial one possibly approved for routine clinical practice is Hemopure.[226] It is from ultrapurified bovine RBCs that have been glutaraldehyde polymerized. It has a higher P_{50} (i.e., 43 instead of 26 mm Hg), which means that it should deliver O_2 to the tissues at least as well, if not better, than human RBCs.[226] It has the added advantage of not requiring type and crossmatch and not transmitting infectious agents such as HIV and hepatitis virus.[225,226] These, of course, are typical characteristics of most synthetic blood products (Table 61-16). Many clinical trials have been safely conducted with a few possibly minor complications, the significance of which are not clear. Complications include a slight increase in mean arterial blood pressure and a decrease in cardiac index, which presumably may be from NO. Most of the clinical trials have shown a decreased use of allogeneic blood transfusions.[227]

However, the most recent information regarding HBOCs is not encouraging. Natanson and colleagues[228] performed a cumulative meta-analysis on 16 trials involving five different products and 3711 patients. They concluded that there was a significant increased risk for myocardial infarction and death when HBOCs were given. An accompanying editorial concluded that a 30% increased risk for death and a three-fold increase in the risk for myocardial infarction should preclude any additional studies.[229] Furthermore, a consistency of harm was found among all the technologies (e.g., cross-linked, polymerized, or conjugated). In essence, investigators must demonstrate that HBOCs are at least as effective in reducing mortality or serious morbidity as the current standards of care. I have reluctantly concluded that use of synthetic blood (HBOCs) is not likely with the current technologic approaches.

Despite the negative conclusion regarding the future of HBOCs, attempts to find useful roles for them occasionally occur.

For example, organ function and systemic oxygenation could be sustained in rats by using perfluorocarbon emulsion (an HBOC) during extreme anemia.[230] The proposal is that perhaps HBOC could be used until blood transfusions were available. Accordingly, a human polymerized hemoglobin, PolyHeme, can provide "life-sustaining" capability in the presence of hemorrhage in trauma patients while waiting for blood products.[231] Olofsson and colleagues[232] used an oxygenated polyethylene glycol–modified Hb to decrease the hypotensive episodes during total hip arthroplasty. Although this was successful, a higher risk for adverse effects was found. These results led Levy[36] to conclude that "it is unlikely that we will have a NO-scavenging agent to treat hypotension or shock until the molecule is sufficiently safe for any benefits provided." Although this possibility seems unlikely, other possible uses of HBOC solutions will likely be proposed.

INFORMED CONSENT

Before any transfusion is given, informed consent should be obtained from the patient or guardian (see also Chapter 11). What constitutes consent varies across the United States and is still changing. If a patient is damaged by a transfusion administered without a valid consent, damages may be recovered even though the defendant did everything properly.[228] Many years ago, the *Paul Gann Blood Safety Act* was passed in California. This law mandates that patients be informed of the risks of blood transfusions and of any alternatives. The changes in transfusion medicine probably dictate an intense, ongoing educational process for clinicians who administer blood products to ensure they are compliant with current laws and regulations. Local hospital transfusion medicine committees can likely provide clinicians with such information.

Chapter 62

Patient Blood Management: Coagulation

THOMAS F. SLAUGHTER

Key Points

- Under normal physiologic conditions, clot formation requires participation of vascular endothelium, platelets, and plasma-mediated hemostasis.
- Tissue factor (extrinsic pathway) initiates plasma-mediated hemostasis, whereas factor XI (intrinsic pathway) amplifies the response.
- Thrombin generation proves the key regulatory enzymatic step in hemostasis.
- Platelets participate in clot formation as (1) anchoring sites for coagulation factor activation complexes, (2) delivery "vehicles" releasing hemostatically active proteins, and (3) major structural components of the clot.
- A carefully obtained history of bleeding remains the most effective means for identifying bleeding and thrombotic tendencies.
- Thrombosis is potentiated by stasis, vascular endothelial injury, and underlying hypercoagulable conditions.
- Heparin-induced thrombocytopenia comprises a heparin-mediated autoimmune response potentiating platelet activation and venous and arterial thromboses.

NORMAL HEMOSTASIS

Hemostasis comprises cellular and biochemical processes that limit blood loss resulting from injury, maintain intravascular blood fluidity, and promote revascularization of thrombosed vessels after injury. Normal physiologic hemostasis necessitates a delicate balance between procoagulant pathways responsible for generation of a stable localized hemostatic "plug" and counterregulatory mechanisms inhibiting thrombus formation beyond the injury site. Vascular endothelium, platelets, and plasma coagulation proteins play equally important roles in this process. Failure to maintain balance commonly leads to excessive bleeding or pathologic thrombus formation.

Vascular endothelial injury—mechanical or biochemical—leads to platelet deposition at the injury site, a process often referred to as primary hemostasis. Although primary hemostasis may prove adequate for a minor injury, control of more significant bleeding necessitates stable clot formation incorporating crosslinked fibrin—a process mediated by activation of plasma clotting factors and often referred to as secondary hemostasis. Although the terms primary and secondary hemostasis remain relevant for descriptive and diagnostic purposes, advances in understanding cellular and molecular processes underlying hemostasis suggest a far more complex interplay between vascular endothelium, platelets, and plasma-mediated hemostasis than is reflected in this model.

VASCULAR ENDOTHELIAL ROLE IN HEMOSTASIS

Under normal conditions, vascular endothelium provides a nonthrombogenic surface to promote blood fluidity. Healthy endothelial cells possess antiplatelet, anticoagulant, and profibrinolytic effects to inhibit clot formation.[1] Negatively charged vascular endothelium repels platelets and produces prostacyclin and nitric oxide (NO), which are potent platelet inhibitors.[2] Adenosine diphosphatase synthesized by vascular endothelial cells degrades adenosine diphosphate (ADP), another potent platelet activator. Given these endogenous antiplatelet effects, nonactivated platelets do not adhere to healthy vascular endothelial cells. Vascular endothelium further expresses several inhibitors of plasma-mediated hemostasis, including thrombomodulin (an indirect thrombin inhibitor), heparin-like glycosaminoglycans, and tissue factor pathway inhibitor (TFPI).[3] Finally, vascular endothelium synthesizes tissue plasminogen activator (t-PA), which is responsible for activating fibrinolysis—a primary counterregulatory mechanism limiting clot propagation.

Despite these natural defense mechanisms to inhibit thrombus generation, a variety of mechanical and chemical stimuli may shift the balance such that the endothelium promotes clot formation. Damage to vascular endothelial cells exposes the underlying extracellular matrix (ECM), including collagen, von Willebrand factor (vWF), and other platelet-adhesive glycoproteins.[4,5] Platelets bind to and are activated by exposure to ECM components. Exposure of tissue factor, constitutively expressed by fibroblasts in the ECM, activates plasma-mediated coagulation pathways to generate thrombin and, ultimately, fibrin clot. Certain cytokines (i.e., interleukin-1, tumor necrosis factor, and γ-interferon) and hormones (i.e., desmopressin acetate or endotoxin) induce prothrombotic changes in vascular endothelial cells, including synthesis and expression of vWF, tissue factor, plasminogen activator inhibitor–1 (PAI-1, an inhibitor of fibrinolysis), and down-regulate normal antithrombotic cellular and biochemical pathways.[6,7] Thrombin, hypoxia, and high fluid shear stress induce prothrombotic vascular endothelial changes. Increased vascular endothelial synthesis of PAI-1 and associated inhibition of fibrinolysis have been implicated in the prothrombotic state and high incidence of venous thrombosis after surgery.[8,9]

PLATELETS AND HEMOSTASIS

Platelets contribute a critical role in hemostasis. Derived from bone marrow megakaryocytes, nonactivated platelets circulate as discoid anuclear cells.[10] The platelet membrane is characterized by numerous receptors and a surface-connected open canalicular system serving to increase platelet membrane surface area and provide rapid communication between the platelet interior and external environment.[11] Under normal circumstances, platelets do not bind vascular endothelium; however, when injury exposes ECM, platelets undergo a series of biochemical and physical alterations characterized by three major phases: adhesion, activation, and aggregation.

Exposure of subendothelial matrix proteins (i.e., collagen, vWF, fibronectin) allows for platelet adhesion to the vascular wall. vWF proves particularly important as a bridging molecule between ECM and platelet glycoprotein Ib/factor IX/factor V receptor complexes.[12] Absence of either vWF (von Willebrand disease) or glycoprotein Ib/factor IX/factor V receptors (Bernard-Soulier syndrome) results in a clinically significant bleeding disorder.

As platelets adhere along the ECM, a series of physical and biochemical changes occur termed platelet activation. Platelets contain two specific types of storage granules: α granules and dense bodies.[11] Alpha granules contain numerous proteins essential to hemostasis and wound repair, including fibrinogen, coagulation factors V and VIII, vWF, platelet-derived growth factor, and others. Dense bodies contain the adenine nucleotides ADP and adenosine triphosphate, as well as calcium, serotonin, histamine, and epinephrine. During the activation phase, platelets release granular contents, resulting in recruitment and activation of additional platelets and propagation of plasma-mediated coagulation.[13] During activation, platelets undergo structural changes to develop pseudopod-like membrane extensions and to release physiologically active microparticles, with both mechanisms serving to increase dramatically platelet membrane surface area. Redistribution of platelet membrane phospholipids during activation exposes newly activated glycoprotein platelet surface receptors and phospholipid binding sites for calcium and coagulation factor activation complexes, which is critical to propagation of plasma-mediated hemostasis.[14]

During the final phase of platelet aggregation, activators released during the activation phase serve to recruit additional platelets to the site of injury. Newly active glycoprotein IIb/IIIa receptors on the platelet surface bind fibrinogen to provide for cross-linking with adjacent platelets (platelet aggregation).[15] The importance of these receptors is reflected by the bleeding disorder associated with their hereditary deficiency, Glanzmann thrombasthenia.

PLASMA-MEDIATED HEMOSTASIS

Plasma-mediated hemostasis, the coagulation cascade, might best be summarized as an amplification system to accelerate thrombin generation from an inactive precursor (i.e., prothrombin). Trace plasma proteins, activated by exposure to tissue factor or foreign surfaces, initiate a cascading series of reactions culminating in conversion of soluble fibrinogen to insoluble fibrin clot.[16] Thrombin generation, the "thrombin burst," represents the key regulatory step in this hemostatic process. Thrombin not only generates fibrin but also activates platelets and mediates a host of additional processes affecting inflammation, mitogenesis, and even down-regulation of hemostasis.[17]

Traditionally, the coagulation cascade describing plasma-mediated hemostasis has been depicted as intrinsic and extrinsic pathways, both of which culminate in a common pathway in which fibrin generation occurs.[18] Although this cascade model has proved an oversimplification, it remains a useful descriptive tool for organizing discussions of plasma-mediated hemostasis (Fig. 62-1). Coagulation factors are, for the most part, synthesized hepatically and circulate as inactive proteins termed zymogens. The somewhat confusing nomenclature of the classic coagulation cascade derives from the fact that inactive zymogens were identified using Roman numerals assigned in order of discovery. As the zymogen is converted to an active enzyme, a lower-case letter "a" is added to the Roman numeral identifier. For example, inactive prothrombin is referred to as factor II and active thrombin is identified as factor IIa. Some numerals were subsequently withdrawn or renamed as our understanding of the biochemistry underlying hemostasis evolved.The coagulation cascade characterizes a series of enzymatic reactions in which inactive precursors—zymogens—undergo activation to amplify the overall reaction. Each stage of the cascade requires assembly of membrane-bound activation complexes, each composed of an enzyme (activated coagulation factor), substrate (inactive precursor zymogen), cofactor (accelerator or catalyst), and calcium.[19] Assembly of these activation complexes occurs on phospholipid membranes (most often platelet or microparticle membranes) that localize and concentrate reactants. In the absence of phospholipid membrane anchoring sites,

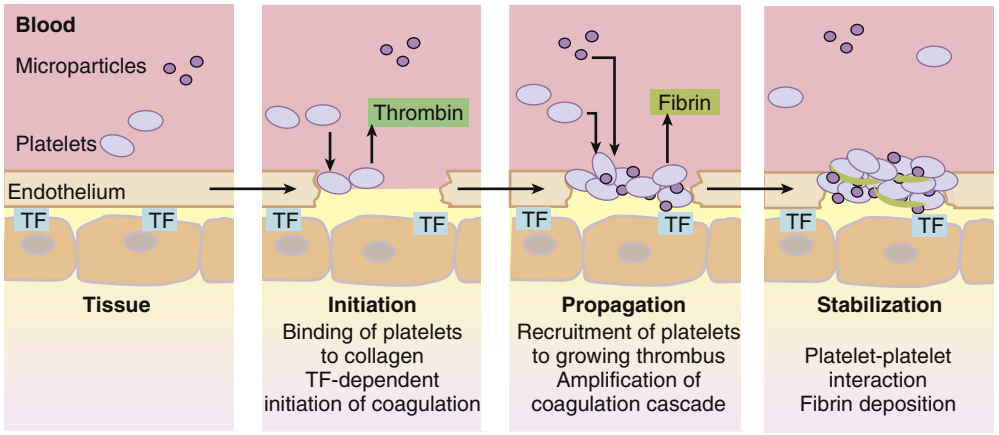

Figure 62-2. Clot formation at vascular injury site. Vascular injury exposes subendothelial tissue factor (*TF*) initiating plasma-mediated hemostasis via the extrinsic pathway. The intrinsic pathway further amplifies thrombin and fibrin generation. Platelets adhere to exposed collagen to undergo activation, resulting in recruitment and aggregation of additional platelets. *(From Mackman N, Tilley RE, Key NS: Role of extrinsic pathway of blood coagulation in hemostasis and thrombosis,* Arterioscleros Thromb Vasc Biol *27:1688, 2007, with permission.)*

activation of coagulation factors slows dramatically, further localizing clot generation to injury sites.

EXTRINSIC PATHWAY OF COAGULATION

The extrinsic pathway of coagulation, widely recognized as the initiating step in plasma-mediated hemostasis, begins with exposure of blood plasma to tissue factor.[20] Tissue factor is prevalent in subendothelial tissues surrounding vasculature; however, under normal conditions the vascular endothelium minimizes contact between tissue factor and plasma coagulation factors. After vascular injury, small concentrations of factor VIIa circulating in plasma form phospholipid-bound activation complexes with tissue factor, factor X, and calcium to promote conversion of factor X to Xa.[21] Recently, the tissue factor/factor VIIa complex has been demonstrated to activate factor IX of the intrinsic pathway, further demonstrating the key role of tissue factor in initiating hemostasis.[22]

INTRINSIC PATHWAY OF COAGULATION

Classically, the intrinsic or contact activation system was described as a parallel pathway for thrombin generation by way of factor XII. However, the rarity of bleeding disorders resulting from contact activation factor deficiencies led to our current understanding of the intrinsic pathway as an amplification system to propagate thrombin generation initiated by the extrinsic pathway.[22] Recent cell-based models of coagulation suggest that thrombin generation by way of the extrinsic pathway is limited by a natural inhibitor, TFPI.[23] However, small quantities of thrombin generated before neutralization of the extrinsic pathway activate factor XI and the intrinsic pathway. The intrinsic pathway subsequently amplifies and propagates the hemostatic response to maximize thrombin generation (Fig. 62-2). Although factor XII may be activated by foreign surfaces (i.e., cardiopulmonary bypass circuits or glass vials), the intrinsic pathway appears to play a minor role in initiation of hemostasis. Proteins of the intrinsic pathway may, however, contribute to inflammatory processes, complement activation, fibrinolysis, kinin generation, and angiogenesis.[22,24]

Common Pathway of Coagulation

The final pathway, common to both extrinsic and intrinsic coagulation cascades, depicts thrombin generation and subsequent fibrin formation. Signal amplification through both extrinsic and intrinsic pathways culminates in formation of prothrombinase complexes (phospholipid membrane–bound activation complexes) comprising factor Xa, factor II (prothrombin), factor Va (cofactor), and calcium ions.[25] Prothrombinase complexes mediate the thrombin burst—a surge in thrombin generation from the

inactive precursor prothrombin. Thrombin proteolytically cleaves fibrinopeptides A and B from fibrinogen molecules to generate fibrin monomers, which polymerize into fibrin strands (i.e., fibrin clot).[25] Finally, factor XIIIa, a transglutaminase activated by thrombin, covalently crosslinks fibrin strands to produce an insoluble fibrin clot resistant to fibrinolytic degradation. Both fibrinogen and factor XIII have been implicated in acquired bleeding disorders. Reduced concentrations of either protein may promote excess postoperative hemorrhage and transfusion requirements. Recent availability of plasma concentrates for both fibrinogen and factor XIII suggest potential for randomized controlled trials to determine efficacy of these biologics in treatment of acquired coagulopathies.[26] Regardless, thrombin generation remains the key enzymatic step regulating hemostasis.[27] Not only does thrombin activity mediate conversion of fibrinogen to fibrin, it also activates platelets and factor XIII, converts inactive cofactors V and VIII to active conformations, activates factor XI and the intrinsic pathway of coagulation, up-regulates cellular expression of tissue factor, and stimulates vascular endothelial expression of PAI-1 to down-regulate fibrinolytic activity.[17,27]

Intrinsic Anticoagulant Mechanisms

Once activated, regulation of hemostasis proves essential to limit clot propagation beyond the injury site. One simple, yet important, anticoagulant mechanism derives from flowing blood and hemodilution. The early platelet and fibrin clot proves highly susceptible to disruption by shear forces within flowing blood. Blood flow further limits localization and concentration of both platelets and coagulation factors such that a critical mass of hemostatic components may fail to coalesce.[25,28] However, later in the clotting process more robust counterregulatory mechanisms are necessary to limit clot propagation. Four major counterregulatory pathways have been identified that appear particularly crucial for down-regulating hemostasis: fibrinolysis, TFPI, the protein C system, and serine protease inhibitors.

The fibrinolytic system comprises a cascade of amplifying reactions culminating in plasmin generation and proteolytic degradation of fibrin and fibrinogen. As with the plasma-mediated coagulation cascade, inactive precursor proteins are converted to active enzymes, necessitating a balanced system of regulatory controls to prevent excessive bleeding or thrombosis (Fig. 62-3). The principal enzymatic mediator of fibrinolysis, plasmin, is generated from an inactive precursor, plasminogen.[29] In vivo, plasmin generation most often is initiated by release of t-PA or urokinase from vascular endothelium. Thrombin provides a potent stimulus for t-PA synthesis.[27] Factor XIIa and kallikrein of the intrinsic pathway activate fibrinolysis after exposure to foreign surfaces. The presence of fibrin accelerates plasmin generation.[30] Rapid inhibition of free plasmin also limits spread of fibrinolytic activity. In addition to enzymatic degradation of fibrin and fibrinogen, plasmin inhibits hemostasis by degrading essential cofactors V and VIII and reducing platelet glycoprotein surface receptors essential to adhesion and aggregation.[31] Fibrin degradation products also possess mild anticoagulant properties.TFPI inhibits the tissue factor/factor VIIa complex and thereby the extrinsic coagulation pathway, which is responsible for initiation of hemostasis. TFPI and factor

Xa form phospholipid membrane–bound complexes that incorporate and inhibit tissue factor/factor VIIa complexes.[3] Most TFPI is bound to vascular endothelium but may be released into circulation by heparin administration. Heparin further catalyzes TFPI inhibitory activity.[32] As TFPI rapidly extinguishes tissue factor/VIIa activity, the critical role of the intrinsic pathway to continued thrombin and fibrin generation becomes apparent.[22]

The protein C system proves particularly important in down-regulating hemostasis because it inhibits thrombin and the essential cofactors Va and VIIIa. Thrombin initiates this inhibitory pathway by binding a membrane-associated protein, thrombomodulin, to activate protein C.[33] Protein C, complexed with the cofactor protein S degrades both cofactors Va and VIIIa. Loss of these critical cofactors limits formation of tenase and prothrombinase activation complexes essential to formation of factor X and thrombin, respectively. Thrombin, once bound to thrombomodulin, is inactivated and removed from circulation, providing another mechanism by which protein C down-regulates hemostasis.[33]

The most significant serine protease inhibitors regulating hemostasis include antithrombin and heparin cofactor II. Antithrombin binds to and inhibits thrombin and factors IXa, Xa, XIa, and XIIa. Heparin cofactor II inhibits thrombin alone. Although the precise physiologic role for heparin cofactor II remains unclear, antithrombin plays a major role in down-regulating hemostasis.[34] Heparin, a catalyst accelerator, binds antithrombin to promote inhibition of targeted enzymes.[35] Heparin-like glycosaminoglycans, located on vascular endothelial cells, provide inhibitory sites for thrombin and factor Xa in vivo.

DISORDERS OF HEMOSTASIS

EVALUATION OF BLEEDING DISORDERS

Few would argue the importance of assessing bleeding risk preoperatively; however, appropriate methods for ascertaining this risk remain subject to debate. Although

routine coagulation testing of all surgical patients preoperatively intuitively may be appealing, this approach lacks predictive value for bleeding disorders and certainly lacks cost effectiveness.[36] A carefully performed history of bleeding remains the single most effective predictor for perioperative bleeding.

A thorough history should focus on prior bleeding episodes.[37] Does the patient have a history of excessive bleeding in association with trauma or prior surgery? Were blood transfusions or reoperation required to control the bleeding? A history suggestive of a bleeding disorder might include frequent epistaxis of a severity necessitating packing the nasal passage or surgical intervention. Oral surgery and dental extractions prove a particularly good test of hemostasis because of high concentrations of fibrinolytic activity in the oral cavity. Von Willebrand disease not infrequently manifests as menorrhagia, and postpartum hemorrhage commonly occurs in women with underlying disorders of hemostasis.[38] A history of spontaneous hemorrhage (nontraumatic) proves particularly concerning when associated with joints (hemarthroses) or deep muscles. Identification of a bleeding disorder at an early age or in family members suggests an inherited, as opposed to acquired, condition.[39] A careful medication history including direct questions relating to consumption of aspirin-containing nonprescription drugs, herbs, and fish oil may prove noteworthy. Finally, inquiries regarding coexisting diseases should be included (i.e., renal, hepatic, thyroid, and bone marrow disorders and malignancy).

For most patients, a thoughtfully conducted bleeding history will eliminate need for preoperative laboratory-based coagulation testing. Regardless, several valid reasons remain for preoperative coagulation testing. Should the preoperative history or physical examination reveal signs or symptoms suggestive of a bleeding disorder, further laboratory-based assessment of coagulation would be indicated. Preoperative screening tests of coagulation may be indicated, despite a negative history, in cases in which major surgery commonly associated with significant bleeding is planned (i.e., cardiopulmonary bypass). Finally, preoperative testing may prove justified in settings in which the patient is unable to provide a bleeding history preoperatively. Should evidence of a bleeding disorder be detected preoperatively, underlying mechanisms must be ascertained if possible before proceeding with surgery.

INHERITED BLEEDING DISORDERS

Although inherited disorders of hemostasis may involve platelet function, plasma-mediated hemostasis, or fibrinolytic pathways, von Willebrand disease characterized by quantitative or qualitative deficiencies of vWF proves the most common of inherited bleeding disorders.[38] Variants include types I and III with varying quantitative vWF deficiencies and type II comprising a collection of qualitative defects affecting vWF function. Under normal conditions, vWF plays a critical role in platelet adhesion to ECM. vWF further acts as a carrier molecule preventing proteolytic degradation of factor VIII in free plasma.[40] Classically, patients with von Willebrand disease describe a history of easy bruising, recurrent epistaxis, and menorrhagia, all characteristic of defects in primary (i.e., platelet mediated) hemostasis. In more severe cases (i.e., type III vWD), concomitant reductions in factor VIII may lead to serious spontaneous hemorrhage, including hemarthroses, which is common in hemophilia. Laboratory testing often demonstrates mild-to-moderate prolongation of the activated partial thromboplastin time (aPTT), prolonged bleeding time, decreased immunoreactive vWF concentrations, and reduced platelet aggregation in response to ristocetin.[38,41] Increasingly, the PFA-100 and similar ex-vivo platelet function tests have replaced bleeding times in assessing for vWD.[42] Measurable reductions in factor VIII activity may occur in severe cases. Mild cases of vWD often respond to desmopressin acetate (DDAVP); however, given a significant bleeding history, specific replacement of vWF and factor VIII with select factor VIII concentrates (i.e., Humate-P (CSL Behring, King of Prussia, Pa.) may be indicated.[43,44]

Although relatively uncommon, the hemophilias merit consideration given their diverse clinical presentation. Hemophilia A, characterized by variable degrees of factor VIII deficiency, is an X-linked inherited bleeding disorder most frequently presenting in childhood as spontaneous hemorrhage involving joints, deep muscles, or both. Hemophilia A occurs with an incidence of 1:5000 males; however, nearly one third of cases represent new mutations with no family history.[45] In mild cases, patients with hemophilia may not be identified until later in life, often after unexplained bleeding with surgery or trauma. Classically, laboratory testing in patients with hemophilia reveals prolongation of the aPTT, whereas the prothrombin time (PT) and bleeding time remain within normal limits. Specific measurement of factor VIII:C is required to confirm the diagnosis and to clarify the severity of factor VIII deficiency. Mild cases of hemophilia A may be treated with desmopressin; however, in most cases, perioperative management of these patients necessitates consultation with a hematologist and administration of recombinant or purified factor VIII concentrates.[43,46] An increasingly common complication of hemophilia, particularly in the case of hemophilia A, has been development of alloantibodies directed against the factor VIII protein. In cases of high-titer antibodies, administration of factor VIII concentrates may fail to control bleeding. Several approaches have reduced bleeding in these patients, including substitution of porcine factor VIII, administration of activated or nonactivated prothrombin complex concentrates, or treatment with recombinant factor VIIa (NovoSeven, Novo Nordisk Inc., Bagsvaerd, Denmark) (see also Chapter 63).[44,47] Also inherited as an X-linked disorder, hemophilia B (i.e., Christmas disease) occurs in approximately 1:40,000 and necessitates blood component replacement with factor IX concentrates.

ACQUIRED BLEEDING DISORDERS

A detailed account of acquired hemostatic disorders is beyond the scope of this discussion; however, given that a limited number of drugs and coexisting medical conditions account for the majority of acquired bleeding disorders, these conditions merit consideration. Heparin,

warfarin, and fibrinolytic drugs historically accounted for most serious drug-induced bleeding complications (Table 62-1).[48,49] More recently, antiplatelet drug therapy further has complicated perioperative management (Table 62-2).[49-52] Unfractionated heparin comprises a heterogeneous mixture of membrane-associated glycosaminoglycans derived from either bovine or porcine mucosal tissues. Specificity and potency of unfractionated heparin varies by molecular weight, which ranges between 5000 and 30,000 daltons.[35] Heparin derives its anticoagulant effect by interacting with plasma antithrombin, which in turn inhibits serine proteases participating in plasma-mediated hemostasis.[34] The half-life of heparin is 1 to 2 hours and varies directly with total dose. Heparin is cleared from the circulation both renally and hepatically. Most often, heparin's anticoagulant effect is monitored using the aPTT with a target prolongation of 1.5 to 2 times control, commonly used for treatment of venous thrombosis.[53] At heparin concentrations exceeding measurement limits of the aPTT, such as during cardiopulmonary bypass or interventional cardiovascular procedures, the activated clotting time (ACT) provides an alternative, albeit less sensitive, measure of heparin anticoagulation.[54] Heparin's anticoagulant effect is rapidly reversible by protamine administration.[55]

More recently, low-molecular-weight heparins (LMWHs) have gained favor as a result of reduced dosing frequency and the lack of need for monitoring. Owing to shorter saccharide chain lengths, LMWHs exhibit reduced inhibitory activity toward thrombin while retaining factor Xa inhibitory activity.[56] Theoretically, LMWHs may be associated with reduced bleeding tendencies. Regardless, LMWHs have a more predictable pharmacokinetic response, fewer effects on platelet function, and a reduced risk for heparin-induced thrombocytopenia (HIT). Although monitoring of LMWHs is not performed routinely, the PT and aPTT most often are unaffected, necessitating measurement of anti–factor Xa activity. Furthermore, should rapid

reversal of LMWH prove necessary, protamine is only partially effective.[57]

Oral anticoagulant therapy in the form of coumarin derivatives, interferes with hepatic synthesis of vitamin K–dependent coagulation factors—factors II, VII, IX, X, protein C, and protein S.[58] Specifically, coumarin inhibits carboxylation of glutamic acid residues essential for anchoring coagulation factor activation complexes to phospholipid membranes. Coumarin therapy is monitored using the international normalized ratio (INR) system derived from the PT. Generally, an INR of 2 to 3 is considered reflective of adequate anticoagulation.[53] In most cases, excessive coumarin anticoagulation is managed by withholding drug administration. However, given a half-life of 2 to 4 days, more rapid reversal in perioperative settings may be needed. Vitamin K administered orally or parentally in doses of 1 to 2 mg reverses coumarin anticoagulation.[58] More rapid reversal may be achieved by administration of plasma or prothrombin complex concentrates.[59] Recombinant factor VIIa also has proved effective at reversing coumarin-associated bleeding.

Despite relatively short half-lives and increasing fibrin specificity, fibrinolytic drug administration continues to be associated with significant bleeding potential. Bleeding after fibrinolytic drugs proves multifactorial resulting from proteolytic degradation of fibrin and fibrinogen, proteolysis of cofactors V and VIII, and digestion of platelet glycoprotein surface receptors.[29] In addition, both fibrin and fibrinogen degradation fragments impair platelet function and inhibit assembly of fibrin monomers into strands. Once the fibrinolytic agent is cleared from plasma, antifibrinolytic drugs prove of limited benefit. Therapy must rely on selective repletion of platelet and plasma protein constituents. In many cases, cryoprecipitate or fibrinogen concentrate will be administered to replace fibrinogen and platelet infusions will be needed to compensate for qualitative platelet dysfunction. Plasma infusions may be required to replete plasma coagulation factors, particularly cofactors V and VIII.

Liver Disease

Hemostatic defects associated with hepatic failure prove complex and multifactorial. Severe liver disease impairs synthesis of coagulation factors, impedes clearance of activated clotting and fibrinolytic proteins, and produces quantitative and qualitative platelet dysfunction. Laboratory findings commonly associated with liver disease include a prolonged PT, possible prolongation of the aPTT, and thrombocytopenia.[60] Prolongation of bleeding time reflects qualitative defects in platelet adhesion and aggregation. Treatment of bleeding in the setting of liver disease most often is based on laboratory abnormalities. Plasma and platelets frequently are administered for acute bleeding. Low fibrinogen concentrations may necessitate administration of cryoprecipitate or fibrinogen concentrate. In addition, low-grade fibrinolysis may benefit from antifibrinolytic drug administration in select settings.

Renal Disease

Platelet dysfunction commonly occurs in association with chronic renal failure, as reflected by a prolonged bleeding time and propensity for bleeding associated with surgery or trauma. Underlying mechanisms appear multifactorial and may include accumulation of guanidinosuccinic acid and NO in uremic plasma.[61] In addition, red blood cell (RBC) concentration has been speculated to play a role as correction of anemia results in shortened bleeding times, presumably related to the role of RBCs in causing platelet margination along the vessel wall under laminar flow conditions.[28] Both dialysis and correction of anemia have been reported to shorten bleeding times in patients with chronic renal failure. Traditionally, cryoprecipitate administration occurs in this setting; however, desmopressin 0.3 μg/kg and conjugated estrogens similarly may shorten bleeding times.[43] Risks associated with these therapies, and the predictive value of bleeding time for subsequent hemorrhage, remain unclear.

Disseminated Intravascular Coagulation

Disseminated intravascular coagulation (DIC) comprises a pathophysiologic hemostatic response to tissue factor/factor VIIa complex exposure and activation of the extrinsic pathway of coagulation. Numerous underlying disorders may precipitate DIC, including trauma, amniotic fluid embolus, malignancy, sepsis, or incompatible blood transfusions.[62] Most often, DIC presents clinically as a diffuse bleeding disorder associated with consumption of coagulation factors and platelets during widespread microvascular thrombotic activity. Underlying fibrinolysis, providing a counterregulatory mechanism to maintain vascular integrity, proves common as well. Laboratory findings typical of DIC include reductions in platelet count; prolongation of the PT, aPTT, and thrombin time (TT); and elevated concentrations of soluble fibrin and fibrin(ogen) degradation products. Chronic DIC states have been identified with relatively normal screening tests of coagulation accompanied by elevated concentrations of soluble fibrin and fibrin(ogen) degradation products.[63] Management of DIC requires alleviating the underlying condition precipitating hemostatic activation. Otherwise, treatment includes selective blood component transfusions to replete coagulation factors and platelets consumed in the process. Antifibrinolytic therapy generally is contraindicated in DIC owing to potential for catastrophic thrombotic complications.

PROTHROMBOTIC STATES

Thrombophilia, a propensity for thrombotic events, most often manifests clinically in the form of venous thrombosis (frequently deep venous thrombosis of the lower extremity).[64] As with bleeding disorders, thrombophilia may result from inherited or acquired conditions (Box 62-1). In the majority of cases, a precipitating event may be identified.[65] For example, thrombotic complications often occur after surgery, during pregnancy, and in association with obesity or underlying malignancy.[66] Random screening of asymptomatic patients for thrombotic risk has not proved cost effective or clinically efficacious.[67,68] As with bleeding disorders, a careful history focusing on prior thrombotic events, family history of thrombosis, and concurrent drug therapy offers greater predictive value than random screening.

High Risk

Heparin-induced thrombocytopenia
Antithrombin deficiency
Protein C deficiency
Protein S deficiency
Antiphospholipid antibody syndrome

Moderate Risk

Factor V Leiden genetic polymorphism
Prothrombin G20210A genetic polymorphism
Hyperhomocysteinemia
Dysfibrinogenemia
Postoperative prothrombotic state
Malignancy
Immobilization

Common Inherited Thrombotic Disorders

Although understanding of thrombotic disorders from a biochemical and molecular level remains limited at present, careful testing may identify an underlying heritable thrombotic predisposition in as many as 50% of patients with venous thromboembolism.[69] Relatively common inherited conditions underlying prothrombotic tendencies include single point mutations in genes for factor V (factor V Leiden) or prothrombin (prothrombin G20210A). In the case of the factor V Leiden mutation, the essential cofactor Va acquires resistance to degradation by protein C.[70] This simple alteration in balance between hemostasis and the protein C counterregulatory system induces a prothrombotic tendency present in approximately 5% of the population. In the case of the prothrombin gene mutation, increased prothrombin concentrations in plasma again generate a hypercoagulable state. Less common inherited forms of thrombophilia include deficiencies of antithrombin, protein C, and protein S.[34] Inherited forms of thrombophilia are characterized by highly variable penetrance affected by blood type, sex, and other confounding variables. In the absence of coexisting precipitating conditions, absolute thrombotic risk secondary to a heritable thrombophilia proves limited.[71] In the presence of a family history or test abnormality suggesting thrombophilia with no history of thrombosis, risks associated with long-term preventive anticoagulation may outweigh potential benefits. After a thrombotic complication, however, these patients most often are managed with life-long anticoagulation.

COMMON ACQUIRED THROMBOTIC DISORDERS

Antiphospholipid Syndrome

Antiphospholipid syndrome describes an acquired autoimmune disorder characterized by venous or arterial thromboses, or both, and recurrent pregnancy loss. This syndrome may occur secondarily to autoimmune disorders such as systemic lupus erythematosus or rheumatoid arthritis, or it may occur in isolation. Characteristically, antiphospholipid syndrome results in mild prolongation of the aPTT and positive testing for lupus anticoagulant or anticardiolipin antibodies.[72] Despite the prolonged aPTT, antiphospholipid syndrome poses no increased bleeding risk but rather increases the potential for thrombosis. Antibodies associated with antiphospholipid syndrome interfere with phospholipids common to many laboratory-based tests of coagulation. Isolated prolongation of an aPTT in a preoperative patient merits consideration of the diagnosis of antiphospholipid syndrome. Patients with this syndrome who have experienced a thrombotic complication are at increased risk for recurrent thrombosis and most often are managed by life-long anticoagulation.[73]

Heparin-Induced Thrombocytopenia

Heparin-induced thrombocytopenia describes an autoimmune-mediated drug reaction occurring in as many as 5% of patients receiving heparin therapy. As opposed to other drug-induced thrombocytopenias, HIT results in platelet activation and potential for venous and arterial thromboses.[74,75] Evidence suggests that HIT is mediated by immune complexes (composed of immunoglobulin G [IgG] antibody, platelet factor 4 [PF4], and heparin) that bind platelet Fcγ receptors to activate platelets. Anti-PF4/heparin antibodies may "activate" vascular endothelium, monocytes, and macrophages by up-regulating tissue factor expression (Fig. 62-4). Patients developing HIT during heparin therapy experience substantially increased risk for thrombosis (odds ratio 20:40, absolute risk 30% to 75%).[74,75]

In most cases, HIT manifests clinically as thrombocytopenia occurring 5 to 14 days after initiating heparin therapy. However, with prior heparin exposure, thrombocytopenia or thrombosis may occur within 1 day. In some reported cases, thrombosis occurred simultaneously with thrombocytopenia, providing no warning. Although HIT remains a clinical diagnosis, laboratory testing provides confirmatory evidence. Both functional (i.e., serotonin platelet release assays or heparin-induced platelet aggregation) and quantitative (i.e., solid-phase enzyme-linked immunosorbent assays [ELISA]) tests for PF4/heparin immune complexes prove beneficial.[75] Recent evidence suggests that PF4/heparin antibodies alone, in the absence of thrombocytopenia or thrombosis, may predict adverse outcomes.[76,77]

A diagnosis of HIT should be entertained for any patient experiencing thrombosis or thrombocytopenia (absolute or relative [≥50% reduction in platelet count]) during or after heparin administration. In cases in which HIT is suspected, heparin must be discontinued immediately (i.e., including unfractionated heparin, heparin-bonded catheters, heparin flushes, LMWH). Alternative nonheparin anticoagulation must be administered concurrently. In most cases, a direct thrombin inhibitor (i.e., bivalirudin, lepirudin, argatroban) is substituted for heparin until adequate prolongation of the INR can be achieved with warfarin.[78,79] Typically, PF4/heparin immune complexes clear from the circulation within 3 months. If possible, patients experiencing HIT should avoid future exposure to unfractionated heparin; however, several reports describe subsequent limited perioperative reexposure to

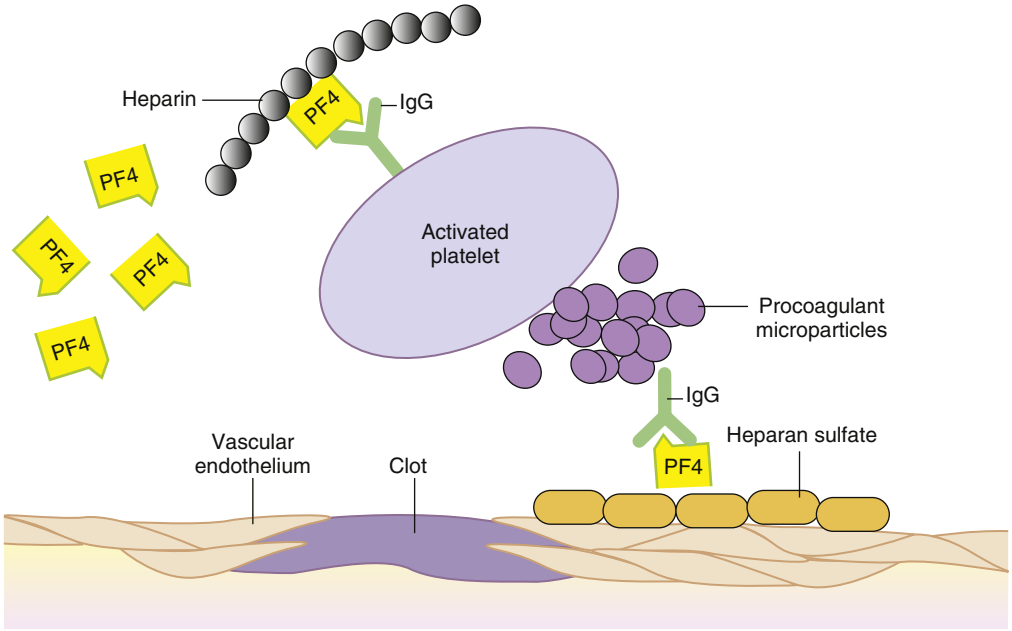

Figure 62-4. Mechanisms underlying thrombosis in heparin-induced thrombocytopenia (HIT). Immune complexes composed of heparin, platelet factor 4 (*PF4*), and antibodies bind to platelet surface Fcγ receptors to activate platelets. PF4/heparin immune complexes further activate vascular endothelium, monocytes, and macrophages to increase tissue factor expression. *IgG,* Immunoglobulin G. *(From Slaughter TF, Greenberg CS: Heparin-associated thrombocytopenia and thrombosis: Implications for perioperative management,* Anesthesiology *87:669, 1997, with permission.)*

unfractionated heparin after laboratory testing to ensure absence of PF4/heparin immune complexes.

MONITORING COAGULATION

Traditionally, perioperative coagulation monitoring has focused on (1) preoperative testing to identify patients at increased risk for perioperative bleeding and (2) intraoperative monitoring of heparin therapy during cardiac and vascular surgery. As discussed previously, routine preoperative coagulation testing lacks either predictive value or cost efficacy.[80] However, in patients with a history suggestive of a bleeding disorder or whose surgery may be associated with a high incidence of bleeding or coagulopathy, baseline preoperative coagulation testing may be advisable.

Given the widely acknowledged pharmacokinetic and pharmacodynamic response to heparin, monitoring anticoagulation during cardiac and vascular surgery remains necessary. Patient-specific factors affecting response to heparin include age, weight, intravascular volume, and plasma and membrane concentrations of antithrombin, heparin cofactor II, PF4, and other heparin-binding proteins. Therefore, patients experience widely divergent anticoagulant responses to identical weight-based doses of heparin. Regardless, monitoring of heparin anticoagulation must be performed if only to prevent the rare, but potentially lethal, complication resulting from inadvertent failure to administer heparin before cardiopulmonary bypass or vascular surgery.

The ideal test of perioperative coagulation would prove simple to perform, accurate, reproducible, diagnostically specific, and cost effective. No current coagulation monitor meets these expectations; however, integrating results from multiple forms of monitoring may provide valuable diagnostic insight into perioperative coagulopathies.

COMMON LABORATORY-BASED MEASURES OF COAGULATION

Activated Partial Thromboplastin Time

The aPTT assesses integrity of the intrinsic and common pathways of plasma-mediated hemostasis. It measures the time required in seconds for clot formation to occur after mixing a sample of patient plasma with phospholipid, calcium, and an activator of the intrinsic pathway of coagulation (i.e., celite, kaolin, silica, or ellagic acid). In most cases, coagulation factor deficiencies are detectable at factor concentrations below 30% to 40% of normal; however, aPTT reagents vary in sensitivity to factor concentrations, necessitating institutional specific determination of "normal" ranges.[81] Prolongation of the aPTT is evaluated further with mixing studies to determine whether delayed clot formation is attributable to a coagulation factor deficiency or an inhibitor (i.e., heparin, antiphospholipid antibody, fibrin split products). The mixing study is performed by mixing the patient's plasma sample with "normal" donor plasma. In the case of a coagulation factor deficiency, time to clot formation will correct and sequential assays for specific coagulation factor concentrations allow for identification of the deficiency. A common means of confirming heparin prolongation of the aPTT is to perform a thrombin clotting time (TCT) test. In this test, the patient's citrate-containing plasma sample is mixed with thrombin and time to clot formation is measured in seconds.[39] The most common mechanism underlying prolongation of the TCT is presence of heparin or a direct thrombin inhibitor anticoagulant; however, dysfibrinogenemia or fibrin(ogen) degradation products also may impair clot formation in this setting.

Prothrombin Time

The PT assesses integrity of the extrinsic and common pathways of plasma-mediated hemostasis. It measures

time required in seconds for clot formation to occur after mixing a sample of patient plasma with tissue factor (thromboplastin) and calcium. As with the aPTT, thromboplastin test reagents vary in sensitivity, limiting the ability to compare results between laboratories. Given the importance of monitoring PT results for patients on long-term warfarin therapy, the INR was introduced as a means of normalizing PT results among different laboratories.[81] Thromboplastin reagents are tested against an international recombinant standard and assigned an international sensitivity index (ISI) based on results. The INR subsequently is calculated as INR = (patient PT/standard PT)ISI, in which the standard PT represents the geometric mean of multiple normal samples from the testing laboratory. Institution of the INR substantially reduced interlaboratory variations in the PT. As with the aPTT, prolongation of the PT is assessed further with mixing studies.

Platelet Count and Bleeding Time

The platelet count remains a standard component in screening for coagulation abnormalities. Automated platelet counts are performed in bulk using either optical-based or impedance-based measurements. Recommendations regarding optimal platelet counts prove somewhat arbitrary; however, platelet counts exceeding 100,000/μL commonly are associated with normal hemostasis. Abnormally low platelet counts merit further assessment, including a visual platelet count using a blood smear. Sample hemodilution and platelet clumping are common causes for false low platelet counts. Ethylenediaminetetraacetic acid (EDTA)-induced platelet clumping, a common artifact underlying thrombocytopenia, may be identified by manually counting platelets or by substituting a citrate anticoagulant (as opposed to EDTA).

With growth in point-of-care platelet function monitors the bleeding time has declined in popularity; however, under controlled conditions the bleeding time may provide useful information regarding primary hemostasis. Employing a commercial template cutting device and a sphygmomanometer adjusted to 40 mm Hg venous pressure, bleeding times of 2 to 10 minutes on the anterior forearm are considered normal. Limitations of the bleeding time include poor reproducibility, time needed to perform the test, and potential for scarring. Furthermore, the bleeding time is affected by numerous confounding variables, including skin temperature, skin thickness, age, ethnicity, anatomic test location, and a host of other factors.[82] In general, the bleeding time has not proved predictive of bleeding and for that reason its use as a preoperative screening test to assess bleeding risk is not recommended.

COMMON POINT-OF-CARE MEASURES OF COAGULATION

Although laboratory-based measures of coagulation remain the mainstay of preoperative coagulation testing, increasing availability of sensitive and specific point-of-care coagulation monitoring may soon offer opportunities to direct blood component and hemostatic drug therapy more specifically without delays inherent to standard laboratory testing. Commercially available point-of-care monitors applicable in the perioperative setting may be considered in four broad categories: (1) functional measures of coagulation or assays that measure the intrinsic ability of blood to generate clot, (2) heparin concentration monitors, (3) viscoelastic measures of coagulation, and (4) platelet function monitors.

Functional Measures of Coagulation

The ACT, described by Hattersley in 1966 as a variation of the Lee-White whole blood clotting time, employs a contact activation initiator, typically celite (diatomaceous earth) or kaolin, to accelerate clot formation and reduce time for assay completion. Kaolin is recommended for use in patients receiving the antifibrinolytic drug aprotinin because celite ACTs in this setting are subject to artifactual prolongation.[83] Failure to appreciate this drug-mediated effect may result in inadequate heparin administration if using celite ACT measurements with aprotinin. Whether high plasma concentrations of aprotinin affect the kaolin ACT remains unclear.

Current commercial ACT monitors automate clot detection. One of the more widely available ACT monitors uses a glass test tube containing a small magnet (Hemochron Response Whole Blood Coagulation System, ITC, Edison, NJ). After adding sample blood, the tube is placed into the analyzer and the tube is rotated slowly at 37° C, allowing the magnet to maintain contact with a proximity detection switch. As fibrin clot forms, the magnet becomes entrapped and dislodged from the detection switch, thereby triggering an alarm to signal completion of the ACT. Another ACT device uses a "plumb bob" flag assembly that is raised and released repeatedly to settle in the sample vial containing blood and contact activator (Hepcon HMS Plus, Medtronic, Minneapolis, Minn.). With clot formation, the descent rate of the flag through the blood sample slows, triggers an optical detector, and sets off an alarm to signal completion of the ACT.

The ACT in normal individuals is 107 ± 13 seconds (mean ± SD). However, the time at which a patient's baseline ACT is measured influences the result.[83] After surgical incision, baseline ACT may decrease. Because the ACT measures clot formation by way of intrinsic and common pathways, heparin and other anticoagulants prolong time to clot formation. The ACT proves somewhat resistant to platelet dysfunction and thrombocytopenia.

ACT testing remains a popular perioperative coagulation monitor because of its simplicity, low cost, and linear operating response at high heparin concentrations. Limitations of ACT monitoring include lack of sensitivity at low heparin concentrations and poor reproducibility.[83] ACT testing performed with and without added heparinase improves sensitivity for detecting low heparin concentrations. Further limitations of the ACT include artifactual prolongation of results with hemodilution or hypothermia and the fact that ACT values beyond 600 seconds exceed the linear response range for the assay. Duplicate measurements improve results; however, newer electrochemically based ACT analyzers (i-STAT, Abbott, Princeton, NJ) improve reproducibility such that single ACT determinations may prove adequate.

The high-dose thrombin time (HiTT) (ITC) provides an alternative functional measure of heparin anticoagulation. Primarily employed in cardiac surgical settings, the HiTT assay contains high thrombin concentrations to cleave fibrinogen directly and generate fibrin clot.[84] Given excess thrombin concentrations, clot formation occurs independently of plasma coagulation factors other than fibrinogen. As a result, HiTT is prolonged by heparin (or other thrombin inhibitors), extreme degrees of hypofibrinogenemia or dysfibrinogenemia, and high concentrations of fibrin split products (as occur with fibrinolysis). During most surgical procedures requiring heparin administration, HiTT prolongation will correlate with heparin anticoagulant effect.

Heparin Concentration Measurement

Protamine titration remains the most popular point-of-care method for determining heparin concentration in perioperative settings. Protamine, a strongly basic polycationic protein, directly inhibits heparin in a stoichiometric manner. In other words, 1 mg of protamine will inhibit 1 mg (~100 units) of heparin, thereby forming the basis for protamine titration as a measure of heparin concentration. As increasing concentrations of protamine are added to a sample of heparin-containing blood, time to clot formation decreases until the point at which the protamine concentration exceeds heparin concentration to delay clot formation. If a series of blood samples with incremental doses of protamine are analyzed, the sample in which the protamine and heparin concentrations are most closely matched will clot first. In this manner, protamine titration methodology allows for heparin concentration estimation. Assuming that the heparin-protamine titration curve for an individual patient remains constant throughout the operative period, protamine titration methods may estimate heparin doses required to achieve a desired plasma heparin concentration or the protamine dose needed to reverse a given heparin concentration in blood.[54] Current point-of-care heparin concentration monitoring employs automated measurement techniques (Hepcon HMS Plus, Medtronic). Advantages of heparin concentration measurement include sensitivity for low heparin concentrations as well as relative insensitivity to hemodilution and hypothermia. In addition, heparin concentration measures are unaffected by aprotinin.

A major limitation of heparin concentration monitoring is failure to assess directly for an anticoagulant effect. To use an extreme example, consider a patient with a homozygous deficiency of antithrombin; in this setting, heparin concentration determination alone would fail to identify the lack of anticoagulant effect after heparin administration.

Viscoelastic Measures of Coagulation

Initially developed in the 1940s, viscoelastic measures of coagulation have undergone a resurgence in popularity. The unique aspect of viscoelastic monitors lies in their ability to measure in whole blood the entire spectrum of clot formation from early fibrin strand generation through clot retraction and eventual fibrinolysis. The early thromboelastograph (TEG) developed by Hartert in 1948 has evolved into two independent viscoelastic monitors: the modern TEG, or TEG 5000 Thromboelastograph Hemostasis Analyzer System (Haemoscope, Braintree, Mass.) and rotational thromboelastometry (ROTEM) (TEM Systems, Durham, NC). In the case of the thromboelastograph (TEG 5000), a small (0.35-mL) sample of whole blood is placed into a disposable cuvette within the instrument. The cuvette is maintained at a temperature of 37° C and continuously rotates around an axis of approximately 5 degrees. A sensor "piston" attached by a torsion wire to an electronic recorder is lowered into the blood within the cuvette. Addition of an activator, most often kaolin or celite, initiates clot formation. As the fibrin-platelet plug evolves, the piston becomes enmeshed within the clot, transferring rotation of the cuvette to the piston, torsion wire, and electronic recorder.[85]

Although variables derived from the TEG tracing do not coincide directly with laboratory-based tests of coagulation, the TEG depicts characteristic abnormalities in clot formation and fibrinolysis. Various parameters describing clot formation and lysis are identified and measured by the TEG. For example, the R value (reaction time) measures time to initial clot formation (normal, 7.5 to 15 minutes). Comparable to the whole blood clotting time, addition of a contact activator (i.e., celite or kaolin) to the sample cuvette reduces time to results. The R value may be prolonged by a deficiency of one or more plasma coagulation factors or inhibitors such as heparin. Maximum amplitude (MA) provides a measure of clot strength and may be decreased by either qualitative or quantitative platelet dysfunction or decreased fibrinogen concentration. Normal MA is 50 to 60 mm. The α angle and K (BiKoatugulierung or coagulation) values measure rate of clot formation and may be prolonged by any variable slowing clot generation such as a plasma coagulation factor deficiency or heparin anticoagulation. Modification of clotting activators may be incorporated to assess platelet or fibrin contributions to clot strength.[86] In a somewhat analogous manner, ROTEM measures viscoelastic changes in a sample of whole blood subjected to activation of coagulation. Specific activators differ from that of the TEG 5000 with resulting quantitative measures termed (1) coagulation time (CT; seconds), (2) α angle (clot formation time; seconds), (3) maximal clot firmness (MCF; millimeter), and (4) lysis time (LT; second).

The Sonoclot Analyzer (Sienco, Arvada, Colo.) provides an alternative viscoelastic measure of coagulation. In contrast to thromboelastography and ROTEM, the Sonoclot Analyzer immerses a rapidly vibrating probe into a 0.4-mL sample of blood. As clot formation proceeds, impedance to probe movement through the blood increases to generate an electrical signal and characteristic clot signature. The analyzer signature may be used to derive the ACT and to provide information regarding clot strength and presence of fibrinolysis.

Viscoelastic monitors generate characteristic diagrams by translating mechanical resistance to sensor movement within a sample of whole blood to an electronic waveform subject to quantitative analysis. One of the more common applications for viscoelastic monitoring has been real-time detection of excess fibrinolysis during liver transplantation or cardiac surgery. Evidence suggests that viscoelastic monitoring may prove beneficial in

differentiating surgically related bleeding from that due to a coagulopathy. When used as one component of a diagnostic algorithm, both thromboelastography and ROTEM have been demonstrated to reduce blood administration. More widespread application of viscoelastic monitoring has been hindered by lack of specificity associated with abnormal findings and qualitative assay interpretation.[86] Digital automation of these instruments has simplified interpretation and improved reproducibility.

PLATELET FUNCTION MONITORS

Assessment of platelet function has proved challenging for several reasons. Historically, tests of platelet function have proved costly, time consuming, and technically demanding. Platelet dysfunction may occur as a result of diverse inherited or acquired disorders affecting surface receptors involved in adhesion or aggregation, storage granules, internal activation pathways, phospholipid membranes, or other mechanisms.[51] Lack of standardized quality controls necessitates use of local donor blood to establish normal control ranges. Furthermore, even established tests such as platelet aggregation lack performance standardization, resulting in widely varying results across laboratories. Complicating assessment further is the fact that platelets are highly susceptible to activation or desensitization during sample collection, transport, storage, and processing.

Although viscoelastic measures of coagulation (i.e., TEG 5000 or ROTEM) may detect platelet dysfunction, sensitivity and specificity prove limited. Incorporation of a platelet mapping assay into thromboelastography provides a method for viscoelastic measurement of drug-induced platelet inhibition with reasonable correlation to optical aggregometry.[85] The standard laboratory-based method for identifying qualitative platelet dysfunction remains optical aggregometry performed using specific platelet agonists and samples of platelet-rich plasma. Flow cytometry employing fluorescent-labeled antibodies provides another sensitive method for quantitating platelet activation, responsiveness, and surface receptor availability.[87] Despite representing standards of care, these measures remain technically challenging, costly, and time-consuming laboratory-based assays.

Fortunately, an increasing array of platelet function assays specifically designed as point-of-care instruments are available.[88,89] As a measure of primary hemostasis, the PFA-100 (Platelet Function Analyzer, Siemens, Tarrytown, NY) increasingly has replaced the bleeding time in assessment of primary hemostasis. Unique among both laboratory-based and point-of-care platelet function monitors, the PFA-100 incorporates high-shear conditions to simulate small vessel injury in the presence of either ADP or epinephrine, both potent platelet activators.[90] Time to clot–mediated aperture occlusion is reported as closure time. The PFA-100 has proved effective in detecting von Willebrand disease and aspirin-mediated platelet dysfunction. This instrument, as a component of a standardized screening protocol, reduces time to identify and classify platelet dysfunction. Limitations of the PFA-100 include interference by thrombocytopenia and hemodilution.

The HemoSTATUS (Medtronic) platelet function test exploits the ability of platelet activating factor (PAF) to accelerate clot formation of the kaolin-activated ACT. HemoSTATUS testing is performed on the Medtronic HMS Plus coagulation analyzer employing a six-channel kaolin ACT cartridge preloaded with serially increasing concentrations of PAF. A clot ratio is determined for each individual patient assay based on the ratio of the PAF-accelerated ACT to the standard ACT. An individual patient's clot ratio is compared with a maximal clot ratio derived from normal volunteers to provide a relative measure of platelet function. In the presence of platelet dysfunction, higher concentrations of PAF are required to achieve a comparable PAF-activated ACT. In cardiac surgery, investigators demonstrated a relationship between platelet dysfunction and postoperative bleeding.[83] Furthermore, the maximal clot ratio as determined by HemoSTATUS improved after desmopressin or platelet administration. Other investigators, however, failed to identify a relationship between platelet dysfunction as measured by HemoSTATUS and postoperative bleeding.

The VerifyNow System (formerly known as the Ultegra Rapid Platelet Function Analyzer, Accumetrics, San Diego, Calif.) is an automated turbidimetric whole blood platelet function assay that assesses ability of activated platelets to bind fibrinogen-coated polystyrene beads. On addition of the whole blood test sample, thrombin receptor activating peptide directly activates platelets within the sample to stimulate glycoprotein IIb/IIIa platelet surface receptor expression. As activated platelets bind and aggregate fibrinogen-coated beads, light transmission through the sample increases to generate a signal. Although the VerifyNow System is simple to operate and provides a rapid bedside measure of platelet function, a baseline reference measurement is suggested for each patient to calculate the extent of subsequent changes in platelet function.[88] Potential applications for this methodology in the perioperative setting remain unclear.

Plateletworks (Helena Laboratories, Beaumont, Tex.) employs a hemocytometer to perform automated platelet counts on whole blood samples collected in the presence and absence of platelet-stimulating agonists such as collagen or ADP. The difference in platelet counts before and after agonist addition provides a direct measure of platelet aggregation (i.e., platelet responsiveness) and is reported as "% aggregation." Preliminary investigations demonstrated reasonable correlations between platelet counts attained with the Plateletworks monitor and laboratory-based instruments.[88] In addition, the Plateletworks assay proved effective in identifying platelet dysfunction in the setting of glycoprotein IIb/IIIa antagonists and appeared to correlate relatively well with laboratory-based measures of platelet aggregation.

Employing a sample of whole blood, the Hemostasis Analysis System (Hemodyne, Bethesda, Md.) measures platelet contractile force, the force produced by platelets during clot retraction, and clot elastic modulus, a measure of clot rigidity. In preliminary investigations, platelet contractile force was reduced after cardiopulmonary bypass and modestly correlated with perioperative blood loss.

Advances in our understanding of hemostasis and thrombosis at the molecular level have contributed directly to recent biotechnologic innovations in

point-of-care testing. Further advances in point-of-care coagulation monitoring offer the opportunity for clinicians to make informed decisions about transfusion therapy and hemostatic drug administration to minimize perioperative bleeding. In considering any point-of-care coagulation testing, it must be recognized that results will not necessarily mirror those reported from laboratory-based testing. Reagent sensitivities vary across manufacturers and even one lot of reagent to another. In addition, point-of-care testing typically relies on whole blood samples for testing as opposed to laboratory-based testing using plasma or processed platelets. A final consideration for which point-of-care platelet function testing provides a particularly relevant example is that monitors from different manufacturers measure differing aspects of platelet-mediated or plasma-mediated hemostasis. In the case of platelet function monitors, a dozen instruments purport to measure platelet function. However, using different instruments results may vary from "severe" platelet dysfunction to "no platelet dysfunction" in a single sample of blood. Before adopting any point-of-care monitoring, an understanding of the quality assurance requirements, test methodology, and concomitant strengths and weaknesses will prove essential to inform patient care.

Chapter 63

Patient Blood Management: Autologous Blood Procurement, Recombinant Factor VIIa Therapy, and Blood Utilization

LAWRENCE T. GOODNOUGH • TERRI G. MONK

Key Points

- The two primary reasons for employing autologous transfusion are avoidance of complications associated with allogeneic transfusion and conservation of blood resources.
- The three types of autologous blood transfusion are preoperative autologous donation (PAD), acute normovolemic hemodilution (ANH), and intraoperative and postoperative blood recovery (salvage).
- PAD became accepted as a standard practice in certain elective surgical settings such as total joint replacement surgery, so that by 1992 more than 6% of the blood transfused in the United States was autologous. Subsequently, substantial improvements in blood safety were accompanied by a decline in PAD as well as an interest in ANH as an alternative, lower-cost strategy. The criteria for autologous donors are different from those for allogeneic donors. Transfusion service policies, implemented under the auspices of hospital transfusion committees, differ regarding collection and use of autologous blood with positive viral markers. It is common practice to exclude autologous blood reactive for hepatitis B surface antigen and hepatitis C and human immunodeficiency viruses because of patients' safety concerns related to wrong blood unit transfused to wrong patient (mistransfusion). Contraindications to autologous blood donation include evidence of infection and risk of bacteremia, scheduled surgery for correction of aortic stenosis, and unstable angina.
- The costs associated with PAD are higher than those associated with the collection of allogeneic blood.
- ANH is the removal of whole blood from a patient while restoring the circulating blood volume with an acellular fluid shortly before an anticipated significant surgical blood loss. The chief benefit of ANH is the reduction of red blood cell losses when whole blood is shed perioperatively at the lower hematocrit levels associated with ANH.
- The term *intraoperative blood collection* or *recovery* describes the technique of collecting and reinfusing blood lost by a patient during surgery. The oxygen transport properties of recovered red blood cells are equivalent to those of stored allogeneic red blood cells. The survival of recovered blood cells appears to be at least comparable to that of transfused allogeneic red blood cells.
- Postoperative blood collection denotes the recovery of blood from surgical drains followed by reinfusion, with or without processing. Postoperative autologous blood salvage and reinfusion are practiced widely but not uniformly.
- Recombinant factor VIIa (rfVIIa) has been approved for treatment of bleeding in patients with hemophilia and inhibitors to factors VIII or IX. Pharmacologic doses of rfVIIa enhance the thrombin generation on activated platelets and therefore may also be of benefit in providing hemostasis in other situations such as those characterized by consumptive coagulopathies or platelet conditions with impaired thrombin generation.
- Level I evidence and guidelines support restrictive transfusion practices. However, no one hemoglobin level should be used as a transfusion trigger, and transfusion decisions should be made for individual patients (see also Chapter 61).
- Bloodless medicine and surgery use a multidisciplinary team approach that incorporates anemia management, controlled hemostasis, autologous blood procurement, and pharmacologic alternatives to blood transfusion.

Blood management has been defined as "the appropriate use of blood and blood components, with a goal of minimizing their use."[1] This goal has been motivated historically by (1) known blood risks, (2) unknown blood risks, (3) preservation of the national blood inventory, and (4) constraints from escalating costs. Known risks of blood include transmissible infectious disease, transfusion reactions, and potential effects of immunomodulation (e.g., postoperative infection or tumor progression). Unknown risks include emerging pathogens transmissible by blood (e.g., new variant Creutzfeldt-Jakob disease and West Nile virus).[2,3] Several studies have linked allogeneic blood transfusions with unfavorable outcomes, including increased risk of mortality and various morbidities.[4] Blood management has been 1 of the 10 key advances in transfusion medicine since the 1960s.[5]

Patient blood management encompasses an evidence-based medical and surgical approach that is multidisciplinary (transfusion medicine specialists, surgeons, anesthesiologists, and critical care specialists) and multiprofessional (physicians, nurses, pump technologists, and pharmacists).[6] Preventive strategies are emphasized: to identify, evaluate, and manage anemia[7-9] (e.g., pharmacologic therapy[10] and reduced iatrogenic blood losses from diagnostic testing)[11]; to optimize hemostasis (e.g., pharmacologic therapy[12] and point-of-care testing[13]); and to establish decision thresholds (e.g., guidelines) for the appropriate administration of blood therapy.[14,15]

In the United States, The Joint Commission developed patient blood management performance measures and submitted these to the National Quality Forum for endorsement. The National Quality Forum did not endorse these submitted performance measures because of a lack of data on the outcomes proposed; as a result, these measures currently do not carry consequences if not met. Because these performance measures were process based rather than outcomes based, data on proposed outcomes are difficult to retrieve. The Joint Commission has placed these performance measures in their Topic Library, where they are to be used as additional patient safety activities and/or quality improvement projects by provider institutions as accreditation goals.[15] The principles of these performance indicators are summarized in Box 63-1.

BOX 63-1 *Patient Blood Management*

TJC Performance Measures	Principles
1. Preoperative Anemia Screening	A. Formulate a plan of proactive management for avoiding and controlling blood loss tailored to the clinical management of individual patients, including anticipated procedures.
2. Preoperative Blood Type and Antibody Screen (Blood Compatibility Testing)	B. Employ a multidisciplinary treatment approach to blood management using a combination of interventions (e.g., pharmacologic, therapy, point-of-care testing).
3. Transfusion Consent	C. Promptly investigate and treat anemia.
4. Blood Administration	D. Exercising clinical judgment, be prepared to modify routine practices (e.g., transfusion triggers) when appropriate.
5. RBC Transfusion Indication	E. Restrict blood drawing for unnecessary laboratory tests.
6. Plasma Transfusion Indication	F. Decrease or avoid the perioperative use of anticoagulants and antiplatelet agents.
7. Platelet Transfusion Indication	

RBC, Red blood cell; *TJC,* The Joint Commission.

AUTOLOGOUS BLOOD PROCUREMENT

The three types of autologous blood transfusion are preoperative autologous donation (PAD), acute normovolemic hemodilution (ANH), and intraoperative and postoperative blood recovery (blood salvage). The advantages, disadvantages, applications, and complications vary with the techniques used.

The two primary reasons for employing autologous transfusion are avoidance of complications associated with allogeneic transfusion and conservation of the national blood inventory. Patients with rare blood phenotypes or alloantibodies can also benefit from autologous transfusion because compatible allogeneic blood may not always be available.[16] Potential complications of allogeneic transfusion that can be eliminated or minimized when autologous blood is administered include acute and delayed hemolytic reactions, alloimmunization, allergic and febrile reactions, and transfusion-transmitted infectious diseases. Intraoperative blood recovery may be the only option for providing a sufficient volume of compatible blood when severe, rapid blood loss occurs. ANH provides the only practical source of fresh whole blood.

The role of autologous blood procurement in surgery is evolving, based on improved blood safety, increased blood costs, and emerging pharmacologic alternatives to blood transfusion.[17-19] PAD became accepted as a standard practice in certain elective surgical settings such as total joint replacement surgery; by 1992 more than 6% of the blood transfused in the United States was autologous.[20] Subsequently, substantial improvements in blood safety were accompanied by a decline in PAD, as well as an interest in ANH as an alternative strategy.[21] Nevertheless, public perception of blood safety and the reluctance to accept allogeneic blood transfusion in the elective transfusion setting,[22] along with possible future blood inventory shortages and the potential for new, emerging blood pathogens, continue to give autologous blood procurement strategies an important role in the surgical arena.

PREOPERATIVE BLOOD DONATION

Patient Selection

The criteria for autologous donors are not as stringent as are those for allogeneic donors. The AABB (formerly,

the American Association of Blood Banks) standards for blood banks and transfusion services require that the donor patient's hemoglobin be no less than 11 g/dL or the hematocrit be no less than 33% before each donation.[23] No age or weight limits exist, and patients may donate 10.5 mL/kg, in addition to testing samples. Donations may be scheduled more than once a week, but the last donation should occur no less than 72 hours before surgery, to allow time for restoration of intravascular volume and for transport and testing of the donated blood.

Transfusion service policies, implemented under the auspices of hospital transfusion committees, differ regarding collection and use of autologous blood with positive viral markers. Some hospitals exclude use of autologous blood reactive for hepatitis B surface antigen, hepatitis C virus, or human immunodeficiency virus (HIV) because of concerns for patients' safety related to a wrong blood unit transfused to the wrong patient (mistransfusion). Other hospitals accept and transfuse autologous blood with any positive viral markers because denying patients infected with HIV the opportunity to receive their own blood may have implications related to the Americans with Disabilities Act.[24]

Candidates for preoperative blood collection are patients scheduled for elective surgical procedures in which blood transfusion is likely. The most common surgical procedures for which autologous blood is predonated are total joint replacements.[25] For procedures that are unlikely to require transfusion (i.e., a maximal surgical blood ordering schedule [MSBOS] suggests that crossmatched blood should not be ordered),[26] the use of preoperative blood collection is not recommended. Autologous blood should not be collected for procedures that seldom (<10% of cases) require transfusion, such as cholecystectomy, herniorrhaphy, vaginal hysterectomy, and uncomplicated obstetric delivery.[27]

In special circumstances, preoperative autologous blood collection can be performed for patients who would not ordinarily be considered for autologous donation. Availability of medical support is important in assessing a patient's suitability. With appropriate volume modification, parental cooperation, and attention to preparation and reassurance, pediatric patients can participate in preoperative blood collection programs.[28] Patients with significant cardiac disease are considered poor risks for autologous blood donation. Despite reports of safety in small numbers of such patients who underwent autologous blood donation,[29] the risks associated with autologous blood donation[30] in these patients are greater than current estimated risks of allogeneic transfusion.[2,3] Box 63-2 summarizes the medical contraindications to a patient's participation in an autologous blood donation program.[31] The collection of autologous blood from women during routine pregnancy is unwarranted,[32] because blood is so seldom needed. PAD can be considered for women with alloantibodies to multiple or high-incidence antigens or with placenta previa or other conditions placing them at high risk for antepartum or intrapartum hemorrhage.[27] AABB standards no longer permit allogeneic transfusion of unused autologous units ("crossover") because autologous donors are not, in the strictest sense, volunteer donors.[23]

BOX 63-2 ***Contraindications to Participation in Autologous Blood Donation Programs***

1. Evidence of infection and risk of bacteremia
2. Scheduled surgery to correct aortic stenosis
3. Unstable angina
4. Active seizure disorder
5. Myocardial infarction or cerebrovascular accident within 6 months of donation
6. Significant cardiac or pulmonary disease in patients who have not yet been cleared for surgery by their treating physician
7. High-grade left main coronary artery disease
8. Cyanotic heart disease
9. Uncontrolled hypertension

Attempts to stratify patients into groups at high and low risk for needing transfusion based on the baseline level of hemoglobin and on the type of procedure show some promise. In a Canadian study using a point score system, 80% of patients undergoing orthopedic procedures were identified to be at low risk (<10%) for transfusion, and therefore autologous blood procurement for these patients would not be recommended.[33] However, one problem with algorithms that consider the estimated blood loss and preoperative hematocrit is that blood losses are difficult to measure[34] or predict because specific surgical procedures performed even by the same surgeon can be accompanied by a wide range of blood loss. Although autologous blood donation programs are popular with patients, the costs associated with autologous blood collection are higher than are those associated with allogeneic blood. The reduced risk of allogeneic blood transfusions has made PAD poorly cost effective.[35,36]

The Role of Aggressive Phlebotomy and the Use of Erythropoiesis-Stimulating Agents

The efficacy of PAD depends on the degree to which the patient's compensatory erythropoiesis increases the production of red blood cells (RBCs).[37] The endogenous erythropoietin response and compensatory erythropoiesis are suboptimal under "standard" conditions of 1 unit of blood donated weekly.[38] As shown in Table 63-1, weekly PAD is accompanied by an expansion in RBC volume of 11% (with no oral iron supplementation) to 19% (with oral iron supplementation), which is not sufficient to prevent increasing anemia in patients undergoing PAD. If the erythropoietic response to autologous blood phlebotomy does not maintain the patient's hematocrit level during the donation interval, the donation of autologous blood actually may be harmful by causing perioperative anemia and an increased likelihood of any blood transfusion.[37,38] A mathematic model has been published to demonstrate the relationships among anticipated surgical blood losses, the desired hematocrit, and the need for autologous blood donation.[39]

In contrast to autologous blood donation under "standard" conditions, studies of "aggressive" autologous blood phlebotomy (twice weekly for 3 weeks, beginning 25 to 35 days before surgery) have demonstrated that endogenous erythropoietin levels do increase,

TABLE 63-2 ADVANTAGES AND DISADVANTAGES OF AUTOLOGOUS BLOOD DONATION

Advantages	Disadvantages
Prevents transfusion-transmitted disease	Does not affect risk of bacterial contamination
Prevents red cell alloimmunization	Does not affect risk of ABO incompatibility error
Supplements the blood supply	Is more costly than allogeneic blood
Provides compatible blood for patients	Results in wastage of blood not transfused with alloantibodies
Prevents some adverse transfusion reactions	Has an increased incidence of adverse reactions to autologous donation
Provides reassurance to patients concerned about blood risks	Subjects patient to perioperative anemia and increased likelihood of transfusion

along with enhanced erythropoiesis representing RBC volume expansion of 19% to 26% (see Table 63-1). The use of erythropoiesis-stimulating agents to stimulate erythropoiesis further (≤50% RBC volume expansion)[40-42] during autologous donation has been approved in the European Union, Canada, and Japan, but not in the United States.[43] Perisurgical erythropoietin therapy is also approved in the United States and Canada for anemic (hematocrit < 39%) patients who are scheduled for noncardiac, nonvascular surgical procedures.

Transfusion Trigger

Advantages and disadvantages of autologous blood transfusion are summarized in Table 63-2. Disagreement exists about the proper hemoglobin and hematocrit levels ("transfusion trigger") at which autologous blood should be given (see Chapter 61).[44] In general, autologous and allogeneic blood transfusion triggers should be similar because the risks from administrative errors associated with both autologous and allogeneic blood are higher than are risks related to the transfusion of allogeneic blood.[45]

ACUTE NORMOVOLEMIC HEMODILUTION

ANH is the removal of whole blood from a patient while restoring the circulating blood volume with an acellular fluid shortly before an anticipated significant surgical blood loss. To minimize the manual labor associated with hemodilution, the blood should be collected in standard blood bags containing anticoagulant on a tilt-rocker with automatic cutoff through volume sensors. The blood is then stored at room temperature and reinfused during surgery after major blood loss has ceased, or sooner if indicated. Simultaneous infusions of crystalloid (3 mL crystalloid for each 1 mL of blood withdrawn) and colloid (dextrans, starches, gelatin, albumin [1 mL for each 1 mL of blood withdrawn]) have been recommended.[46] Blood units are reinfused in the reverse order of collection because the first unit collected and therefore the last to be infused will have the highest hematocrit and concentration of coagulation factors and platelets.

Reduction of Red Blood Cell Losses

The chief benefit of ANH is the reduction of RBC losses when whole blood is shed perioperatively at lower hematocrit levels associated with ANH.[47] Mathematic modeling suggests that severe ANH to preoperative hematocrit levels of less than 20%, accompanied by substantial blood losses, would be required before the RBC volume "saved" by ANH would become clinically important.[48] A clinical analysis of patients who had undergone "minimal" ANH (representing ≤15% of patients' blood volume) estimated that only 100 mL of RBCs (the equivalent of 0.5 unit of blood)[49] was "saved" under these conditions.[50] With moderate hemodilution (target hematocrit levels of 28%), the "savings" become more substantial. The removal of 3 blood units in a patient who subsequently underwent a blood loss of 2600 mL resulted in surgical RBC losses

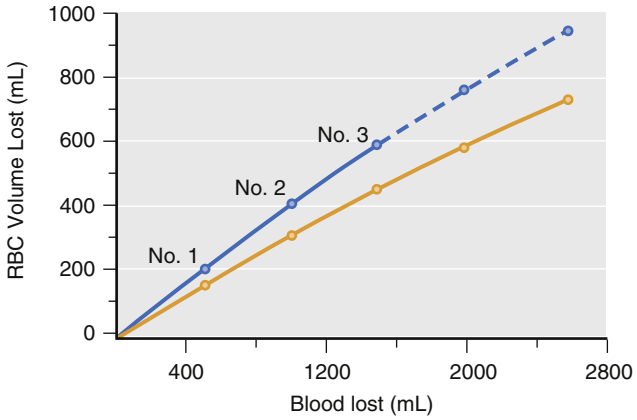

Figure 63-1. The relationship between whole blood volume (mL) lost (*abscissa*) and red blood cell (RBC) volume lost (*ordinate*) in a 100-kg patient undergoing hemodilution: RBC volume lost with 2800 mL whole blood lost intraoperatively after hemodilution of 1500 mL whole blood (*solid blue line*); RBC volume lost with 2800 mL whole blood lost during hemodilution at each of three 500 mL volumes (*solid orange line*); cumulative RBC volume lost intraoperatively, derived for 2800 mL whole blood lost if hemodilution had not been performed (*blue dashed line*). A net of 215 mL reduction in RBC volume lost with hemodilution is illustrated by the divergence of the two curves. *(From Goodnough LT, Grishaber JE, Monk TG, et al: Acute normovolemic hemodilution in patients undergoing radical suprapubic prostatectomy: a case study analysis,* Anesth Analg *78:932-937, 1994, with permission.)*

"saved" by hemodilution of 215 mL, or the equivalent of 1 unit of allogeneic blood (Fig. 63-1).[50] This RBC volume approaches the RBC volume expansion generated by autologous blood predonation under standard phlebotomy conditions.

The benefit of ANH has been determined in a mathematic model[46]. An adult with an estimated 5-L blood volume and an initial hematocrit of 40%, with surgical blood losses of up to 3000 mL, would have a hematocrit level that would remain 25% postoperatively without an autologous blood intervention. This level is generally considered safe for patients without known risk factors. In this model, the performance of ANH with initial hematocrit levels of 40% to 45% would allow up to 2500 to 3500 mL of surgical blood loss, yet the nadir level of hematocrit could be maintained at 28%.

Improved Oxygenation

Withdrawal of whole blood and replacement with crystalloid or colloid solution decrease arterial oxygen content, but compensatory hemodynamic mechanisms and the existence of surplus oxygen delivery capacity make ANH safe. A sudden decrease in RBC concentration reduces blood viscosity, thereby decreasing peripheral resistance and increasing cardiac output. If cardiac output can effectively compensate, oxygen delivery to the tissues at a hematocrit of 25% to 30% is as good as, but no better than, oxygen delivery at a hematocrit of 30% to 35%.[51]

Preservation of Hemostasis

Because blood collected by ANH is stored at room temperature and is usually returned to the patient within 8 hours of collection, deterioration of platelets or coagulation factors is minimal. The hemostatic value of blood collected by ANH is questionable for orthopedic or urologic surgery because plasma and platelets are rarely indicated in this setting. Its value in protecting plasma and platelets from the acquired coagulopathy of extracorporeal circulation in cardiac surgery (known as "blood pooling") is better established.[52]

Clinical Studies

Prospective randomized studies in patients undergoing radical prostatectomy,[53] knee replacement,[54] and hip replacement[55] suggested that ANH can be considered equivalent to PAD as a method of autologous blood procurement. Selected clinical trials of ANH are summarized in Table 63-3.[56-72] Commentaries on the relative merits of ANH have been published.[73-75] When ANH and reinfusion are accomplished in the operating room by on-site personnel, the procurement and administration costs are minimized. Blood obtained during ANH does not require the commitment of the patient's time, transportation, costs, and loss of work time that can be associated with PAD. The wastage of PAD units (approximately 50% of units collected)[27] also is eliminated with ANH. Additionally, autologous blood units procured by ANH require no inventory or testing costs. Because the blood never leaves the patient's room, ANH minimizes the possibility of an administrative or clerical error that could lead to an ABO-incompatible blood transfusion and death, as well as bacterial contamination associated with prolonged storage at 4° C.

An ANH program has some important practical considerations. Decisions about ANH should be based on the surgical procedure and on the patient's preoperative blood volume and hematocrit, target hemodilution hematocrit, and other physiologic variables. The institution's policy and procedures and the mechanisms for educating staff should be established and periodically reviewed.

The patient's circulating volume and perfusion status should be carefully monitored during the procedure. Blood must be collected in an aseptic manner, ordinarily into standard blood collection bags with citrate anticoagulant. Units must be properly labeled and stored. The label must contain, at a minimum, the patient's full name, medical record number, date and time of collection, and the statement "For Autologous Use Only." Room temperature storage should not exceed 8 hours. If more time elapses between collection and transfusion, the blood should be stored in a monitored refrigerator. Suggested criteria for patient selection are listed in Box 63-3.

Cost-Effective Analysis of Acute Normovolemic Hemodilution Versus Preoperative Autologous Donation

Most clinical trials compared ANH to PAD as the "standard of care." Medicolegal concerns may also prevent the inclusion of a treatment arm consisting of only allogeneic blood transfusion because blood safety acts in several states mandate that physicians offer autologous blood options before elective surgical procedures.[18] These studies found ANH to be similar to PAD in eliminating

BOX 63-3 ***Criteria for Selection of Patients for Acute Normovolemic Hemodilution***

1. Likelihood of transfusion exceeding 10% (i.e., blood requested for crossmatch according to a maximum surgical blood order schedule)
2. Preoperative hemoglobin level of at least 12 g/dL
3. Absence of clinically significant coronary, pulmonary, renal, or liver disease
4. Absence of severe hypertension
5. Absence of infection and risk of bacteremia

the need for allogeneic blood transfusions during elective surgery.[76] Other outcomes including anesthesia and surgery times, intraoperative hemodynamic values, and length of hospital stays were also equivalent in PAD and ANH. Even though only a few studies included economic evaluations comparing the cost of autologous blood techniques, all these studies demonstrated that ANH is much less costly than PAD.[76] Therefore, ANH can be considered a cost-minimizing technique for autologous blood procurement for elective surgery.

INTRAOPERATIVE CELL SALVAGE

The term *intraoperative blood collection* or *recovery* or *cell salvage* describes the technique of collecting and reinfusing blood lost by a patient during surgery. The oxygen transport properties of recovered RBCs are equivalent to those of stored allogeneic RBCs. The survival of recovered RBCs appears to be at least comparable to that of transfused allogeneic RBCs.[77] Intraoperative collection is contraindicated when certain procoagulant materials (e.g., topical collagen) are applied to the surgical field because systemic activation of coagulation may result. Microaggregate filters (40 μm) are most often used because recovered blood may contain tissue debris, small blood clots, or bone fragments.

Cell washing devices can provide the equivalent of 12 units/hour of banked blood to a massively bleeding patient.[77] Data on adverse events of reinfusion of recovered blood have been published.[78] Air embolus is a potentially serious problem. Three fatalities from air embolus were reported over a 5-year interval to the New York State Department of Public Health, for an overall fatality risk of 1 in 30,000.[35] Hemolysis of recovered blood can occur during suctioning from the surface instead of from deep pools of shed blood. For this reason, manufacturers' guidelines recommend a maximum vacuum setting of no more than 150 mm Hg; one study found that vacuum settings as high as 300 mm Hg could be used, when necessary, without causing excessive hemolysis.[79] Patients exhibit a level of plasma free hemoglobin that is usually higher than after allogeneic transfusion. The clinical importance of free hemoglobin in the concentrations usually seen has not been established, although excessive free hemoglobin may indicate inadequate washing. Positive bacterial cultures from recovered blood are sometimes observed; however, clinical infection is rare.[80] Most programs use machines that collect shed blood, wash it, and concentrate the RBCs. This process typically results in 225-mL units of saline-suspended RBCs with a hematocrit of 50% to 60%.

Clinical Studies

As with PAD and ANH, collection and recovery of intraoperative autologous blood should undergo scrutiny with regard to both safety and efficacy.[81] A controlled study in cardiothoracic surgery demonstrated a lack of efficacy when transfusion requirements and clinical outcomes were followed.[80] A second study found that only a minority of patients undergoing major orthopedic and cardiac surgery achieved cost equivalence with intraoperative blood recovery using semiautomated instruments compared with banked blood.[82] Although the collection of a minimum of one blood unit equivalent is possible for less expensive (with unwashed blood) methods, at least two blood unit equivalents must be recovered using a cell recovery instrument (with washed blood) to achieve cost effectiveness.[83] The value of intraoperative blood collection is apparent for vascular surgical procedures with large blood losses, such as aortic aneurysm repair and liver transplantation.[84] However, a prospective, randomized trial of intraoperative recovery and reinfusion in patients undergoing aortic aneurysm repair showed no benefit in a reduction of allogeneic blood exposure.[83] The value of this technology may be in cost savings and blood inventory considerations in patients with substantial blood losses.[85]

Collection devices that neither concentrate nor wash shed blood before reinfusion increase the risk of adverse effects. Shed blood has undergone varying degrees of coagulation or fibrinolysis and hemolysis, and infusion of large volumes of washed or unwashed blood has been described in association with disseminated intravascular coagulation (DIC).[84] In general, blood collected at low flow rates or during slow bleeding from patients who are not systemically anticoagulated will have undergone coagulation and fibrinolysis and will not contribute to hemostasis on reinfusion. The high suction pressure and surface skimming during aspiration and the turbulence or mechanical compression that occurs in roller pumps and plastic tubing make some degree of hemolysis inevitable. High concentrations of free hemoglobin may be nephrotoxic to patients with impaired renal function. Many programs limit the quantity of recovered blood that may be reinfused without processing. To minimize hemolysis, the vacuum level should ordinarily not exceed 150 mm Hg, although higher levels of suction may occasionally be needed during periods of rapid bleeding.

An alternative approach is to collect blood in a canister system designed for direct reinfusion and then to concentrate and wash the recovered RBCs in a blood bank cell washer. Intraoperatively collected and recovered blood must be handled in the transfusion service laboratory similarly to any other autologous unit. The unit should be reinfused through a filter.

Some practical considerations for cell recovery programs are listed in Box 63-4. If collected under aseptic conditions with a saline-wash device and if properly labeled, blood may be stored at room temperature for up to 4 hours or at 1° C to 6° C for up to 24 hours, provided storage at 1° C to 6° C is begun within 4 hours of ending the collection.[23] The allowable interval of room temperature storage is shorter for recovered blood (4 hours) than for ANH blood (8 hours). Storage times are the same for recovered blood whether unwashed or washed.

BOX 63-4 ***Practical Considerations for Intraoperative Cell Recovery, Storage, and Reinfusion***

1. If not transfused immediately, units collected from a sterile operating field and processed with a device for intraoperative blood collection that washes with 0.9% saline, USP, shall be stored under one of the following conditions before initiation of transfusion:
   a. At room temperature for up to 4 hours after terminating collection
   b. At 1° C to 6° C for up to 24 hours, provided storage at 1° C to 6° C is begun within 4 hours of ending the collection
2. Transfusion of blood collected intraoperatively by other means shall begin within 6 hours of initiating the collection.
3. Each unit collected intraoperatively shall be labeled with the patient's first name, last name, and hospital identification number; the date and time of initiation of collection and of expiration; and the statement "For Autologous Use Only."
4. If stored in the blood bank, the unit shall be handled like any other autologous unit.
5. The transfusion of shed blood collected under postoperative or posttraumatic conditions shall begin within 6 hours of initiating the collection.

POSTOPERATIVE CELL SALVAGE

Postoperative blood collection denotes the recovery of blood from surgical drains followed by reinfusion, with or without processing.[62] In some programs, postoperative shed blood is collected into sterile canisters and reinfused, without processing, through a microaggregate filter. Recovered blood is dilute, is partially hemolyzed and defibrinated, and may contain high concentrations of cytokines. For these reasons, most programs set an upper limit on the volume (e.g., 1400 mL) of unprocessed blood that can be reinfused. If transfusion of blood has not begun within 6 hours of initiating the collection, the blood must be discarded.

Clinical Studies

The evolution of cardiac surgery has been accompanied by broad experience in postoperative conservation of blood. Postoperative autologous blood transfusion is practiced widely but not uniformly. Prospective and controlled trials have disagreed over the efficacy of postoperative blood recovery in cardiac surgical patients; at least three such studies demonstrated lack of efficacy,[58,60] whereas at least two studies showed benefit.[57] The disparity of results in these studies may be explained, in part, by differences in transfusion practices. Modification of physicians' transfusion practices may have been an uncredited intervention in these blood conservation studies.

In the postoperative orthopedic surgical setting, several reports have similarly described the successful recovery and reinfusion of washed[56] and unwashed[59] wound drainage blood from patients undergoing arthroplasty. The volume of reinfused drainage blood

has been reported to be as great as 3000 mL and averages more than 1100 mL in patients undergoing cementless knee replacement.[59] Because the RBC content of the fluid collected is low (hematocrit levels of 20%) the volume of RBCs reinfused is often small.[61] A prospective, randomized study of postoperative salvage and reinfusion in patients undergoing total knee or hip replacement found no differences in perioperative hemoglobin levels or allogeneic blood transfusions between patients who had joint drainage devices and those who did not.[86]

The safety of reinfused unwashed orthopedic wound drainage has been controversial. Theoretic concerns have been expressed regarding infusion of potentially harmful materials in recovered blood, including free hemoglobin, RBC stroma, marrow fat, toxic irritants, tissue or methacrylate debris, fibrin degradation products, activated coagulation factors, and complement. Although two small studies reported complications,[87,88] several larger studies reported no serious adverse effects when the drainage was passed through a standard 40-μm blood filter.[56,59,89]

The potential for decreasing exposure to allogeneic blood among orthopedic patients undergoing postoperative blood collection, whether the blood is washed or unwashed, is greatest for cementless bilateral total knee replacement, revision hip or knee replacement, and long-segment spinal fusion. As in the case of intraoperative recovery, blood loss must be sufficient to warrant the additional cost of processing technology.[90] One study demonstrated comparable costs between postoperative cell salvage and allogeneic transfusion for patients undergoing total knee arthroplasty, but the investigators found that cell salvage represented a significant savings in patients undergoing total hip arthroplasty.[91] As in the selection of patients who can benefit from PAD and ANH, the prospective identification of patients who can benefit from intraoperative and postoperative autologous blood recovery is possible if patients' preoperative hemoglobin level, anticipated surgical blood loss, and perioperative "transfusion trigger" are taken into account.

RECOMBINANT FACTOR VIIa

Recombinant factor VIIa (rfVIIa) has been approved for treatment of bleeding in patients with hemophilia who have inhibitors, patients with congenital factor VII deficiency, and patients with inherited qualitative platelet defects. Pharmacologic doses of rfVIIa enhance the thrombin generation on platelets and therefore may also likely be of benefit in providing hemostasis in clinical settings characterized by profuse bleeding and impaired thrombin generation,[92] such as in patients with thrombocytopenia and in those with functional platelet defects.[93,94] Additionally, it has been used successfully in a variety of less well-characterized surgical bleeding situations in patients with dilutional or consumptive coagulopathies and in patients with impaired liver function.[95-97] Policies for the approval of rfVIIa therapy in nonapproved settings should therefore undergo periodic review and revision as relevant new information and data are generated.[98] Because of the trends in rfVIIa usage in nonapproved settings, significant concerns about the safety, efficacy, and costs of rfVIIa have arisen. Additionally, dosing of rfVIIa for these potentially broad clinical applications is not standardized.

COMPLEX SURGERY AND TRAUMA RESULTING IN PROFUSE BLEEDING

A hemostatic effect has been demonstrated after the administration of rfVIIa in a limited number of patients after trauma and bleeding (see also Chapters 61 and 62).[95,96] Seven trauma patients treated with rfVIIa after failure of conventional measures to achieve hemostasis reported cessation of diffuse bleeding and correction of abnormal coagulation assays; three of the seven patients died of reasons other than bleeding or thromboembolism.[96]

Anecdotal case reports have been published that describe the successful use of rfVIIa in patients with substantial perisurgical bleeding. The experience of rfVIIa use in trauma with excessive bleeding, as well as in profuse postoperative bleeding, based largely on case reports, has indicated a hemostatic effect of rfVIIa given in doses ranging from 20 to 120 μg/kg. The issue of preemptive, preoperative rfVIIa (40 to 90 μg/kg) was studied in nine patients with coagulopathy and urgent neurosurgical intervention.[99] Post-rfVIIa coagulation parameters normalized as early as 20 minutes after infusion, with no noted procedural or operative complications. No associated thromboembolic complications were observed. Subsequently, a prospective, randomized study of rfVIIa (20 or 40 μg/kg) versus placebo perioperatively in 36 patients undergoing radical retropubic prostatectomy found that the cohorts receiving rfVIIa had substantially less median operative blood loss compared with placebo (1235 mL, 1089 mL, and 2688 mL, respectively).[100] This study was not powered to demonstrate reductions in blood transfusions.

In single-center series, 51 patients undergoing rfVIIa therapy for intractable blood loss after cardiac surgery were compared with 51 matched controls.[101] The investigators found that bleeding 1 hour after therapy was reduced in the treated cohort, compared with the control cohort. No differences in serious adverse events were noted. A subsequent review from the same institution of 114 cardiac surgical patients who received rfVIIa compared with 541 concurrent patients who did not receive rfVIIa concluded that rfVIIa is not associated with increased risk of adverse events, and early treatment may be associated with better outcomes.[102] A second series of rfVIIa in 53 patients during cardiac surgery found a significant decrease in doses of all blood products.[103] However, a third series of 24 patients treated with rfVIIa for refractory bleeding after cardiac surgery, compared with 24 matched controls, found no differences in RBC or plasma units transfused over a 24-hour period.[104]

A pilot study of 20 patients undergoing complex noncoronary cardiac surgery who were randomized to receive either placebo or rfVIIa (90 μg/kg) prophylactically after completion of cardiopulmonary bypass and

reversal of heparin found a significantly reduced need for allogeneic transfusion in the cohort who received rfVIIa.[105] However, a pediatric study of 76 pediatric patients undergoing surgery for congenital heart disease found no benefit of rfVIIa (40 μg/kg) prophylaxis as determined by chest closure time after cardiopulmonary bypass[106] (see also Chapter 94).

Two randomized placebo-controlled trials of rfVIIa as adjunctive therapy for control of bleeding in trauma patients were published.[107] In an analysis of 143 patients with blunt trauma, the percentage of patients alive at 48 hours after receiving more than 20 units of RBCs was reduced from 33% to 14% ($P = .03$). For 143 patients with penetrating trauma, the reduction from 19% to 7% was not significant ($P = .08$). No differences in serious adverse events between the rfVIIa-treated and placebo cohorts were observed (see also Chapters 62 and 81).

DOSE

A retrospective review of 40 patients with coagulopathic bleeding in a variety of medical and surgical settings from 13 hospitals in an Internet-based database (excluding history of coagulopathy and trauma patients) who received rfVIIa (15 to 180 μg/kg, with 38 patients receiving fewer than 5 doses) found that 32 patients (80%) achieved complete ($n = 18$) or partial ($n = 14$) cessation of bleeding.[108] Responses occurred in all dose ranges, without any evidence of a dose-response effect; the percentages of complete, partial, or absent responses were not different at doses of less than 70 μg/kg, 70 to 90 μg/kg, or more than 90 μg/kg. Significantly fewer blood products were administered after rfVIIa therapy. Twenty-three (58%) patients died, thus reflecting the unstable clinical status of the patients at the decision point for considering rfVIIa therapy. On the basis of this study, one recommended dosage strategy is for a 4.8-mg vial administered to an adult patient weighing 50 to 100 kg, which represents a 100 to 50 μg/kg dose.[98]

PATIENTS RECEIVING ORAL ANTICOAGULANT THERAPY

One report described the use of rfVIIa in seven adult patients with a prolonged international normalized ratio (INR); three of these patients required surgery. The doses administered ranged from 20 to 90 μg/kg, and all patients were reported to have a positive outcome.[109] These observations indicate that rfVIIa may be used to reverse the effect of warfarin (Coumadin) or other vitamin K–antagonist therapy when the administration of vitamin K alone has been found to be insufficient. Two published reports of a total of 15 patients treated with rfVIIa for reversal of excessive anticoagulation with warfarin supported a dosage of 20 μg/kg, or 1.2 mg for an adult patient.[110,111] A review of 12 patients with acute warfarin-associated intracranial hemorrhage over this same time period at one institution (all these patients received rfVIIa [30 to 135 μg/kg] as well as vitamin K [10 mg/day for 3 days] and fresh frozen plasma [1307 ± 652 mL] for treatment) found that treatment was associated with rapid correction of the INR, and single doses appeared safe in this high-risk population.[112] However, more recent guidelines from several medical societies have discouraged the off-label use of rfVIIa in this setting[12] (see also Chapter 62).

PATIENTS WITH IMPAIRED LIVER FUNCTION

A multicenter trial studied 71 patients with advanced liver disease who were undergoing laparoscopic liver biopsy.[115] The patients were randomized to receive 1 of 4 doses of rfVIIa (5, 20, 80, or 120 μg/kg); 48 (74%) of 65 patients achieved hemostasis within 10 minutes. One thrombotic event and a single case of DIC were reported, and they were not believed to be related to rfVIIa therapy. Despite these complications, the authors concluded that laparoscopic liver biopsy can be performed safely and reliably by using rfVIIa in patients in whom the standard procedure may be contraindicated because of coagulopathy.

The safety and efficacy of rfVIIa in patients with cirrhosis and upper gastrointestinal hemorrhage were studied in a randomized study of 245 patients with a composite primary end point including failure to control bleeding within 24 hours after first dose, failure to prevent rebleeding within 24 hours to 5 days, or death within 5 days.[116] No significant differences were found between the placebo compared with the rfVIIa (8 doses at 100 mg/kg over 30 hours) cohorts: failures on composite end point were 16% and 14%, respectively ($P = .72$). Similarly, a randomized controlled study of patients with cirrhosis who underwent partial hepatectomy found no benefit to rfVIIa compared with placebo when the volume of blood products administered, or the percentage of patients transfused, was analyzed.[115] Finally, no value for peri-adjuvant rfVIIa was found in patients undergoing liver transplantation, when compared with placebo[114] (see also Chapter 62).

PATIENTS WITH NORMAL HEPATIC FUNCTION

A prospective, randomized, double-blind multicenter study evaluated the efficacy of two different doses of rfVIIa compared with placebo on RBC transfusions for adult patients without cirrhosis who were undergoing partial hepatectomy.[117] Mean RBC volume transfused was 1024, 1354, and 1036 mL for placebo, 20 μg/kg rfVIIa, and 80 μg/kg rfVIIa, respectively ($P > .05$). Similarly, no differences were noted in the percentage of patients transfused and in intraoperative blood losses. Serious adverse event rates were not different.

PATIENTS WITH HEMORRHAGIC STROKE

A prospective, randomized, double-blind placebo-controlled trial of three doses of rfVIIa compared with placebo was reported in patients presenting with acute (<4 hours) hemorrhagic stroke.[118] At 24 hours after treatment, the percentage of patients showing expansion was 28%, 16%, 14%, and 11% for the placebo, 40 μg/kg, 80 μg/kg, and 160 μg/kg, respectively ($P < .05$ treatment cohorts versus placebo). The percentage

of patients who died was 29%, 18%, 18%, and 19%, respectively ($P < .05$, treatment cohorts versus placebo). Impairment scored at 90 days was also improved in the treatment cohorts compared with placebo. However, a follow-up, clinical trial (placebo, 40 μg/kg, and 80 μg/kg) failed to show a mortality benefit for rfVIIa compared with placebo.[119]

SAFETY

Of the more than 170,000 standard doses of rfVIIa given after its approval (almost all to patients with hemophilia and inhibitors), only rare (<1 in 11,300) thrombotic events have been reported.[92] Thrombotic complications have also been reported with rfVIIa therapy in patients without inhibitors to factor VIII or IX. An acute cerebrovascular accident and death occurred in a clinical trial of rfVIIa (90 μg/kg) before and after minor surgery or dental procedures in patients with factor XII deficiency.[120] The last of 10 patients enrolled in an open-label, dose-escalation trial to prevent rebleeding after subarachnoid hemorrhage developed middle cerebral artery thrombosis after receiving rfVIIa.[121] In a high-risk trauma population, 3 of 40 (7.5%) patients who were deemed at high risk for thrombosis developed thrombotic complications after receiving rfVIIa.[122]

Although significant adverse events and thrombotic events were distributed evenly among treatment and placebo cohorts in several large randomized clinical trials of patients undergoing radical prostatectomy,[100] trauma,[109] upper gastrointestinal bleeding,[114] or partial hepatectomy,[120] an uneven distribution of thromboembolic events was found in the clinical trial of patients with hemorrhagic stroke.[120] Total events in this last trial were 2 (2%), 7 (6%), 4 (5%), and 10 (10%) for the placebo, 40, 80, and 160 μg/kg cohorts, respectively. Most of these events were arterial, including thrombotic stroke and myocardial infarction. Whether these serious adverse events can be attributed to rfVIIa or to a population at risk for these events will need to be determined in a follow-up clinical trial.

A summary of thromboembolic events reported to the U.S. Food and Drug Administration (FDA) from March 1999 to December 2004 indicated a total of 151 events in settings with unlabeled indications for rfVIIa.[123] These events included deep vein thrombosis (42), cerebrovascular accident (39), acute myocardial infarction (34), pulmonary thromboembolus (32), arterial thrombosis (26), and clotted devices (10). Thirty-eight percent of cases had concomitant use of other hemostatic agents. In 36 (72%) of 50 reported deaths, rfVIIa was listed as the probable cause. The authors concluded that randomized clinical trials are necessary to demonstrate the safety and efficacy of rfVIIa in nonapproved settings. A subsequent report analyzed safety data from 13 clinical trials in patients treated with rfVIIa for cirrhosis, trauma, or reversal of anticoagulant therapy.[124] The authors reported thrombotic adverse events in 5.3% of patients who received placebo, compared with 6.0% in patients who received rfVIIa ($P = .57$).

In cardiac surgical patients, cohort-matched studies[100,101] and a systematic review found no differences in serious adverse events in patients treated with rfVIIa[125] (see also Chapter 62). We reported a patient who had fatal thrombosis after administration of activated prothrombin complex concentrate (PCC) and who had also received two doses of rfVIIa more than 6 hours earlier, while supported by extracorporeal membrane oxygenation.[126] Because of this experience, we recommend that patients should not receive combination therapy with both activated PCC and rfVIIa.

In summary, the safety profile of rfVIIa in controlled trials in patients with spontaneous *intracerebral hemorrhage* suggests that an increased risk of thrombotic arterial events may be underreported by treating physicians.[127] Thromboembolic events associated with rfVIIa were reported to the FDA in approximately 2% of treated patients in clinical trials, but sufficient data were not available to identify the incidence in patients who received rfVIIa for warfarin reversal.[123] A careful case review of 285 trauma patients revealed that 27 (9.4%) had thromboembolic complications after administration of rfVIIa, including 3 patients who were treated for warfarin reversal.[128] Levi and colleagues analyzed 35 randomized trials with 4468 subjects and found that 11.1% had thromboembolic events. Rates of venous thromboembolic events were similar for subjects who received rfVIIa compared with placebo (5.3% and 5.7%, respectively); arterial events, however, were significantly higher (5.5% versus 3.2%, $P < .003$) in subjects receiving rfVIIa compared with placebo, particularly for older patients (>75 years of age) and/or higher doses.[129]

Dose, timing, and safety of rfVIIa have yet to be defined in this diverse patient population, and formal prospective trials are needed. Consensus-based recommendations on the use of rfVIIa in nonapproved settings have been developed.[130] The decisions on when and where to use rfVIIa for patients with uncontrolled bleeding must be made by individual physicians, assisted by their hospital pharmacotherapeutic or transfusion committees.[98,131]

BLOOD UTILIZATION

Of the estimated 39 million discharges in the United States in 2004, 5.8% (2.3 million) were associated with blood transfusion.[132] Blood transfusion occurred in more than 10% of all hospital stays that included a procedure and was the most frequently performed procedure in 2009. The rate of blood transfusion more than doubled from 1997 to 2009.[133] Increased provider awareness of the costs associated with blood transfusion[134] and recognition of the potential negative outcomes have stimulated multidisciplinary, multiprofessional, and institution-based approaches to patient blood management (see also Chapter 61).

Guidelines for blood transfusion attest to the inadequacy of discrete hemoglobin levels as "triggers" for transfusion, and in addition to recommending transfusion of one blood unit each treatment event, they also acknowledge the necessity of considering other more physiologic criteria.[14] It is generally agreed that transfusion is not of benefit when hemoglobin levels are greater than 10 g/dL and is beneficial when hemoglobin levels are lower than 6 g/dL.[15,135] The variability in transfusion

outcomes in patients undergoing cardiothoracic surgery continues to persist even after adjusting for patient- and institution-related factors.[136,137] Moreover, prospective randomized trials in patients undergoing cardiac[138] and noncardiac[139,140] surgery demonstrated that such patients can tolerate perioperative anemia without transfusion to hemoglobin levels between 7 and 8 g/dL, and these patients have equivalent clinical outcomes comparable to transfusions to hemoglobin levels greater than 10 g/dL. The FOCUS trial found that older (mean > 80 years of age) high-risk (factors for coronary artery disease) patients who underwent hip fracture surgery tolerated a hemoglobin trigger as low as 8 g/dL (or higher if symptomatic).[140]

A Cochrane meta-analysis of prospective randomized trials comparing "high" and "low" hemoglobin thresholds in more than 3700 patients found that (1) "low" hemoglobin thresholds were well tolerated, (2) RBC transfusions were reduced (≈37%) significantly in patients randomized to the "low" hemoglobin cohorts, (3) infections were reduced by 34% in patients in the "low" hemoglobin cohorts, and (4) a hemoglobin of 7 g/dL was sufficient for most patients.[141] More recently, a randomized controlled trial of 2016 older patients with history or risk factors of cardiovascular disease who underwent hip surgery demonstrated that mortality rates, inability to walk independently, and in-hospital morbidity rates were similar in patients transfused according to liberal criteria and in patients transfused according to restrictive guidelines despite significantly fewer transfusions in the restrictive group.[140] On the basis of this study, the AABB guidelines recommend the use of a restrictive transfusion approach (hemoglobin 7 to 8 g/dL) in stable patients who do not have cardiovascular risk factors.[142]

Data from the most recent National Blood Collection and Utilization Survey show a progressive annual decrease in the number of patients and the percentage of hospitals who have canceled elective surgical procedures because of blood inventory constraint.[143] Current initiatives in research for blood transfusions are reflected in the growing literature on adverse effects of blood storage and their possible implications for oxygen delivery by blood transfusion.[144]

INDICATIONS FOR PLASMA TRANSFUSION

In an evidence-based review, the Transfusion Practices Committee of the AABB recommended plasma therapy for only a few clinical indications, based on the available evidence in the literature (which was assessed to be of "weak quality"[145]): trauma patients with substantial hemorrhage, patients undergoing complex cardiovascular surgery, and patients with intracranial hemorrhage requiring emergency reversal of warfarin-associated coagulopathy[146] (see also Chapter 62). Patients with mild prolongations of the INR (< 1.7) are not at risk of bleeding and do not need plasma therapy for minor procedures.[147] Therefore, for most clinical settings, ample evidence indicates that plasma transfusions are inappropriate. However, logistic or technical barriers that prevent effective and timely plasma therapy (possibly resulting in plasma therapies that are "too little, too late") have probably contributed to the paucity of evidence demonstrating any benefit for plasma therapy.[12]

Lack of enthusiasm and logistic or technical barriers in this and other settings have led to approaches for plasma therapy that are perhaps too little, too late. First, transfusion services must identify the patient's blood group type before issuing blood type–compatible plasma; for patients unknown to the institution and/or without a historic blood type in the patient record within the past year, considerable time (up to 60 minutes) can elapse from presentation until a blood type can be ordered, drawn, and determined by the transfusion service. Second, because plasma is stored frozen at −18° C, further time (30 to 45 minutes) may be required to thaw and issue plasma. Third, the volume for each plasma unit infused (≈200 to 250 mL) represents a challenge regarding volume overload, which occurs commonly in an older population who may have preexisting comorbidities such as atrial fibrillation or other cardiovascular disease. The dosing of plasma needed to correct the coagulopathy has often been underestimated and therefore may be subtherapeutic in some clinical practices; plasma therapy of 15 to 30 mL/kg is necessary to restore hemostatic clotting factor levels to 30% to 50% of normal in acute reversal of warfarin toxicity.[12]

In the coagulopathy of liver disease, plasma therapy may not represent appropriate management.[148] In liver disease, the extent of coagulopathy as measured by the prothrombin time or INR is not predictive of bleeding complications.[149-151] Thrombin-generation assays,[152,153] which measure platelet procoagulant activity, have found that patients with cirrhosis have primary hemostasis through cell-mediated pathways that are not measured by traditional laboratory assays such as prothrombin time and partial thromboplastin time. Increasing evidence indicates that these patients can undergo major hemostatic challenges such as liver biopsies and surgical procedures without plasma therapy and without bleeding complications.[154] Moreover, normalization of laboratory tests in this setting is rarely achieved by plasma therapy.[155] The most clinically relevant bleeding problems are a consequence of local vascular abnormalities and increased venous pressures.[151,156] Thus, a more conservative plasma therapy approach would be to avoid volume and fluid overload that paradoxically favors hemorrhage, such as portal hypertension and endothelial damage.[157] Alternative therapies to plasma infusion have been proposed to improve hemostasis in patients with liver disease, including the infusion of low-volume PCCs or antifibrinolytic agents, which lack the side effects of volume overload.[148]

One of the largest prospective studies of plasma transfusions and their effect on INR and bleeding included both medical and surgical patients with pretransfusion INR of between 1.1 and 1.85.[158] The authors reported that less than 1% of patients had normalization of their INR and only 15% had at least 50% correction. The median dose of plasma was 2 units (only 5 to 7 mL/kg), and no correlation was found between plasma dose and change in INR. This study had many of the limitations common to other reports[154] in this clinical arena: lack of control groups, only modest prolongation in coagulation tests, poorly defined clinical end points (e.g., change in hemoglobin or need for transfusion), and/or an inadequate dose of plasma therapy. Point-of-care testing, coupled with algorithms for targeted plasma therapy

in settings such as cardiothoracic surgery, liver transplantation, and trauma surgery, shows promise in improving blood utilization and patient outcomes[159] (see also Chapter 61).

The paucity of evidence for benefit of plasma transfusion therapy is accompanied by growing evidence that risks of plasma have been underrecognized. In a prospective study, 6% of transfused patients developed transfusion-associated excessive cardiac volume,[160] a percentage that is much higher than previously reported rates in retrospective studies.[161,162] Transfusion-related acute lung injury is a significant cause of morbidity and mortality from blood transfusions.[163] The incidence of this complication has declined with use of plasma from male donors or from female donors who have no history of pregnancy.[164]

PROTHROMBIN COMPLEX CONCENTRATES

PCCs are either activated (i.e., to allow for bypassing inhibitors to factor VIII or factor IX in the treatment of patients with hemophilia A or B) or nonactivated. The nonactivated PCC products currently available worldwide are listed in Table 63-4,[12] and they are further categorized based on the presence (four factor) or absence (three factor) of sufficient levels of factor VII.[165] PCCs that contain all four (including factor VII) of the vitamin K–dependent clotting factors are approved in the European Union,[166] as well as in various other countries such as Canada and Australia, and are now approved in the United States for emergency reversal of warfarin coagulopathy in patients with major bleeding[167,168] and also for perioperative management of patients receiving warfarin therapy.[169] Three-factor PCCs are approved in the United States only for the replacement of factor IX. Use of these three-factor PCCs for reversal of warfarin is controversial; although these agents can be demonstrated to normalize INR,[170] one report showed a suboptimal effect in correcting INR because of minimal increments in levels of factor VII.[165] A review of the role of PCCs and other options for reversing warfarin-associated coagulopathy has been published.[12]

Guidelines for acute reversal of warfarin coagulopathy have been published by several medical societies (Table 63-5).[171-177] One review of emergency reversal of anticoagulation therapy in neurosurgical patients recommended the concomitant administration of a three-factor concentrate (4000 International Units) and rfVIIa (1.0 mg) for patients treated at one trauma center in the United States.[178] Another review of PCCs for reversal of warfarin concluded that "PCC should be compared directly in randomized controlled trials [with] other

‡Use of plasma only when PCCs not available.

treatment strategies including fresh frozen plasma and rfVIIa, evaluating effect on patient outcomes."[179] Normalization of the INR is just a surrogate end point.[180] The role of PCC therapy relative to plasma therapy is in evolution, in part related to the following: the variability in PCC contents and clotting factor levels[165,181]; their regulatory approval status in different countries; their uncertain availability among hospital formularies, particularly in community hospitals; and their potential risks of thrombogenicity.

Product information for activated PCCs such as FEIBA VH Immuno and Autoplex-T (Baxter, Deerfield, Ill.) states, under warnings, that these agents "must be used only for patients with circulating inhibitors to one or more coagulation factors and should not be used for the treatment of bleeding episodes resulting from coagulation factor deficiencies."[182,183] Additionally, the presence of DIC is a stated contraindication to PCC use in the package inserts.

The safety of PCCs in the setting of emergency reversal of warfarin anticoagulation remains a subject of debate. One prospective study of 173 patients treated with PCC found that 4.6% of patients had a thrombotic event, but the investigators attributed these adverse events to cessation of anticoagulant therapy for underlying and ongoing risks of thrombosis.[184] A study in a pig model of coagulopathy with blunt liver injury found that although 35 International Units/kg PCC improved coagulation and attenuated blood loss, increased doses (50 International Units/kg) of PCC therapy appeared to increase the risk of thromboembolism and DIC.[185] Thrombogenicity has been a recognized problem for patients,[186,187] in part related to the presence of activated clotting factors (for which heparin and antithrombin III have been added to some preparations) and in part because of the presence of other preexisting thromboembolic risk factors that resulted in initiation of warfarin therapy in these patients (e.g., venous thrombosis, atrial fibrillation) or new, concurrent risk factors (e.g., trauma, head injury).

We previously reported a patient who was initially successfully treated with rfVIIa for refractory, massive hemorrhage while on extracorporeal membrane oxygenation (ECMO) after cardiothoracic surgery but who suffered massive thrombosis after subsequently receiving an activated PCC.[126] Another case of fatal intracardiac thrombosis following rapid administration of activated PCC for urgent warfarin coagulation reversal was also reported.[188] The reported incidence of thromboembolic events published between 1998 and 2008 ranged from 0% to 7% (overall weighted mean, 2.3%), with higher and repeated dosing potentially associated with higher risk.[179] Multinational trials of patients receiving a four-factor PCC product at various infusion speeds for urgent vitamin K antagonist reversal supported the safety and efficacy of rapid infusion of PCC in these patients.[189,190] However, the recommendation that "whenever possible, patients receiving PCCs should be under low dose heparin prophylaxis"[181] underscores that the use of PCCs in this setting is accompanied by risks of thrombosis. One review of eight clinical studies identified a thromboembolic event rate of 0.9% associated with PCC therapy.[191] Studies of optimal dosing strategies for PCC, including fixed versus variable (weight-based) dosage, provide a basis for future research.[192]

As pooled blood product derivatives, PCCs also have potential risks of transmitting infectious agents.[193] Various processing methods such as nanofiltration, solvent detergent treatment, and vapor heating have been used to inactivate pathogens in commercially available PCCs and pooled plasma products.[194] The cost effectiveness of such products with pathogen reduction technology is an area of current debate.[195,196] Potential risks and limitations of PCC therapy compared with plasma therapy are summarized in Table 63-6.

INDICATIONS FOR PLATELET TRANSFUSION

The Joint Commission developed a performance indicator for prophylactic platelet transfusions in patients with malignant hematologic diseases or in patients who undergo stem cell transplantation, in which a platelet count threshold of $10{,}000/mm^3$ is appropriate for prophylactic platelet transfusions.[197]

Current guidelines from the European Union and United States recommend a transfusion trigger of 10×10^9/L for platelets transfused prophylactically.[158,198] These guidelines are based on outcomes from four randomized clinical trials that compared prophylactic triggers of 10×10^9/L versus 20×10^9/L in patients with acute leukemia and in autologous and allogeneic hematopoietic stem cell transplant recipients.[197,199-202] Two additional prospective studies also demonstrated safety with the lower threshold

of 10 × 10^9/L for prophylactic platelet transfusions.[203,204] The impact of these thresholds on numbers of platelet and blood transfusions is variable; however, one study demonstrated a 36% and 16% reduction in platelet and blood transfusions, respectively,[204] whereas another showed no differences.[203]

Another trial demonstrated that "low-dose" prophylactic platelet transfusions are as effective as "standard-dose" or "high-dose" transfusions.[205] For therapeutic platelet transfusions, algorithms based on point-of-care testing have demonstrated promise in patients who have platelet-derived bleeding, such as in cardiothoracic surgery[13,206] and in trauma.[207] As for the evidence-based literature for plasma therapy, additional studies in platelet transfusion are needed (see also Chapter 61).[208]

TABLE 63-6 POTENTIAL RISKS AND LIMITATIONS OF PLASMA AND PROTHROMBIN COMPLEX CONCENTRATE THERAPY

Product	Risks and Limitations
I. Single-donor plasma	1. Longer time to administer 2. Volume constraints 3. Transmissible disease, known/unknown 4. Allergic reactions 5. Transfusion-related acute lung injury (TRALI)
II. Prothrombin complex concentrates	1. Limited availability 2. Some preparations lack factor VII 3. Donor pools: 3,000 to 20,000 4. Transmissible disease, known or unknown (for nonenveloped pathogens) 5. Thrombogenicity

BLOODLESS MEDICINE

Some patients object to receiving blood or blood products as part of their medical treatment. Many of these individuals are Jehovah's Witnesses and refuse the transfusion of another person's blood based on strict interpretations of both Old and New Testament texts that refer to the sanctity of blood.[209] This religious group currently has more than 6 million active and 14 million associated followers worldwide, and its publications are translated into more than 200 different languages. In the 1980s, bloodless medicine programs were started at the request of Jehovah's Witness patients who wanted hospitals where they could receive the best medical care and have their desire to avoid allogeneic blood transfusions respected.[209]

Many people in the United States, regardless of their religious background, have voiced concern about the safety of blood transfusions. A telephone survey found that only 61% of the respondents believed the blood supply in the United States to be safe, and 33% said that they would refuse blood transfusions if hospitalized.[22] Since 2000, public concerns about problems with the blood supply and shortages in the availability of volunteer blood donors have also led to the development of bloodless medicine centers.

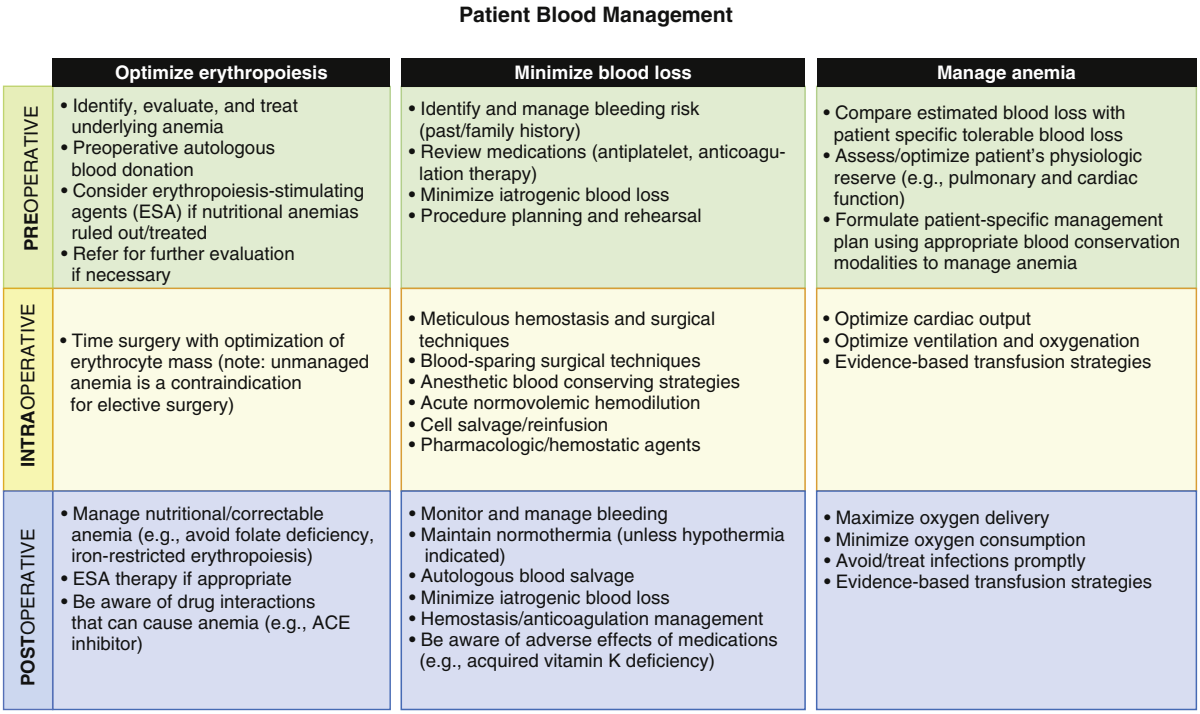

Figure 63-2. Patient blood management. These principles applied in the perisurgical period enable treating physicians to have the time and tools to provide patient-centered evidenced-based patient blood mangement to minimize allogeneic blood transfusions. *(From Goodnough LT, Shander A: Patient blood management,* Anesthesiology *116:1367-1376, 2012.)*

Bloodless medicine and surgery are defined as a team approach "that reduces blood loss and uses the best available alternatives to allogeneic transfusion therapy while focusing on the provision of the best possible medical care to all patients."[16] The objectives of a bloodless medicine program should include "providing leadership within an institution for bloodless medicine and being the advocate for patients not accepting transfusion."[210] All clinicians should realize that a philosophy of blood management that incorporates avoidance of unnecessary blood transfusions in all patients is appropriate even if a bloodless medicine center does not exist at their institutions.[16] The principles of patient blood management can serve to achieve a goal of minimizing allogeneic blood transfusions, not only for Jehovah's Witness patients, but also for all patients (Fig. 63-2).[6]

CONCLUSION

Blood transfusions carry risks, they are costly, and the supply of blood is limited (see also Chapter 61). Blood transfusion outcomes are therefore undergoing renewed scrutiny by health care institutions to reduce blood use. In addition to accreditation organizations, professional societies are also well positioned to incorporate blood transfusion outcomes as quality indicators in their own guidelines and recommendations.[211]

The foundations of patient blood management in the perisurgical period are illustrated in Figure 63-2: (1) optimize erythropoiesis, (2) minimize blood loss, and (3) manage anemia. Strategies begin with preoperative preadmission testing and extend throughout the intraoperative and postoperative intervals, thus enabling treating physicians to minimize allogeneic blood transfusions while delivering safe and effective health care. Physicians and hospital quality or clinical effectiveness departments should incorporate the principles of patient blood management into hospital-based process improvement initiatives that enhance patient safety and clinical outcomes.

Chapter 64

Anesthesia and Treatment of Chronic Pain

CHRISTOPH STEIN • ANDREAS KOPF

Key Points

- The normal physiology of neuronal function, receptors, and ion channels, is altered by persistent pain.
- Because of the large number of sources and manifestation of chronic pain, classification must include cancer-related, neuropathic, inflammatory, arthritis, and musculoskeletal pain.
- Interdisciplinary management of chronic pain must include specialists in psychology, physical therapy, occupational therapy, neurology, and anesthesiology.
- Drugs used for chronic pain are multiple and include opioids, nonsteroidal antiinflammatory drugs and antipyretic analgesics, serotonin receptor ligands, antiepileptics, antidepressants, topical analgesics (e.g., nonsteroidal antiinflammatory drugs, capsaicin, local anesthetics, opioids), and adjuvants such as local anesthetics, α_2-agonists, baclofen, botulinum toxin, antiemetics, laxatives, novel drugs such as cannabinoids, and ion channel blockers.
- Interventional management of chronic pain includes the use of diagnostic blocks, therapeutic blocks, continuous catheter techniques (peripheral, epidural, intrathecal), and stimulation techniques such as acupuncture, transcutaneous electrical nerve stimulation, and spinal cord stimulation.
- Perioperative management of patients with chronic pain involves the following: the use of opioid and nonopioid analgesics; evaluation for dependence, addiction, and pseudoaddiction; and practical considerations.

PHYSIOLOGIC CHANGES IN PERSISTENT PAIN

EXCITATORY MECHANISMS

Pain may be roughly divided into two broad categories: physiologic and pathologic pain. Physiologic (acute, nociceptive) pain is an essential early warning sign that usually elicits reflex withdrawal and thereby promotes survival by protecting the organism from further injury. In contrast, pathologic (e.g., neuropathic) pain is an expression of the maladaptive operation of the nervous system; it is pain as a disease.[1] Physiologic pain is mediated by a sensory system consisting of primary afferent neurons, spinal interneurons and ascending tracts, and several supraspinal areas. Trigeminal and dorsal root ganglia (DRGs) give rise to high-threshold Aδ and C fibers innervating peripheral tissues (skin, muscles, joints, viscera). These specialized primary afferent neurons, also called nociceptors, transduce noxious stimuli into action potentials and conduct them to the dorsal horn of the spinal cord (Fig. 64-1). When peripheral tissue is damaged, primary afferent neurons are sensitized or directly activated, or both, by a variety of thermal, mechanical, and/or chemical stimuli. Examples are protons, sympathetic amines, adenosine triphosphate (ATP), glutamate, neuropeptides (calcitonin gene–related peptide, substance P), nerve growth factor, prostanoids, bradykinin, proinflammatory cytokines, and chemokines.[2,3] Many of these agents lead to opening (gating) of cation channels in the neuronal membrane. Such channels include the capsaicin-, proton-, and heat-sensitive transient receptor potential vanilloid 1 (TRPV1), or the ATP-gated purinergic $P2X_3$ receptor. Gating produces an inward current of sodium (Na^+) and calcium (Ca^{2+}) ions into the peripheral nociceptor terminal. If this depolarizing current is sufficient to activate voltage-gated Na^+ channels (e.g., $Na_v1.8$), they too will open, further depolarizing the membrane and initiating a burst of action potentials that are then conducted along the sensory axon to the dorsal horn of the spinal cord.[3,4] Thereafter, these impulses are transmitted to spinal neurons, brainstem, thalamus, and cortex.[5,6]

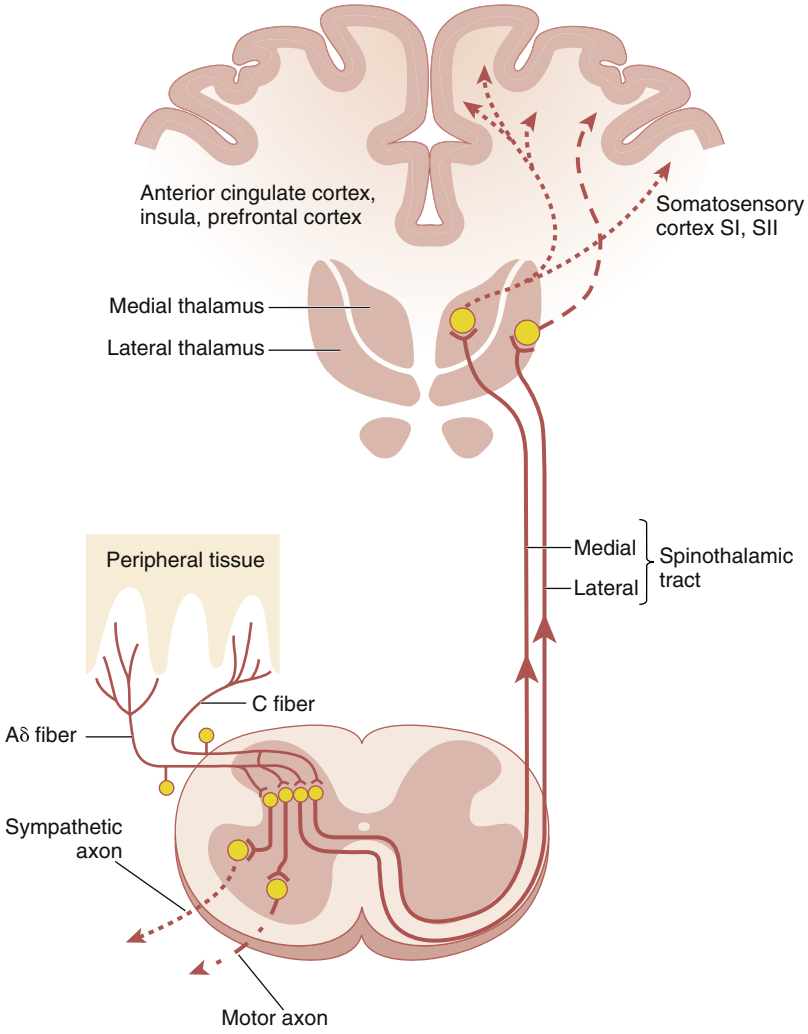

Figure 64-1. Nociceptive pathways. For details see text. *(Modified from Brack A, Stein C, Schaible HG: Periphere und zentrale Mechanismen des Entzündungsschmerzes. In Straub RH, editor:* Lehrbuch der klinischen Pathophysiologie komplexer chronischer Erkrankungen, *vol 1, Göttingen, Germany, 2006, Vandenhoeck & Ruprecht, pp 183-192.)*

Transmission of input from nociceptors to spinal neurons that project to the brain is mediated by direct monosynaptic contact or through multiple excitatory or inhibitory interneurons. The central terminals of nociceptors contain excitatory transmitters such as glutamate, substance P, and neurotrophic factors that activate postsynaptic *N*-methyl-D-aspartate (NMDA), neurokinin (NK_1), and tyrosine kinase receptors, respectively. Repeated nociceptor stimulation can sensitize both peripheral and central neurons (activity-dependent plasticity). In spinal neurons, such a progressive increase of output in response to persistent nociceptor excitation has been termed wind-up. Later, sensitization can be sustained by transcriptional changes in the expression of genes coding for various neuropeptides, transmitters, ion channels, receptors, and signaling molecules (transcription-dependent plasticity) in both nociceptors and spinal neurons. Important examples include the NMDA receptor, cyclooxygenase-2 (COX-2), Ca^{2+} and Na^{+} channels, cytokines, and chemokines expressed by neurons and/or glial cells.[7,8] In addition, physical rearrangement of neuronal circuits by apoptosis, nerve growth, and sprouting occurs in the peripheral and central nervous systems.[1,5]

INHIBITORY MECHANISMS

Concurrent with the events just described, powerful endogenous mechanisms counteracting pain unfold both in the periphery and in the central nervous system. In injured tissue, this process results from interactions between leukocyte-derived opioid peptides and peripheral nociceptor terminals carrying opioid receptors[9,10] and/or by antiinflammatory cytokines.[2] Inflammation of peripheral tissue leads to increased expression, axonal transport, and enhanced G-protein coupling of opioid receptors in DRG neurons as well as enhanced permeability of the perineurium. These phenomena depend on sensory neuron electrical activity, the production of proinflammatory cytokines, and the presence of nerve growth factor within the inflamed tissue. In parallel, opioid peptide–containing immune cells extravasate and accumulate in the inflamed tissue.[10] These cells up-regulate the gene expression of opioid precursors and the enzymatic machinery for their processing into functionally active peptides.[11,12] In response to stress, catecholamines, corticotropin-releasing factor, cytokines, chemokines, or bacteria, leukocytes secrete opioids. The latter activate peripheral opioid receptors and produce analgesia by inhibiting the excitability

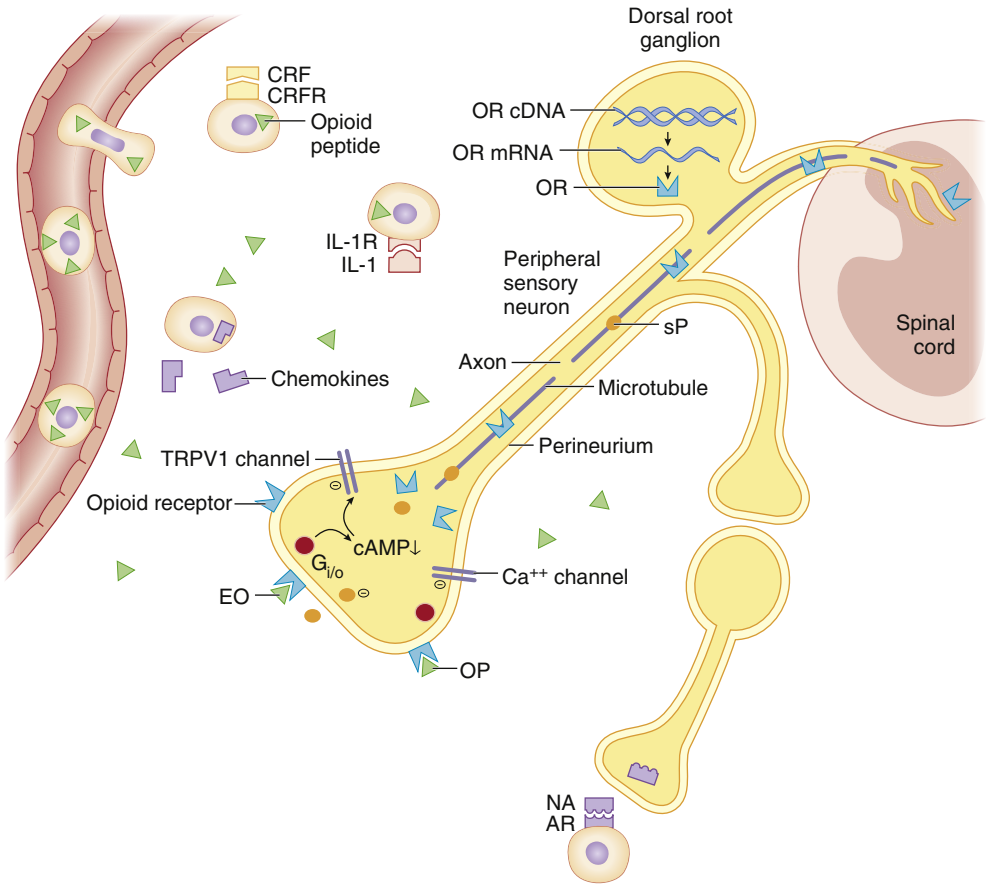

Figure 64-2. Endogenous antinociceptive mechanisms within peripheral injured tissue. Opioid peptide-containing circulating leukocytes extravasate upon activation of adhesion molecules and chemotaxis by chemokines. Subsequently, these leukocytes are stimulated by stress or releasing agents to secrete opioid peptides. For example, corticotropin-releasing factor (CRF), interleukin-1β (IL-1) and norepinephrine (noradrenaline [NA], released from postganglionic sympathetic neurons) can elicit opioid release by activating their respective CRF receptors (CRFR), IL-1 receptors (IL-1R), and adrenergic receptors (AR) on leukocytes. Exogenous opioids (EO) or endogenous opioid peptides (OP, *green triangles*) bind to opioid receptors (OR) that are synthesized in dorsal root ganglia and are transported along intraaxonal microtubules to peripheral (and central) terminals of sensory neurons. The subsequent inhibition of ion channels (e.g., TRPV1, Ca^{2+}) (see Fig. 64-3 and text) and of substance P (sP) release results in antinociceptive effects. *cAMP,* Cyclic adenosine monophosphate. *(Modified from Stein C, Machelska H: Modulation of peripheral sensory neurons by the immune system: implications for pain therapy,* Pharmacol Rev *63:860-881, 2011.)*

of nociceptors, the release of excitatory neuropeptides, or both[10,13] (Fig. 64-2). The clinical relevance of these mechanisms was shown in studies demonstrating that patients with knee joint inflammation expressed opioid peptides in immune cells and opioid receptors on sensory nerve terminals within synovial tissue.[14] After knee surgery, pain and analgesic consumption were enhanced by blocking the interaction between the endogenous opioids and their receptors with intraarticular naloxone[15] and diminished by stimulating opioid secretion.[16]

In the spinal cord, inhibition is mediated by the release of opioids, γ-aminobutyric acid (GABA), or glycine from interneurons, which activate presynaptic opioid or GABA receptors, or both, on central nociceptor terminals to reduce excitatory transmitter release. In addition, the opening of postsynaptic potassium (K^+) or chloride (Cl^-) channels by opioids or GABA, respectively, evokes hyperpolarizing inhibitory potentials in dorsal horn neurons. During ongoing nociceptive stimulation, spinal interneurons up-regulate gene expression and the production of opioid peptides.[17,18] Powerful descending inhibitory pathways from the brainstem also become active by operating mostly through noradrenergic, serotonergic, and opioid systems. A key region is the periaqueductal gray, which projects to the rostral ventromedial medulla, which then projects along the dorsolateral funiculus to the dorsal horn.[19] The integration of signals from excitatory and inhibitory neurotransmitters with cognitive, emotional, and environmental factors (see later) eventually results in the central perception of pain. When the intricate balance of biologic, psychological, and social factors becomes disturbed, chronic pain can develop.

TRANSLATION OF BASIC RESEARCH

Basic research on pain continues at a rapid pace, but translation into clinical applications has been difficult.[20] Animal studies are indispensable. However, for ethical reasons these studies are restricted to days or weeks, whereas human chronic pain can last for months or years. Therefore, animal models do not mirror the truly chronic clinical situation and should be more cautiously termed

reflections of persistent pain.[21,22] Brain imaging is an area of intense research, and numerous studies have investigated changes in patients with various pain syndromes. However, such studies have not yet provided reproducible findings specific for a disease or a pathophysiologic basis for individual syndromes.[21] Neuroimaging can detect only alterations associated with nociceptive processes, whereas clinical pain encompasses a much more complex subjective experience that critically relies on self-evaluation. Thus, imaging cannot provide an objective proxy, biomarker, or predictor for pain[23] (see also the next section). Similarly, although basic research has produced some evidence for genetic control of pain, such findings are not expected to serve as a guide to individualized (personalized) clinical pain therapy any time soon.[21,24]

CLINICAL DEFINITIONS, PREVALENCE, AND CLASSIFICATION OF CHRONIC PAIN

DEFINITIONS

The International Association for the Study of Pain (IASP) defines pain as "an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage."[25,26] This classification further states that pain is always subjective and that it is a sensation in parts of the body. At the same time, pain is unpleasant and therefore also has an emotional component. Aside from malignant disease, many people report pain in the absence of tissue damage or any likely pathophysiologic cause. Usually, no way exists to distinguish their experience from a condition resulting from tissue damage. If patients regard their experience as pain or if they report it in the same ways as pain caused by tissue damage, it should be accepted as pain. This definition avoids tying pain to a stimulus. *Nociception* is neurophysiologic activity in peripheral sensory neurons (nociceptors) and higher nociceptive pathways and is defined by the IASP as the "neural process of encoding noxious stimuli." Nociception is not synonymous with pain. Pain is always a psychological state, even though it often has a proximate physical cause. *Chronic pain* is defined by the American Society of Anesthesiologists as "extending in duration beyond the expected temporal boundary of tissue injury and normal healing, and adversely affecting the function or well-being of the individual."[27] The IASP subcommittee on taxonomy defined it in 1986 as "pain without apparent biological value that has persisted beyond the normal tissue healing time usually taken to be three months." The presence or extent of chronic pain often does not correlate with the documented tissue disorder.

PREVALENCE

Beyond these general definitions, no common understanding exists about the characteristics of the patient with chronic pain. This may be one reason that estimates of pain prevalence differ greatly from one publication to another. Heterogeneous populations, the occurrence of undetected comorbidity, different definitions of chronic pain, and different approaches to data collection have resulted in estimates of 20% to 60%. Some surveys indicate a more frequent prevalence among women and older adults. Chronic pain has enormous socioeconomic costs. In the United States alone, annual expenditures amount to more than $600 billion for health care, disability compensation, lost work days, and related expenses. Similar figures have been reported by other countries.[28,29]

CLASSIFICATION

Traditionally, a distinction is made between malignant (related to cancer and its treatment) and nonmalignant (e.g., neuropathic, musculoskeletal, inflammatory) chronic pain. To separate somatic and psychological mechanisms is probably not warranted. Patients with cancer tend to have more serious health restrictions than do patients with chronic nonmalignant pain. Patients with nonmalignant pain may report higher pain scores and expect more pain relief than do patients with cancer.[30] Nonmalignant chronic pain is frequently classified into inflammatory pain (e.g., arthritic), musculoskeletal pain (e.g., low back pain), headaches, and neuropathic pain (e.g., postherpetic neuralgia, phantom pain, complex regional pain syndrome, diabetic neuropathy, human immunodeficiency virus–associated neuropathy). Frequent symptoms of neuropathic pain include the following: spontaneous lancinating, shooting, or burning pain; hyperalgesia; and allodynia; or any combination of such pain.[31] Cancer pain can originate from invasion of the tumor into tissues innervated by primary afferent neurons (e.g., pleura, peritoneum) or directly into a peripheral nerve plexus. In the latter situation, neuropathic symptoms may be predominant. A problem in the treatment of cancer pain is the lack of correlation between the patient's self-reporting and the assessment of clinical staff. Pain may be underestimated by medical staff and family members, thus resulting in poor pain control.[29] Many treatments for cancer are associated with severe pain. For example, cytoreductive radiation therapy or chemotherapy frequently causes painful oral mucositis, especially in patients undergoing bone marrow transplantation.[32]

BIOPSYCHOSOCIAL CONCEPT OF CHRONIC PAIN

Patients with chronic pain who have cancer or nonmalignant diseases have in common the complex influences of biologic (tissue damage), cognitive (memory, expectations), emotional (anxiety, depression), and environmental factors (reinforcement, conditioning). Many patients present with limited mobility, lack of motivation, depression, anger, anxiety, and fear of reinjury, all of which hamper the return to normal work or recreational activities. Such patients may become preoccupied with pain and somatic processes, which may disrupt sleep, cause irritability, and social withdrawal. Other cognitive factors such as patients' expectations or beliefs (e.g., perceived inability to control the pain) influence psychosocial and physical functioning. Pain behavior such as limping, medication intake, or avoidance of activity is subject to operant conditioning; that is, it responds to reward and punishment. For example, pain behavior may be positively reinforced by attention from a spouse or health

care provider (e.g., by inadequate use of nerve blocks or medications). Conversely, such behavior can be extinguished when it is disregarded and incremental activity is reinforced by social attention and praise.[33] Respondent learning mechanisms (i.e., classic conditioning) may also contribute to chronicity.[34] Other issues often coexist, such as substance abuse problems, family dysfunction, and conflicts with legal or insurance systems. Consequently, care seeking is an integral feature of the pain experience, and excessive use of the health care system ensues. The interplay among these biologic, psychological, and social factors results in the persistence of pain and illness behaviors.[33,34] Treating only one aspect of this complex syndrome is obviously insufficient. Therefore, a biopsychosocial concept of pain has been adopted. This concept was first described by Engel in 1959,[35] but its implementation into daily practice has been tardy, especially concerning patients with chronic pain.[36,37] This concept helps us understand why chronic pain may exist without obvious physical cause or why pathologic somatic findings may remain unnoticed by the patient. The experience and regulation of social and physical pain may share a common neuroanatomic basis.[38] In a multimodal approach, pain management addresses physical, psychological, and social skills and underscores the patients' active responsibility to regain control over life by improving function and well-being.[34,39]

INTERDISCIPLINARY MANAGEMENT OF CHRONIC PAIN

The anesthesiologist John J. Bonica was the first to appreciate the need for a multidisciplinary approach to chronic pain. His early experiences in and after World War II convinced Bonica that complex pain problems could be more effectively treated when different disciplines contributed their specialized knowledge and skills to the common goal of making a correct diagnosis and developing the most effective therapeutic strategy. The first multidisciplinary facility was put into practice at the Tacoma General Hospital in the state of Washington, followed by the University of Washington in 1960. From 1970 through 1990, the number of pain management facilities continued to increase in North America and Europe, and they were mostly directed by anesthesiologists. Such comprehensive pain centers should have personnel and facilities to evaluate and treat the biomedical, psychosocial, and occupational aspects of chronic pain and to educate and teach medical students, residents, and fellows. Guidelines for characteristics of pain treatment facilities have been published by the IASP.[40] Multidisciplinary and multimodal management results in increased physical and psychosocial function, reduced health care use, and vocational rehabilitation. A meta-analysis found that such programs offer the most efficacious and cost-effective, evidence-based treatment of chronic nonmalignant pain.[37] Treatment of chronic pain without an interdisciplinary approach is inadequate and may lead to misdiagnoses. For example, overlooking psychological processes in a patient with presumed discogenic back pain or overlooking a somatic etiology in a presumed "psychogenic" pain disorder may lead to the wrong conclusion.[41] Moreover, conventional monomodal approaches such as pharmacotherapy alone only perpetuate the expensive, futile, and endless search for medical solutions.[37,39]

The core team usually comprises a pain management physician (anesthesiologist with subspecialty training), a psychologist, a physical therapist, and an occupational therapist. Other medical specialties, such as neurology, may be involved. Depending on the local circumstances, administrators, nurse specialists, and/or pharmacists can also be involved. The initial screening of the patient by members of the core team determines what other specialists will be needed for a complete assessment. After this evaluation, the patient is presented to the entire core team, and a comprehensive treatment plan is developed. This plan is tailored to the patient's needs, abilities, and expectations, with a focus on achieving measurable treatment goals established with the patient. For some patients, education and medical management may suffice, whereas for others, an intensive full-day rehabilitation program over several weeks may be needed. Early stratification of the management according to the patient's prognosis (low, medium, or high risk for persistent disability because of pain) results in significantly higher clinical and cost effectiveness.[42] To foster patient compliance, an open discussion of treatment goals with regard to the patient's anticipations is essential. Many patients expect complete resolution of pain and return to full function, a goal that may not be achievable. In many cases, realistic options are as follows: reduction of pain; improvement of physical function, mood, and sleep; development of active coping skills; and return to work. Thus, rehabilitation rather than cure is the most appropriate therapeutic option.[37]

PSYCHOLOGY

The role of the psychologist includes the initial assessment and treatment approaches such as education, cognitive-behavioral therapy, and relaxation training. Assessment of the patient addresses the sensory, affective, cognitive, behavioral, and occupational dimensions of the pain problem. The assessment includes an extensive biographic history and behavioral analysis, along with the obligatory use of questionnaires. Most questionnaires include scoring systems for pain intensity (e.g., numeric or visual analog scales), pain behavior (e.g., West-Haven-Yale Multidimensional Pain Inventory), multidimensional pain quality, cognitive coping, fear (e.g., State-Trait-Anxiety-Inventory), depression, and other associated symptoms. Indications for psychological pain management are relevant somatization, depressive disorders, inadequate coping, drug abuse, and high levels of pain behavior reinforced by the environment (e.g., family members). Patients with some types of pain syndromes, such as chronic headache, inflammatory rheumatic pain, or unspecific back pain, may specifically benefit from behavioral therapy.[34,37] This usually means a complete change of approach for the patient, from a purely passive recipient of curative treatment to an active, self-reliant participant in functional restoration, vocational rehabilitation, and reduced health care use despite pain. Thus, pain reduction alone is no longer the focus of therapy.[37]

PHYSICAL THERAPY

The role of the physical therapist includes initial evaluation of the musculoskeletal system, assessment of the patient's work place and home, education in active physical coping skills, and management of the physical rehabilitation process. An intensive exercise program emphasizing the patient's responsibility for self-management is an integral part of comprehensive programs for chronic nonmalignant pain.[37,43] Improving fitness, mobility, and posture counteracts the effects of disuse and complements behavioral treatment. The physical therapist encourages the adoption of regular exercise into daily life, facilitates repeated exposure to movement as much as possible despite pain, and reinforces education in the biopsychosocial model of pain management. Different techniques of exercise such as muscle conditioning and aerobics are efficacious in improving function, pain, disability, and fear avoidance behavior.[44,45] In contrast, passive treatments such as massage or chiropractic interventions are not beneficial.[46] The regimen of graded exercise follows the original concept of Fordyce.[33] Patients are instructed to find a baseline tolerance level for each exercise. Next, a program of improvement is negotiated and agreed upon. Patients note improvements on a daily basis and are required to complete the exercise plan regardless of how they feel. Thus, the control over exercise behavior is contingent upon plan rather than pain because exercise and pain are disconnected. Individual motivation is an important factor in determining how well patients learn to manage pain.[47]

OCCUPATIONAL THERAPY

The occupational therapist teaches the patient to achieve life goals despite pain and to overcome the limitations imposed by pain. Occupational therapy assessment includes a history of working life and place, family life, and daily activities, as well as a physical examination to determine range of motion and the presence of movement disorders or deformities that could hinder performance. The primary therapeutic objectives are reduction of pain and associated disability, promotion of optimal function in everyday life, and the encouragement of meaningful family, social, and work relationships.[48] An important target is supporting the patient's return to work, including specific work conditioning.[49] The chance of returning to work after a period of sick leave from low back pain, for example, apparently decreases over time, thereby generating enormous costs to society through wage compensation, social support, and loss of production.[29] Barriers to return to work include job dissatisfaction and perceptions of the impact of work on the cause of pain. Together with the patient, the occupational therapist should develop a program to increase self-esteem, restore self-efficacy, and promote optimal occupational and recreational function despite pain.

ANESTHESIOLOGY

The role of the anesthesiologist in the treatment of chronic pain has changed considerably over the last decades. "Nerve block practices" have been replaced by interdisciplinary pain management centers. In this context the anesthesiologist acts as both a physician-educator and a technical expert. The challenge is to complement regional anesthesia skills and pharmacologic knowledge optimally with the psychosocial components of chronic pain to render more comprehensive pain management services. Anesthesiologists must use their expertise in pharmacotherapy, nerve blocks, and skilled techniques within the broad-based biopsychosocial approach. The focus is not only on reducing pain but also on decreasing disability, improving quality of life, and increasing function. The conventional way of administering medication "as needed" or the use of nerve blocks for short-term pain relief may risk reinforcement of pain behavior and the patient's belief in an underlying physical abnormality that is best managed by biomedical procedures.[39] Moreover, false expectations are maintained; for example, the patient cannot be the passive recipient, but rather must be an active participant in the process. Patients may believe that pain is the primary problem in their lives. This belief neglects psychosocial factors, perpetuates the expensive and futile search for unidimensional biomedical solutions, and promotes iatrogenic somatization, medicalization, and high health care use by patients with chronic pain.[39]

The role of the anesthesiologist within the interdisciplinary team differs depending on the type of patient being treated. Management of cancer pain and of acute pain demands the full range of the anesthesiologist's technical skills and pharmacologic knowledge. In chronic nonmalignant pain, the anesthesiologist's abilities as an educator, coach, and motivator are far more important. As a member of the interdisciplinary team, the anesthesiologist must reinforce and maintain the biopsychosocial focus, respond appropriately to somatic concerns, and manage medications. In concert with the other members of the team, the anesthesiologist uses motivational strategies to encourage the patient to attain self-managed reactivation goals in physical, psychosocial, recreational, and vocational domains. At the same time, the anesthesiologist's presence provides "white coat credibility" and is essential to avoid the patient's pejorative conclusion that the pain is "all in my head." The anesthesiologist monitors the patient's physical status, potential development of new medical problems, and medications. In addition, the anesthesiologist provides real-time reassurance and education regarding the absence of relevant abnormalities, discusses the minimal role of surgery, and conveys medical information to make informed choices. The anesthesiologist plays a crucial role within the multidisciplinary team to direct the patient toward a multimodal pain treatment plan. This role is reflected in the fact that most pain therapists worldwide are anesthesiologists. In the described clinical setting, anesthesiologists work closely with other health care professionals and thereby gain added recognition outside the operating room.[39]

DRUGS USED FOR CHRONIC PAIN

Analgesic drugs interfere with the generation or transmission, or both, of impulses following noxious stimulation in the nervous system (nociception). This action can

TABLE 64-1 ANALGESIC DRUGS, TARGETS, MECHANISMS, AND SIDE EFFECTS

Drugs	Targets	Mechanisms	Functional Consequences	Side Effects
Opioids	G-protein coupled μ, δ, κ receptors	↓ cAMP ↓ Ca^{2+} currents ↑ K^+ currents	↓ Excitability of peripheral and central neurons ↓ Release of excitatory neurotransmitters	μ, δ: Sedation, nausea, euphoria/reward, respiratory depression, constipation κ: Dysphoria/aversion, diuresis, sedation
NSAIDs	Cyclooxygenases (COX-1, COX-2)	↓ Prostaglandins ↓ Thromboxanes	↓ Sensitization of sensory neurons ↑ Inhibition of spinal neurons	Nonselective: gastrointestinal ulcers, perforation, bleeding, renal impairment COX-2: thrombosis, myocardial infarction, stroke
Serotonin agonists	G-protein coupled 5-HT receptors 5-HT_3: ion channels	↓ cAMP (5-HT_1) ↑ cAMP ($5\text{-HT}_{4\text{-}7}$) ↑ PLC (5-HT_2)	↓ Release of excitatory neuropeptides ↓ Neurogenic inflammation ↑ Vasoconstriction	Myocardial infarction, stroke, peripheral vascular occlusion
Antiepileptics	Na^+, Ca^{2+} channels GABA receptors	↓ Na^+ currents ↓ Ca^{2+} currents ↑ GABA receptor activity	↓ Excitability of peripheral and central neurons ↓ Release of excitatory neurotransmitters	Sedation, dizziness, cognitive impairment, ataxia, hepatotoxicity, thrombocytopenia
Antidepressants	Norepinephrine/5-HT transporters Na^+, K^+ channels	↓ Norepinephrine/5-HT reuptake ↓ Na^+ currents ↑ K^+ currents	↓ Excitability of peripheral and central neurons	Cardiac arrhythmia, myocardial infarction, sedation, nausea, dry mouth, constipation, dizziness, sleep disturbance, blurred vision

Ca^{2+}, Calcium; *cAMP,* cyclic adenosine monophosphate; *GABA,* γ-aminobutyric acid; *5-HT,* 5-hydroxytryptamine (serotonin); *K^+*, potassium; *Na^+*, sodium; *NSAIDs,* nonsteroidal antiinflammatory drugs; *PLC,* phospholipase C.

occur at both the peripheral and central levels of the neuraxis. The therapeutic aim is to diminish the perception of pain. Analgesics aim at modulating either the formation of noxious chemicals (e.g., prostaglandins) or the activation of neuronal receptors or ion channels transducing or transmitting noxious stimuli (e.g., peptide, kinin, monoamine receptors, Na^+ channels). Drugs currently used in chronic pain include opioids, nonsteroidal antiinflammatory drugs (NSAIDs), serotonergic compounds, antiepileptics, and antidepressants (Table 64-1). Other classes, such as adrenergic receptor agonists, excitatory amino acid receptor (e.g., NMDA) antagonists, neurotrophin antagonists, neuropeptide (e.g., calcitonin gene–related peptide) receptor antagonists, kinin receptor antagonists, prostaglandin E receptor (EP) antagonists, cannabinoids, and ion channel (e.g., TRP, P2X) blockers are under investigation. Local anesthetics are used for local and regional anesthetic techniques. Mixed drugs combine different mechanisms, for example, norepinephrine reuptake inhibition and opioid agonist effects (tramadol, tapentadol), or opioid agonist and NMDA antagonist effects (ketamine). Various routes of drug administration (e.g., oral, intravenous, subcutaneous, intrathecal, epidural, topical, intraarticular, transmucosal) can be used, depending on the clinical circumstances. In addition, placebo treatments have shown impressive analgesic effects, mediated by opioid and nonopioid mechanisms.[50] Chronic pain requires a multidisciplinary approach encompassing various pharmacologic and nonpharmacologic (psychological, physiotherapeutic) treatment strategies (see the previous section on the interdisciplinary management of chronic pain).

OPIOIDS

Opioids act on heptahelical G-protein–coupled receptors (see also Chapter 31). Three types of opioid receptors (μ, δ, κ) have been cloned. Several subtypes (e.g., μ_1, μ_2, δ_1, δ_2), possibly resulting from gene polymorphisms, splice variants, or alternative processing, have been proposed. Opioid receptors are localized and can be activated along all levels of the neuraxis, including peripheral and central processes of primary sensory neurons (nociceptors), spinal cord (interneurons, projection neurons), brainstem, midbrain, and cortex. All opioid receptors couple to G proteins (mainly G_i/G_o) and subsequently inhibit adenylyl cyclase, decrease the conductance of voltage-gated Ca^{2+} channels, or open rectifying K^+ channels, or any combination of these effects (Fig. 64-3, *top*). These effects ultimately result in decreased neuronal activity. The prevention of Ca^{2+} influx inhibits the release of excitatory (pronociceptive) neurotransmitters. A prominent example is the suppression of substance P release from primary sensory neurons, both within the spinal cord and from their peripheral terminals within injured tissue. At the postsynaptic membrane, opioids produce hyperpolarization by opening K^+ channels, thereby preventing excitation or propagation of action potentials in second order projection neurons. In addition, opioids inhibit sensory neuron-specific tetrodotoxin-resistant Na^+ channels, TRPV1 channels, and excitatory postsynaptic currents evoked by glutamate receptors (e.g., NMDA) in the spinal cord. The results are decreased transmission of nociceptive stimuli at all levels of the neuraxis and profoundly reduced perceptions of pain. Endogenous opioid receptor ligands are derived from the precursors proopiomelanocortin

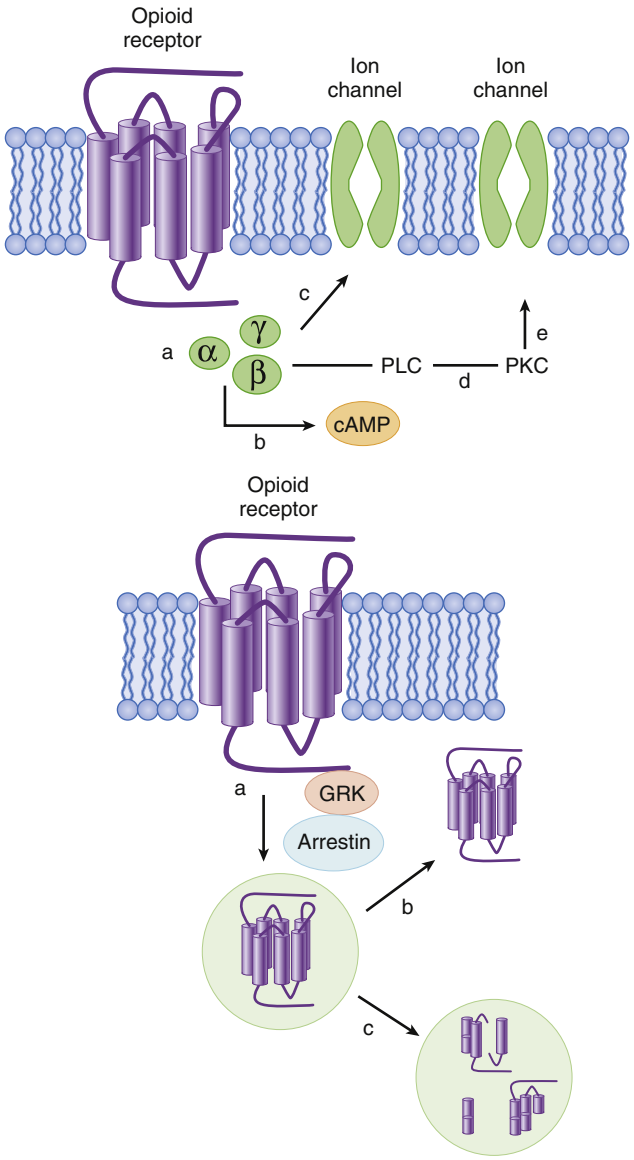

Figure 64-3. Opioid receptor signaling and recycling. *Upper panel:* Opioid ligands induce a conformational change at the receptor that allows coupling of G-proteins to the receptor. The heterotrimeric G-protein dissociates into active Gα and Gβγ subunits *(a),* which can inhibit adenylyl cyclase and reduce cyclic adenosine monophosphate (cAMP) *(b),* decrease the conductance of voltage-gated calcium (Ca^{2+}) channels, or open rectifying potassium (K^+) channels *(c).* In addition, the phospholipase C (PLC)/phosphokinase C (PKC) pathways can be activated *(d)* to modulate Ca^{2+} channel activity in the plasma membrane *(e). Lower panel:* Opioid receptor desensitization and trafficking is activated by G-protein–coupled receptor kinases (GRK). After arrestin binding, the receptor is in a desensitized state at the plasma membrane *(a).* Arrestin-bound receptors can then be internalized via a clathrin-dependent pathway and can either be recycled to the cell surface *(b)* or degraded in lysosomes *(c). (Modified from Zöllner C, Stein C: Opioids,* Handb Exp Pharmacol *177:31-63, 2007.)*

(encoding β-endorphin), proenkephalin (encoding Met-enkephalin and Leu-enkephalin), and prodynorphin (encoding dynorphins). These peptides contain the common Tyr-Gly-Gly-Phe-Met/Leu sequence at their amino terminals, known as the opioid motif. β-Endorphin and the enkephalins are potent antinociceptive agents acting at μ and δ receptors. Dynorphins can elicit both pronociceptive and antinociceptive effects through NMDA receptors and κ opioid receptors, respectively. A fourth group of tetrapeptides (endomorphins) with yet unknown precursors does not contain the pan-opioid motif but binds to μ receptors with high selectivity. Opioid peptides and receptors are expressed throughout the central and peripheral nervous systems, in neuroendocrine tissues, and in immune cells.[10,51] Extracellular opioid peptides are susceptible to rapid enzymatic inactivation by aminopeptidase N and neutral endopeptidase. Both peptidases are expressed in the central nervous system, peripheral nerves, and leukocytes; among opioids, enkephalins are considered their preferred substrates. Preventing the extracellular degradation of endogenous opioid peptides by peptidase inhibitors, both in central and peripheral compartments, has been shown to produce potent analgesic effects in many animal models and in some small human trials.[52,53]

The commonly available opioid drugs (morphine, codeine, methadone, and fentanyl and its derivatives) are μ agonists. Naloxone is a nonselective antagonist at all three receptors. Partial agonists must occupy a greater fraction of the available pool of functional receptors than full agonists to induce a response of equivalent magnitude. Mixed agonist-antagonists (buprenorphine, butorphanol, nalbuphine, and pentazocine) may act as agonists at low doses and as antagonists (at the same or a different receptor type) at higher doses. Such compounds typically exhibit ceiling effects for analgesia, and they may elicit an acute withdrawal syndrome when administered together with a pure agonist. All three receptors (μ, δ, κ) mediate analgesia but have differing side effects. μ Receptors mediate respiratory depression, sedation, reward and euphoria, nausea, urinary retention, biliary spasm, and constipation.[54] κ Receptors mediate dysphoric, aversive, sedative, and diuretic effects. δ Receptors mediate reward and euphoria, respiratory depression, and constipation.[51] Immunosuppressive effects of opioids were frequently proposed in experimental trials but have not been verified in clinical studies.[55] Tolerance and physical dependence may occur with prolonged administration of pure agonists, and abrupt discontinuation or antagonist administration can result in a withdrawal syndrome (see also the later section on perioperative management of patients with chronic pain).

Tolerance describes the phenomenon that the magnitude of a given drug effect decreases with repeated administration of the same dose, or that increasing doses are needed to produce the same effect. Tolerance is not synonymous with dependence (see the later section on perioperative management of patients with chronic pain). All opioid effects (e.g., analgesia, nausea, respiratory depression, sedation, constipation) can be subject to tolerance development, albeit to different degrees. For example, tolerance to respiratory depression, sedation, and nausea often develops faster than does tolerance to constipation or miosis[54-57] (see also the later section on other analgesics and adjuvants). Incomplete cross-tolerance among opioids or genetic differences may explain clinical observations that switching drugs ("opioid rotation") is occasionally useful in patients with inadequate pain relief or intolerable side effects.[58] Opioid-induced adaptations occur at multiple levels in the nervous and other organ

systems, beginning with direct modulation of opioid receptor signaling and extending to complex neuronal networks including learned behavior. Proposed mechanisms in pharmacodynamic tolerance include opioid receptor–G-protein uncoupling, decreased receptor internalization and recycling, and increased sensitivity of the NMDA receptor[51,59] (see Fig. 64-3, *bottom*). In addition, pharmacokinetic (e.g., altered distribution or metabolism of the opioid) and learned tolerance (e.g., compensatory skills developed during mild intoxication), as well as increased nociceptive stimulation by tumor growth, inflammation, or neuroma formation, may be possible reasons for increased dose requirements.[56,60] Carefully controlled studies that unequivocally demonstrate pharmacodynamic tolerance to opioid analgesia (i.e., reduction of clinical pain) in patients are lacking.[61]

Whether opioids may paradoxically induce hyperalgesia continues to be debated. However, most studies have, in fact, shown withdrawal-induced hyperalgesia, a well-known phenomenon following the abrupt cessation of opioids (see also the later section on perioperative management of patients with chronic pain).[62,63] At ultralarge doses, occasionally encountered in patients with extreme cancer pain, singular cases of allodynia have been observed and attributed to neuroexcitatory effects of opioid metabolites.[64] No conclusive evidence indicates that hyperalgesia occurs during perioperative or long-term administration of regular opioid doses in patients.[62]

Opioids are effective in the periphery (e.g., topical or intraarticular administration, particularly in inflamed tissue), at the neuraxis (intrathecal, epidural, or intracerebroventricular administration), and systemically (intravenous, oral, subcutaneous, sublingual, or transdermal administration).[51,65] The clinical choice of a particular compound or its formulation is based on pharmacokinetic considerations (route of administration, desired onset or duration, lipophilicity) and on side effects associated with the respective route of drug delivery.[65] Dosages depend on patients' characteristics, the type of pain, and the route of administration. Systemically and spinally administered opioids can produce similar side effects, depending on dosage and rostral or systemic redistribution. For intrathecal application, lipophilic drugs are preferred because they are trapped in the spinal cord and are less likely to migrate to the brain within the cerebrospinal fluid. Adverse side effects can be minimized by careful dose titration and close patient monitoring, or these effects can be treated by comedication (antiemetics, laxatives) or opioid receptor antagonists (e.g., naloxone). No significant side effects have been reported for the peripheral (e.g., topical) application of small, systemically inactive doses of opioids. Current research pursues the development of systemically applicable peptidase inhibitors and opioids aiming at the selective activation of peripheral but not central opioid receptors.[10,52,53,66,67]

Opioids are considered the most effective analgesics for severe acute and cancer-related chronic pain. However, the long-term use of opioids in chronic noncancer (e.g., neuropathic, musculoskeletal) pain is highly controversial. Randomized controlled trials (RCTs) have been conducted only for a maximum period of 3 months. In meta-analyses, the reduction in pain scores was clinically insignificant, and epidemiologic data suggest that quality of life and functional capacity are not improved.[68,69] Adverse side effects (e.g., nausea, sedation, constipation, dizziness) and lack of analgesic efficacy led to the dropout of high numbers of subjects, both in RCTs and in uncontrolled observational studies beyond 3 months.[69,70] Psychosocial outcome variables were rarely investigated and showed only modest improvement. Thus, consistent with the multifactorial nature of chronic pain, opioids alone probably cannot produce an analgesic response. Examples would be the presence of a major affective component or a situation in which learned pain behavior is the main problem; clearly, the entire patient must be evaluated, not just the pain.[71] The target of intervention is not only the source of nociception (if at all identifiable) but suffering, dysfunction, psychosocial factors, and dependence on the health care system. In addition, addiction has been reported in up to 50% of patients treated with opioids for chronic pain,[72,73] and overdoses, death rates, and abuse of prescription opioids have become public health problems.[74,75] Thus, the use of opioids as a sole treatment modality in chronic nonmalignant pain is not recommended.

NONSTEROIDAL ANTIINFLAMMATORY DRUGS AND ANTIPYRETIC ANALGESICS

The acidic NSAIDs and the nonacidic antipyretic analgesics (e.g., acetaminophen, phenazones) inhibit COX, the enzyme that catalyzes the transformation of arachidonic acid (a ubiquitous cell component generated from phospholipids) to prostaglandins and thromboxanes (see also Chapter 32).[76] Two isoforms, COX-1 and COX-2, are constitutively expressed in peripheral tissues and in the central nervous system. In response to injury and inflammatory mediators (e.g., cytokines, growth factors), both isoforms can be up-regulated, resulting in increased concentrations of prostanoids. In the periphery, prostanoids (mainly prostaglandin E_2 [PGE_2]) sensitize nociceptors by phosphorylation of ion channels (e.g., Na^+, TRPV1) through EP receptor activation. As a result, nociceptors become more responsive to noxious mechanical (e.g., pressure, hollow organ distention), chemical (e.g., acidosis, bradykinin, neurotrophic factors), or thermal stimuli. In the spinal cord PGE_2 blocks glycinergic neuronal inhibition, enhances excitatory amino acid release, and depolarizes ascending neurons. These mechanisms facilitate the generation of impulses within nociceptors and their transmission through the spinal cord to higher brain areas. By blocking COX, prostanoid formation diminishes. Subsequently, nociceptors become less responsive to noxious stimuli, and spinal neurotransmission is attenuated.

Less severe pain states (e.g., early arthritis, headache) are commonly treated with nonselective NSAIDs (e.g., aspirin, ibuprofen, indomethacin, diclofenac) or antipyretic analgesics (e.g., acetaminophen), mostly used orally. Some analgesic drugs are available for parenteral, rectal, or topical application. Over-the-counter availability and self-medication have led to frequent abuse and toxicity.[77] Adverse side effects are attributed to COX-1–induced blockade of thromboxane production and impairment of platelet function (gastrointestinal and other bleeding disorders), decrease of tissue-protective prostanoids

(gastrointestinal ulcers, perforation), decrease of renal vasodilatory prostanoids (nephrotoxicity), and formation of highly reactive metabolites (acetaminophen hepatotoxicity). The development of selective COX-2 inhibitors was driven by the assumptions that COX-2 expression is selectively induced in inflamed tissue and that the constitutive tissue-protective COX-1 would be spared. It has now become clear that COX-2 expression is constitutive in many tissues (e.g., gastrointestinal epithelium, vascular endothelium, spinal cord), and COX-2 inhibition may exacerbate inflammation, impair ulcer healing, and decrease formation of vasoprotective prostacyclin. COX inhibitors confer an increased risk of thrombosis, myocardial infarction, renal impairment, hypertension, stroke, and liver toxicity, and they can cause rare anaphylactic reactions. Acetaminophen (paracetamol) has relatively weak antiinflammatory and antiplatelet activity and is used for osteoarthritis, headache, and fever.[76,78]

SEROTONERGIC DRUGS

Serotonin (5-hydroxytryptamine [5-HT]) is a monoamine neurotransmitter found in the sympathetic nervous system, in the gastrointestinal tract, and in platelets. It acts on 5-HT receptors expressed at all levels of the neuraxis and on blood vessels. Within the dorsal horn of the spinal cord, serotoninergic neurons contribute to endogenous pain inhibition. With the exception of 5-HT_3 (a ligand-gated ion channel), 5-HT receptors are G-protein–coupled receptors. 5-$HT_{1B/1D}$ agonists (triptans) have been studied extensively and are effective against neurovascular (migraine, cluster) headaches. Migraine is thought to be related to the release of neuropeptides (e.g., calcitonin gene–related peptide) from trigeminal sensory neurons innervating meningeal and intracranial blood vessels. This process leads to vasodilation, an inflammatory reaction, and subsequent pain. Triptans inhibit neurogenic inflammation through 5-HT_{1D} receptors on trigeminal afferents, with possible additional sites of action on thalamic neurons and in the periaqueductal gray. The activation of vascular 5-HT_{1B} receptors constricts meningeal (and coronary) vessels. These last effects have stimulated a search for nonvasoconstrictor approaches such as highly selective $5HT_{1D}$ and $5HT_{1F}$ agonists. However, none has demonstrated clinical antimigraine effects so far.

Triptans can be applied orally, subcutaneously, or transnasally, and these drugs have been used in the treatment of migraine. All triptans narrow coronary arteries through 5-HT_{1B} receptors by up to 20% at clinical doses and should not be administered to patients with risk factors for coronary, cerebrovascular, or peripheral vascular disease. Some triptans have the potential for significant drug-drug interactions (e.g., with monoamine oxidase inhibitors, propranolol, cimetidine, hepatic cytochrome P450–metabolized medications, or p-glycoprotein pump inhibitors). Rational use of triptans should be restricted to patients with disability associated with migraine.[79]

ANTIEPILEPTIC DRUGS

Antiepileptics are used in neuropathic pain resulting from lesions to the peripheral (e.g., diabetes, herpes) or central nervous system (e.g., stroke) and for migraine prophylaxis. Neuropathic syndromes have been attributed to ectopic activity in sensitized nociceptors from regenerating nerve sprouts, recruitment of previously "silent" nociceptors, or spontaneous neuronal activity (or any combination of these processes). These events may result in sensitization of primary afferents and subsequent sensitization of second- and third-order ascending neurons. Among the best studied mechanisms are the increased expression and trafficking of ion channels (e.g., Na^+, Ca^{2+}, TRP) and increased activity at glutamate (NMDA) receptor sites. The mechanisms of action of antiepileptics include neuronal membrane stabilization by blockage of pathologically active voltage-sensitive Na^+ channels (carbamazepine, phenytoin, lamotrigine, topiramate), blockage of voltage-dependent Ca^{2+} channels (gabapentin, pregabalin), inhibition of presynaptic release of excitatory neurotransmitters (gabapentin, lamotrigine), and enhanced activity of GABA receptors (topiramate).[80,81]

The most common adverse effects are impairments in mental status (somnolence, dizziness, cognitive impairment, fatigue) and motor function (ataxia), which limit clinical use, particularly in older patients. Serious side effects have been reported, including hepatotoxicity, thrombocytopenia, and life-threatening dermatologic and hematologic reactions. Plasma drug concentrations should be monitored.[79] Antiepileptics are frequently coadministered with antidepressants.

ANTIDEPRESSANTS

Antidepressants are used in the treatment of neuropathic pain, headache, and other conditions. They are divided into nonselective norepinephrine–5-HT reuptake inhibitors (amitriptyline, imipramine, clomipramine, duloxetine, venlafaxine), preferential norepinephrine reuptake inhibitors (desipramine, nortriptyline), and selective 5-HT reuptake inhibitors (citalopram, paroxetine, fluoxetine). The reuptake block leads to a stimulation of endogenous monoaminergic pain inhibition in the spinal cord and brain. Tricyclic antidepressants also have NMDA receptor antagonist, endogenous opioid enhancing, Na^+ channel blocking, and K^+ channel opening effects, which can suppress peripheral and central sensitization. Block of cardiac ion channels by tricyclic antidepressants can lead to arrhythmias. The selective 5-HT transporter inhibitors have a different side effect profile and are safer in cases of overdose. Tricyclic antidepressants require monitoring of plasma drug concentrations to achieve optimal effect and avoid toxicity, unless sufficient pain relief is obtained with low doses. Patients with ischemic heart disease may have an increased risk of sudden arrhythmia, and in patients with recent myocardial infarction, arrhythmia, or cardiac decompensation, tricyclic antidepressants should not be used at all. Tricyclic antidepressants also block histamine, cholinergic, and adrenergic receptor sites. Adverse events of antidepressants include sedation, nausea, dry mouth, constipation, dizziness, sleep disturbance, and blurred vision.[82,83]

TOPICAL ANALGESICS

The topical application of various analgesics is an area of considerable interest because many chronic pain syndromes depend to some degree on the peripheral activation of primary afferent neurons. The localized administration

can potentially optimize drug concentrations at the site of pain generation while avoiding high plasma levels, systemic side effects, drug interactions, and the need to titrate doses into a therapeutic range. RCTs have demonstrated effectiveness for topical NSAIDs, tricyclic antidepressants, capsaicin, local anesthetics, and opioids.[79,84,85]

Topical NSAIDs are typical over-the-counter medications, widely advertised and used for acute and chronic pain. Many formulations (cream, gel, ointment) are commercially available, with varying drug delivery to the skin and subcutaneous tissues. Meta-analyses concluded that topical NSAIDs are effective in osteoarthritis.[77] Local adverse effects include rash and pruritus. A topical tricyclic (doxepin) showed efficacy in a mixed group of patients with neuropathic pain and, as a mouthwash, in patients with chemotherapy-induced oral mucositis. Side effects included burning discomfort.[84]

Capsaicin is the active pungent ingredient in chili peppers. Topically applied capsaicin interacts with nociceptive neurons through the vanilloid receptor (TRPV1). It causes an initial activation of these neurons with release of substance P. This action is perceived as a burning or itching sensation with a flare response and occurs in a high number (≤80%) of patients. After repeated application desensitization occurs, probably secondary to depleting sensory neurons of substance P. Another potential mechanism is a direct neurotoxic effect resulting in the degeneration of small-diameter sensory nerve fibers.[84] Topical capsaicin was shown to provide pain relief in postherpetic neuralgia, postmastectomy syndrome, osteoarthritis, and a variety of neuropathic syndromes. Systematic reviews revealed moderate to poor effectiveness, with numbers needed to treat between 5.7 and 12.[86,87] Thus, topical capsaicin may be a supplement for the treatment of neuropathic pain in a limited number of patients unresponsive to or intolerant of other therapeutic approaches.

Topical formulations of local anesthetics block Na^+ channels in primary afferent neurons. Blockade of Na^+ channels reduces impulse generation both in normal and in damaged sensory neurons. Such neurons exhibit spontaneous and ectopic firing, possibly contributing to certain conditions of chronic neuropathic pain. Under these conditions the altered expression, distribution, and function of ion channels along axons is associated with increased sensitivity to local anesthetics. Thus, pain relief can be achieved with local anesthetic concentrations lower than those that totally block impulse conduction.[88] Controlled studies using lidocaine patches and gels showed reduction of allodynia in postherpetic neuralgia.[79,89] In addition, patients with painful diabetic polyneuropathy, complex regional pain syndrome, postmastectomy syndrome, or postthoracotomy syndrome have been shown to experience pain relief. Except for skin irritation, no reports of serious side effects have been published. Gel formulations of lidocaine were also beneficial in diabetic neuropathy and oral mucositis.[90,91]

Topically applied or locally injected opioids produce analgesia by activating opioid receptors on primary afferent neurons. This action leads to inhibition of Ca^{2+}, Na^+, and TRPV1 currents, which are activated by inflammatory agents.[10,92] Subsequently, the excitability of nociceptors, the propagation of action potentials, and the release of proinflammatory neuropeptides (substance P) from sensory nerve endings are inhibited. All these mechanisms result in analgesia or antiinflammatory effects, or both.[9,10,67] Other mechanisms accounting for the particular efficacy of peripheral opioids in pain associated with inflammation include up-regulation[93] and accelerated centrifugal transport of opioid receptors in sensory neurons,[94] enhanced G-protein coupling of peripheral opioid receptors,[95] and disruption of the perineural barrier facilitating access of opioid agonists to their receptors.[96,97] Consistently, the perineural application of opioids along uninjured nerves (e.g., axillary plexus) does not reliably produce analgesic effects.[98] In addition, the production and secretion of endogenous opioid peptides from immune cells within inflamed tissue[2,14] appear to produce additive-synergistic interactions,[99] rather than tolerance at peripheral opioid receptors.[100] Peripheral opioid administration is regularly used and well documented in the case of perioperative intraarticular morphine.[101-103] Intraarticular morphine also produces analgesia in chronic rheumatoid and osteoarthritis. In these diseases, the potency of its effect was shown to be similar to that of standard intraarticular steroids and long lasting (≤7 days), possibly because of morphine's antiinflammatory activity.[10,67] In numerous small studies, locally applied opioids (e.g., in gels) have shown analgesic efficacy in the treatment of skin ulcers, cystitis, cancer-related oral mucositis, corneal abrasion, and bone injury. No significant adverse effects have been reported.[84,85]

OTHER ANALGESICS AND ADJUVANTS

Local anesthetics have been used topically, orally, intravenously, in trigger point injections, and in regional anesthetic techniques for selected chronic pain syndromes (see the later section on interventional methods used in chronic pain and also Chapters 30, 36, 56, and 57). The systemic application of local anesthetics (e.g., oral mexiletine) exhibited mixed success in various neuropathies. Evidence supports mexiletine as a third-line drug in selected patients with diabetic neuropathy.[79] Meta-analyses indicated that intravenous local anesthetics produce moderate analgesic effects of questionable clinical significance in neuropathic pain.[104,105] Severe side effects including arrhythmias, dizziness, nausea, and fatigue limit the systemic application of local anesthetics.

α_2-Adrenergic receptors are G-protein coupled. Similar to opioids, α_2-agonists (clonidine) lead to opening of K^+ channels, inhibition of presynaptic Ca^{2+} channels, and inhibition of adenylyl cyclase. Thus, like opioids, α_2-agonists reduce neurotransmitter release and decrease postsynaptic transmission, resulting in an overall inhibitory effect.[106] Epidural or systemic clonidine is analgesic in patients with complex regional pain syndrome and in neuropathic and cancer pain. However, its use is limited by a frequent incidence of sedation, hypotension, and bradycardia.[79] Flupirtine is used in musculoskeletal pain, but its mechanism of action is unknown. Initial studies postulated involvement of descending adrenergic pathways, indirect actions at NMDA receptors, and activation of G-protein–regulated K^+ channels.[107]

Cannabinoids have been studied extensively in the past decade. Animal and in vitro models have shown that derivatives of tetrahydrocannabinol produce

antinociceptive effects and that cannabinoid receptors and their endogenous ligands are expressed in pain processing areas of the brain, spinal cord, and periphery.[10,108] Peripheral cannabinoid receptors likely play a prominent role in pain inhibition.[10] Meta-analyses of human studies concluded that the analgesic effects of cannabinoids are modest, not superior to those of other analgesics, and of questionable clinical significance. Psychotropic side effects, sedation, dizziness, cognitive impairment, nausea, dry mouth, and motor deficits are limiting factors in clinical practice.[109]

Drugs reducing muscle spasm (e.g., benzodiazepines) are often used in musculoskeletal pain. However, the available evidence does not indicate lasting beneficial effects, and drowsiness and dizziness are frequently encountered[110] (see also Chapter 30). Baclofen activates $GABA_B$ receptors presynaptically and postsynaptically, thereby leading to a decrease in excitatory and an increase in inhibitory neurotransmission. In some reports, baclofen was found to exhibit analgesic effects in trigeminal neuralgia and central neuropathic pain. The most common side effects are drowsiness, dizziness, and gastrointestinal distress.[111] Botulinum toxin inhibits acetylcholine release at the neuromuscular junction and may alleviate muscle spasticity. The use of botulinum toxin injections has produced inconsistent results in headaches,[112] and it was not effective in myofascial trigger points, orofacial, or neck pain.[113-115] Side effects include pain and erythema at the injection site and unintended paralysis of adjacent muscles.[116]

The synthetic peptide ziconotide blocks N-type voltage-sensitive Ca^{2+} channels and thereby inhibits release of excitatory neurotransmitters from central terminals of primary afferent neurons in the spinal cord. Ziconotide has been approved for intrathecal application. However, it produces substantial side effects (dizziness, confusion, abnormal gait, memory impairment, nystagmus, hallucinations, vertigo, delirium, apnea, hypotension) and thus is suitable for only a small subset of patients with otherwise intractable (e.g., neuropathic) pain.[117] Under the assumption of antiinflammatory activity, steroid injections are frequently used epidurally or perineurally, albeit without convincing evidence for effectiveness (see the later section on therapeutic nerve blocks).

Antiemetics are used to treat nausea, a frequent side effect of analgesics (particularly opioids) and a frequent complaint in patients with cancer (see Chapters 96 and 97). Recommendations for the treatment of postoperative nausea and vomiting cannot readily be extrapolated to the patient with chronic pain. For example, in patients with cancer, causes other than opioids must be considered, such as radiation therapy and chemotherapy, uremia, hypercalcemia, bowel obstruction, and increased intracranial pressure. In addition, pain itself, as well as anxiety, can cause nausea. Opioid-related nausea usually diminishes by tolerance within a few days (see also Chapter 31). Management guidelines for the treatment of nausea and vomiting are available, and the selection of antiemetics should be mechanism based[54,118] (see also Chapters 96 and 97). The medullary chemoreceptor trigger zone, gastrointestinal stimulation or failure, and vestibular and cortical mechanisms, as well as alterations of taste and smell, may contribute to nausea and vomiting, particularly in patients with cancer. Most recommendations for the choice of antiemetic medication include gastrointestinal prokinetics (metoclopramide), phenothiazines (e.g., levomepromazine), dopamine receptor antagonists (e.g., haloperidol), serotonin antagonists (e.g., ondansetron), and antihistamines (e.g., cyclizine). In addition, the use of dexamethasone (unknown mechanism), anticholinergics (e.g., scopolamine), and neurokinin-1 receptor antagonists has been reported. Combinations of antiemetics with different modes of action can be used. Many of these drugs cause undesirable side effects by themselves (e.g., sedation, drowsiness, confusion, and extrapyramidal symptoms).[54,118] The efficacy of cannabinoids and benzodiazepines is considered comparatively low, and these drugs are not recommended as first-line treatment.[118,119]

Laxatives are indicated when bowel movements are less frequent than three per week and are associated with difficulty or discomfort. Risk factors for constipation include opioid medication, older age, advanced cancer, hypokalemia, and immobilization, as well as therapy with tricyclic antidepressants, phenothiazines, anticonvulsants, diuretics, and iron supplements. Opioid-related constipation is mediated through intestinal and (partially) through central μ receptors.[51,120] It is the most commonly occurring side effect of opioid medication in patients with cancer and frequently does not exhibit tolerance. Ample fluid intake, fiber-rich nutrition, and mobilization are nonpharmacologic approaches to prophylaxis. Laxatives include the following: bulk-forming, osmotic, and hyperosmolar agents; substances for colonic lavage; prokinetic drugs; and opioid antagonists. Recommendations usually include lactulose, senna, or polyethylene glycol as a first choice.[54] However, lactulose should be avoided in patients with impaired fluid intake, such as older adults and patients with advanced cancer. If this approach is insufficient, the drugs of first choice may be combined with paraffin or anthraglycosides (bisacodyl). Rectal sorbitol and contrast medium are the choices for the next more intensified step. Prokinetic drugs, such as metoclopramide, are sometimes added for refractory constipation. Possible alternatives in opioid-related constipation are opioid antagonists. To avoid central effects that reduce analgesia or produce withdrawal, oral naloxone and the peripherally restricted antagonists methylnaltrexone and alvimopan were developed. The use of these drugs in clinical practice is limited by relatively low response rates, adverse effects, and high costs.[120,121] In malignant bowel obstructions, different algorithms must be followed.[122]

DEVELOPMENT OF NOVEL ANALGESICS

Areas of intense research and examples emerging as potential drug targets include opioid receptors, cannabinoid receptors, bradykinin receptors, Na^+ channels expressed in peripheral nociceptive neurons ($Na_v1.8$, $Na_v1.7$), voltage-gated Ca^{2+} channels (e.g., $Ca_v2.2$), K^+ channels, the capsaicin receptor TRPV1, and the P2X receptors[123] (see also Chapter 32). Increasing attention is paid to novel enzyme inhibitors that prevent the degradation of endogenous opioids and cannabinoids, with a focus on the activation of peripheral receptors to avoid central side effects,[52,53] as well as to nanomaterials for drug delivery.[124] However, failures

in clinical phases of analgesic drug development are common and have been attributed to inappropriate animal models or nociceptive tests, species differences, publication bias, lack of mechanistic understanding, and shortcomings in experimental design, randomization, blinding, and statistical analysis.[20,22]

INTERVENTIONAL METHODS USED FOR CHRONIC PAIN

The popularity of interventional methods has decreased over time. Although early pain therapists (e.g., Leriche) were generally using "blocks" to treat pain, the biopsychosocial concept of chronic pain led to a much more cautious and judicial use of such techniques (see the earlier section on interdisciplinary management of chronic pain), particularly because most of these methods are not evidence based. Block therapy alone is usually not curative, but it can facilitate participation in rehabilitation and therefore does have a role in the management of chronic pain. Regardless of which procedure is considered, a consensus decision on its use must be reached within the interdisciplinary team.[40]

DIAGNOSTIC NERVE BLOCKS

Neural blockade is thought to be a useful tool to understand the mechanisms underlying pain in an individual patient better and to provide a prognosis for planned neuroablative procedures, particularly in cancer pain (see also Chapters 57 and 58). Differential blockade aims to block either single peripheral nerves selectively, to identify an anatomic pain source, or to block only one type of nerve fiber selectively (autonomic versus somatic).[125] Often active and nonactive compounds are injected sequentially to differentiate drug-related from placebo responses. Differential neural blockade can be performed at the peripheral and central (neuraxial) level. A popular protocol is the sequential intrathecal application of short- and long-acting local anesthetics (or opioids), or increasing concentrations of a local anesthetic. Diagnostic neural blockade is used in low back pain, headache, neuropathic pain, and complex regional pain syndrome. Examples include zygapophyseal (facet) joint injections and medial branch blocks,[126] sacroiliac joint injections,[127] trigger point injections, spinal nerve blocks, occipital nerve blocks, and sympathetic blocks.[125] Sympathetic blocks may be achieved by local anesthetic injections at the sympathetic chain (e.g., stellate ganglion) or by intravenous regional infusions of sympatholytic drugs (e.g., phentolamine). However, an extensive review of the experimental and clinical literature concluded that none of these procedures has unequivocally proved clinical usefulness in controlled studies.[125] This finding was confirmed in systematic reviews.[126,127] In particular, the validity of diagnostic nerve blocks is limited by the complexity of factors determining pain perception (see the earlier sections on biopsychosocial concept of pain and interdisciplinary management of chronic pain). Furthermore, the assumption that local anesthetics can selectively produce conduction block of only one fiber type in a nerve is probably false.[125] Nevertheless, experienced and observant clinicians have found that such procedures may occasionally provide information that is helpful in guiding subsequent therapy even though systematic reviews have methodologic limitations.[128,129] Provided the clinician takes great care in carrying out the technique, interpreting the results, and integrating them into interdisciplinary decisions, nerve blockade may still play a role in the comprehensive diagnostic workup of patients with chronic pain.[125]

THERAPEUTIC NERVE BLOCKS

Cancer Pain

Therapeutic nerve blocks are used for only a minority of patients in the management of cancer-related pain. In these cases, interventional treatment represents the fourth step in the World Health Organization analgesic ladder.[130] Approximately 90% to 95% of patients usually obtain adequate pain relief from pharmacologic management.[131] A comprehensive biopsychosocial approach to pain management and careful balancing of the risks against the benefits in individual patients are prerequisites for successful use of interventional techniques.[132] Therapeutic nerve blocks extend the treatment range when conservative methods fail to achieve tolerable pain or side effect levels, or both. For example, neuropathic pain and incidental (breakthrough) pain are sometimes poorly controlled by systemic analgesics and may be indications for invasive therapy. Well-evaluated interventional techniques such as celiac plexus block, hypogastric plexus block, and saddle blocks should not be withheld from patients with cancer in the context of palliative symptom control.[133]

In patients with unresectable pancreatic cancer, neurolysis of the celiac plexus may be used for pain treatment (Fig. 64-4). Patients with other upper abdominal

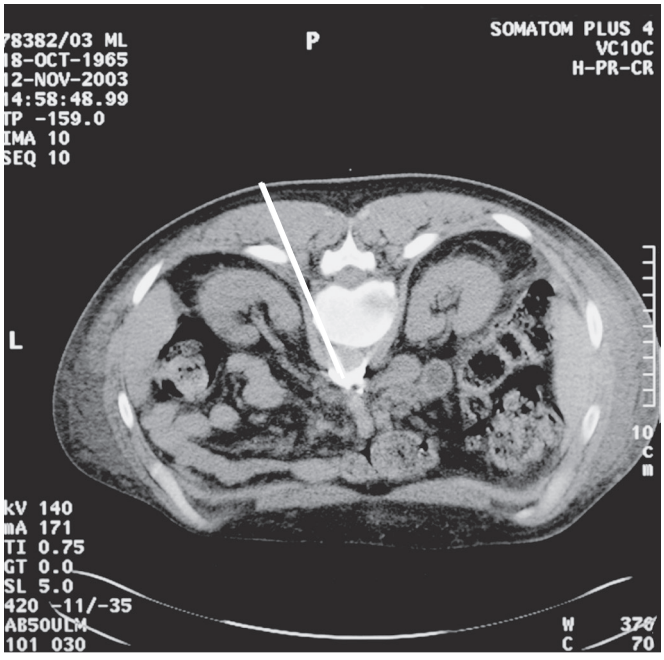

Figure 64-4. Transaortic approach for neurolysis of the celiac plexus with typical dye distribution ventral to the aorta. For details see text.

malignancies, such as hepatic or gastric cancer, may also benefit from this intervention. This technique is based on the assumption that nociceptive stimulation is transmitted along primary afferent fibers that travel with the sympathetic fibers of the splanchnic nerves arising from T5-T12 and with the parasympathetic efferent fibers that together form the celiac plexus. The ganglia are situated in the retroperitoneal space adjacent to the L1 vertebral body. Anatomic landmarks can be identified with the help of computed tomography, fluoroscopy, and ultrasound,[134] and they are particularly recommended for celiac plexus blocks.[135,136] The most common dorsal techniques include the bilateral transcrural and unilateral transaortic approaches using alcohol (50% to 100%) or phenol (7% to 12 %).[131] In patients undergoing laparotomy, intraoperative neurolysis of the celiac plexus can also be used.[137] Most centers advocate a diagnostic local anesthetic block to predict analgesic and side effects (mostly diarrhea and hypotension).[138] Systematic reviews of RCTs comparing neurolytic celiac plexus blockade with standard treatment (oral NSAIDs and morphine) plus sham blockade, or sham blockade alone, concluded that celiac plexus neurolysis was associated with lower pain scores, decreased morphine use, and reduced constipation, albeit with minimal clinical significance.[133,139]

Less common sites for neurolyses are intercostal nerves (e.g., in rib metastasis), the superior hypogastric ganglion, the ganglion impar, and the lumbar sympathetic ganglia (e.g., for pelvic tumors). In perineal pain secondary to local infiltration of rectal cancer, intrathecal neurolysis may be considered if bladder and sphincter function is not of concern.[133,140] An indication for thoracic intrathecal or epidural neurolysis may be advanced lung cancer.[141] As a neurolytic agent, alcohol may be preferred because of its perceived higher success rate and longer duration of pain relief (3 to 6 months) compared with phenol (2 to 3 months), although no studies directly comparing these two agents are available. Depending on the patient's survival prognosis, the duration of pain relief provided by alcohol may be sufficient.

A diagnostic local anesthetic block to predict analgesic and side effects is advocated. Because alcohol is hypobaric and phenol is hyperbaric, the patient must be positioned accordingly during administration of intrathecal neurolysis. In many cases, pain relief is incomplete, but intake and side effects of opioids decrease. The limited period of pain reduction and the limited possibility of repeat injections are reasons that neurolysis is mostly used in patients with short life expectancies.[142]

Non–Cancer-Associated Pain

Both the complexity of factors contributing to pain perception and perpetuation (see the earlier sections on the biopsychosocial concept of pain and interdisciplinary management of chronic pain) and the detrimental long-term effects of nerve destruction (neuropathic pain caused by spontaneous ectopic neuronal discharges, up-regulation of neuronal ion channels, and excitatory amino acid receptors (see the earlier sections on the physiologic changes in persistent pain and antiepileptic drugs) caution against neuroablative procedures in the patient who does not have cancer. Nonetheless, many practitioners advocate radiofrequency ablations or cryoneurolysis at facet joints and sacroiliac joints, as well as several other destructive procedures.[143,144] However, such interventions did not provide long-term pain relief in RCTs,[145,146] or in systematic reviews,[147] except for the use of pulsed radiofrequency in cervical radicular pain.[148]

Nondestructive procedures include trigger point, epidural, perineural, and intraarticular injections of local anesthetics or steroids, or both. Steroids are used under the assumption of antiinflammatory activity. For example, in chronic back or neck pain (the most common patient complaints), injections into facet or zygapophyseal joints or along the medial branch from the posterior ramus of the spinal nerve root are frequently performed, although without convincing documented long-term results.[146,147] Similarly, injections into sacroiliac joints, trigger points, or occipital nerve blocks show no consistent long-lasting effects.[128,149,150] Epidural steroids are also used extensively for low back and neck pain,[151] but they provided questionable long-term pain relief in RCTs,[152] and these injections are recommended only after careful individual patient selection.[153] The same applies to lumbar transforaminal epidural steroid injections.[154] Although it has been asserted that transforaminal steroid injections are more efficacious than interlaminar injections, supporting evidence is limited. In summary, epidural steroids may provide short-term relief for radicular symptoms, but only limited long-term effects for relief of back pain.[155] Further, no evidence indicates that the addition of other agents such as hyaluronic acid produces better results.[146,152] Neither preoperative nor postoperative nerve blocks provide consistent improvement of phantom limb pain.[156] Some RCTs indicate that epidural or intrathecal steroids with local anesthetics can be effective in herpes zoster and postherpetic neuralgia.[157] In addition, local infiltration of herpes zoster lesions provides inconsistent relief of pain.

Sympathetic nerve blocks with local anesthetics, often carried out as a series, such as in herpes zoster–associated pain and complex regional pain syndrome, are commonly used, but evidence from RCTs is lacking. Especially in adolescents and children, the role of sympathetic and other nerve blocks has been questioned.[158] Some studies were able to demonstrate short-term effects, but no clear reduction of the risk to develop postherpetic neuralgia.[157,159] Similarly, the long-term effectiveness of sympathetic blockade in complex regional pain syndrome was not demonstrated in RCTs.[160,161] Anecdotal reports have described sympathetic blocks for ischemic pain, such as in peripheral vascular or Raynaud disease.

In contrast to the lack of evidence for long-term effects, interventional techniques can produce short-term pain relief. In the context of interdisciplinary management, such techniques can be effectively used to facilitate initial physical therapy in chronic nonmalignant pain.[143,162]

CONTINUOUS CATHETER TECHNIQUES

Continuous drug delivery to the intrathecal or epidural space can be accomplished by using programmable implanted pumps, implanted accessible reservoir systems, and tunnelled exteriorized catheters. The principal benefit

appears to be the reduction of systemic side effects. As with nerve blocks, the evidence of effectiveness of these approaches is stronger for cancer pain than for chronic nonmalignant pain.

Cancer Pain

Only a few patients with cancer require neuraxial drug delivery because of intolerable side effects, but in patients refractory to systemic analgesics, such methods may be underused.[163,164] The preponderance of evidence supporting this mode of drug delivery is derived from nonrandomized, uncontrolled studies.[134,165] The advantage of the epidural technique is its ubiquitous availability in most anesthesia departments, but its disadvantages are the chance of inhomogeneous distribution of the analgesics, high drug volume requirements and possible systemic absorption, and limited duration of therapy as a result of local granuloma formation and technical failures.[134] The intrathecal approach allows homogeneous distribution of the analgesics, low-volume injections, control of catheter positioning with cerebrospinal fluid aspiration, and long-term therapy with minimal infection rates, although case reports on catheter tip inflammatory granulomas have occurred. Usually, morphine (1 to 5 mg, depending on the preceding systemic dosage) or hydromorphone is recommended as a drug of first choice. For refractory pain, combinations with bupivacaine, clonidine, ziconotide, and other compounds have been used.[165] This approach should be used only if the treatment facility has the capacity for emergency in-house treatment, 24-hour emergency calls, and adequate home care service with stringent protocols to avoid infections. To transfer the patient from high-dose systemic analgesia to intraspinal analgesia, 24-hour monitoring is required. The initial intrathecal morphine dose is approximately 1% of the oral morphine equivalent. Thereafter, the systemic opioid dose is reduced by 50% and then is slowly tapered by 10% daily to avoid withdrawal, at the same time allowing usual systemic opioid doses as rescue medication.

Non–Cancer-Associated Pain

No RCTs are available, but observational reports described continuous catheter techniques for chronic noncancer pain.[134,166] Most of these studies used intrathecal morphine, and some used hydromorphone, baclofen, or ziconotide in patients with chronic low back pain. On average, these patients exhibited increasing daily morphine doses over time and a high incidence (≤25%) of complications, such as catheter obstruction, catheter-tip granuloma formation, pruritus, urinary retention, and infection. Effectiveness of these techniques in relieving pain or improving function compared with placebo, natural history, or other treatments either has not been shown[134,166] or is limited.[167]

STIMULATION TECHNIQUES

Stimulation techniques frequently used in pain management include acupuncture, spinal cord (or dorsal column) stimulation (SCS), and transcutaneous electrical nerve stimulation (TENS). Acupuncture has long been popular among patients and lately has also generated interest within the conventional medical community. Systematic reviews of sham-controlled studies in migraine prophylaxis and arthritic pain showed that treatments using traditional Chinese concepts of meridians and specified classic points are as effective as the selection of acupuncture points at random.[168,169] The conclusion was that acupuncture has no specific effect compared with standard medical migraine prophylaxis.[168] In osteoarthritis, adequately blinded studies yielded inconclusive results.[169,170] In rheumatoid arthritis, acupuncture was not recommended.[171] In chronic low back pain, several reviews concluded that, in the long term, acupuncture is not more effective than other treatments.[172-174] With respect to pain relief in patients with cancer, available data do not support the effectiveness of acupuncture, either.[175]

The idea of modulating neural transmission by electrical stimulation dates back to ancient Rome, with the observation that gout pain was alleviated through accidental contact with a torpedo fish. The gate control theory of pain in the 1960s proposed that pain perception was influenced by the balance of firing between large and small nerve fibers, and that retrograde nonpainful stimulation of large fibers would "close the gate" by adjusting the level of voltage.[134] This theory prompted the development of TENS, SCS, and various techniques of brain stimulation that have been applied in patients with refractory complex regional pain syndrome or neuropathic, low back, and ischemic pain. None of these methods have been validated by adequately powered and blinded RCTs for chronic pain.[176,177] Unblinded studies suggest that selected patients with complex regional pain syndrome or back pain, especially with failed back surgery syndrome, may benefit from SCS, but controlled trials are needed.[178] Complications include electrode displacement, infection, and battery failure.[177,179] Because it is noninvasive and easy to administer, TENS is used widely. However, systematic reviews of its application for chronic low back pain[180] and painful rheumatoid arthritis or osteoarthritis[181,182] have not yielded conclusive evidence of its effectiveness.

PERIOPERATIVE MANAGEMENT OF PATIENTS WITH CHRONIC PAIN

CHARACTERISTICS OF PATIENTS WITH CHRONIC PAIN IN THE PERIOPERATIVE PERIOD

The patient with chronic pain has certain distinctive features important for perioperative management (see also Chapter 98). Enhanced central sensitization or reduced endogenous inhibition may result in increased and prolonged pain after surgery.[183] Moreover, altered opioid sensitivity secondary to long-term exposure to opioid medications must be considered.[184] Patients with chronic pain also frequently exhibit higher preoperative expectations of pain, anxiety, depression, or hypervigilance.[185,186] It may be difficult to distinguish normal from maladaptive anxiety, but patients with cancer pain are more likely to be anxious than are patients with cancer who do not have pain. In addition, the patient with chronic pain, including the patient with cancer, is not as

BOX 64-1 ***Risk Factors in the Perioperative Management of the Patient With Chronic Pain***

- Conventional perioperative analgesia regimens do not meet the needs of the patient with chronic pain.
- Unrelieved postoperative pain resulting from undermedication may provoke withdrawal.
- Patients tend to underreport their medication.
- With uncontrolled anxiety or fear of pain, patients tend to overestimate the effect of painful stimuli.
- Epidural and intravenous opioid (including PCA) requirements can be two to four times higher in opioid-consuming than in opioid-naïve patients.
- Expect prolonged recovery and the need for postoperative analgesia.
- Anxiety and insufficient coping result in poor compliance with analgesic strategies.
- Individual variations in response to opioids may necessitate selection of the optimal drug and dosing by sequential trials.
- Individual titration of doses is required to find the optimal balance between analgesia and adverse effects.
- Adjuvant medication may interfere with anesthesia and postoperative analgesia.

PCA, Patient-controlled analgesia.

confident of recovery as are other patients with chronic diseases.[187] Thus, difficult perioperative pain control and, possibly, an increased risk of chronic pain development after surgery must be expected. However, patients with chronic pain, with or without long-term opioid medication, opioid abuse, or opioid misuse, require and must receive adequate pain control.

The preanesthetic visit should therefore include questions regarding chronic pain and regular use of analgesics and adjuvant medication (see also Chapter 38). Although some characteristics, including increased opioid demand, underreporting of pain, and noncompliance, are known, only few specific recommendations are available, such as adequate increase of opioid dose for analgesia, continuation of preoperative analgesics to prevent withdrawal, and intensive education to strengthen the patient's coping potential. No differences among specific techniques for postoperative analgesia (e.g., systemic patient-controlled, or regional analgesia) have been demonstrated so far. Furthermore, preoperative intensity of pain alone, independent of the use of analgesics, correlates positively with postoperative pain.[188] Patients with chronic pain often suffer from prolonged inactivity or neurologic deficits, or both, that increase the risk for adverse events during the perioperative period. Some key issues are summarized in Box 64-1.

LONG-TERM USE OF ANALGESICS AND ADJUVANT DRUGS

Patients with chronic pain are often pretreated with opioids, COX inhibitors, and antidepressants or anticonvulsants, or both. Tolerance, drug interactions, and side effects may occur. In addition, inappropriate or excessive medication is commonly observed.[74,75,189] Patients with chronic pain tend to underestimate and underreport their medication use.[190] Thus, undertreatment in the perioperative period may be unnoticed and may induce a neuroexcitatory withdrawal syndrome with associated cardiopulmonary strain.

Long-term opioid medication has been discussed thoroughly in the literature (see the earlier section on opioids). Together with aggressive marketing, this information has gradually led to decreasing reservations among practitioners toward the use of these drugs. As a result, opioids are used more frequently in patients with cancer pain and noncancer pain, and most patients with noncancer pain are now prescribed opioid medication.[74,75,190] Although this approach this seems justified in cancer pain and certain chronic destructive diseases, indications for the use of opioids in patients with chronic noncancer pain are less convincing (see the earlier section on opioids). Nevertheless, anesthesia providers are increasingly confronted with patients receiving long-term opioid treatment. Such pretreatment can result in a severalfold increased and prolonged requirement for systemic and epidural analgesics in the perioperative period compared with opioid-naïve patients.[57,61,191,192] Patients with chronic pain and prior opioid consumption may also exhibit higher postoperative pain scores.[192] The increased postoperative analgesic demands may result from lower pain thresholds or a need for higher drug concentrations. In addition, opioid requirements can be influenced by gender, genetic predisposition, age, type of surgery, and preoperative pain levels.[58,188] Conversely, opioid-related side effects (e.g., nausea and pruritus) may be less dominant. Physicians and nurses may overestimate tolerance, addiction, and sedation but underestimate dependence. A paramount concern is the maintenance of adequate perioperative opioid dosing to prevent withdrawal[61,192] (see Box 64-1).

COX inhibitors are the most commonly used nonopioid analgesics. Unlike opioids, they are not associated with tolerance and physical dependence, but they produce serious side effects, mainly in the gastrointestinal tract, kidneys, and cardiovascular and coagulation systems (see the earlier section on drugs used for chronic pain). Major concerns for the anesthesiologist are coagulation disturbances and the increased risk for hematoma formation associated with spinal and epidural anesthesia. Practice guidelines do not differentiate between selective COX-2 and nonselective COX inhibitors. European and American societies disagree in their recommendations. Before neuraxial anesthesia, a 24- to 72-hour (in case of aspirin) drug-free interval is recommended by the German Society of Anesthesiology and Intensive Care Medicine and by the Spanish Consensus Forum, whereas the American Society of Regional Anesthesia and Pain Medicine does not believe that these drugs pose any added significant risk. This discrepancy likely arises from the findings that the development of a spinal or epidural hematoma is a rare event (≈1 in 220,000 spinal and 1 in 150,000 epidural anesthetics) and that none of the studies to date has a large enough patient population to predict the risk of hematoma formation when COX inhibitors are continued preoperatively.[193]

Antiepileptic drugs can interfere with anesthesia in different ways. Sedation produced by anticonvulsant drugs may have additive effects with anesthetics, whereas drug-induced enzyme induction could alter responses to or contribute to the organ toxicity of anesthetics. Gabapentin has a favorable side effect profile, and its relative absence of drug interactions allows continuation and rapid titration in the perioperative period.[194] Phenytoin and carbamazepine accelerate recovery from nondepolarizing muscle relaxants, but the mechanism is unclear. Preoperative exclusion of toxic serum levels of phenytoin is recommended, to reduce the risk of atrioventricular conduction block. States of disorientation, nystagmus, ataxia, and diplopia may be manifestations of excessive plasma concentrations. Carbamazepine may produce sedation, ataxia, nausea, and (rarely) bone marrow depression or hepatorenal dysfunction. Plasma sodium levels must be monitored perioperatively to avoid hyponatremia. Oral valproic acid is commonly used for prophylaxis of migraine, and intravenous valproic acid may be used to control episodic headaches.[195] This drug may inhibit activity of hepatic microsomal enzymes and interfere with platelet aggregation.[196] To avoid central nervous system hyperexcitability, antiepileptics should never be discontinued abruptly. Stable dosages must be maintained throughout the perioperative period.

Antidepressants are frequently used for neuropathic pain and for associated depression. Adverse effects are numerous and include sedation, anticholinergic effects, and cardiovascular changes. Electrocardiographic changes can occur, such as prolongation of the PR interval and widening of the QRS complex, but previous suggestions of increased risk of perioperative cardiac dysrhythmias have not been substantiated in the absence of drug overdose.[197] Therefore, antidepressants need not be discontinued before anesthesia, but increased anesthetic requirements may be expected because of enzyme induction. Postoperatively, the likelihood of delirium and confusion may be increased as a result of additive anticholinergic effects. Selective serotonin reuptake inhibitors and atypical antidepressants such as mirtazapine or venlafaxine are less likely to interfere with anesthesia.

Ketamine is a mixed opioid agonist–NMDA antagonist that can produce analgesia at subanesthetic doses in selected patients with neuropathic pain[198,199] (see also Chapter 32). Very rarely, patients taking oral ketamine medication on a long-term basis are encountered. In these cases, perioperative administration of ketamine should be discontinued because correct conversion from oral to intravenous ketamine is difficult.[200] Within analgesic dose ranges, the risk of a withdrawal syndrome is small.[199,201]

Benzodiazepines are not analgesic and are rarely used in chronic pain, with the exception of palliative care situations.[110,202] Nevertheless, chronic pain is a predictor of increased benzodiazepine use.[203] Side effects relevant to anesthesia include sedation and skeletal muscle weakness. Because of the long half-life of these drugs, delayed withdrawal should be anticipated and avoided by maintaining stable perioperative dosage. Neuroleptics are also inappropriate, but they are sometimes used in chronic pain.[79] In the perioperative period, patients treated with antipsychotic drugs can develop a neuroleptic malignant syndrome. Hyperthermia, hypertonicity of skeletal muscles, fluctuating levels of consciousness, and autonomic nervous system instability are typical symptoms (see also Chapter 43).

DEPENDENCE, ADDICTION, AND PSEUDOADDICTION

Physical dependence is defined as a state of adaptation that is manifested by a drug class–specific withdrawal syndrome that can be elicited by abrupt cessation, rapid dose reduction, decreased blood level of the drug, or administration of an antagonist (see also Chapter 110).[204] Dependence is not synonymous with tolerance (see the earlier section on opioids). All opioids, benzodiazepines, and anticonvulsants produce clinically relevant physical dependence when administered for a prolonged period of time, but sometimes physical dependence can develop within hours of agonist exposure.[205] Thus, all patients with continuous preoperative opioid intake should be considered at risk for withdrawal syndrome if adequate substitution of opioids in the perioperative period is withheld. Opioid and benzodiazepine withdrawal syndromes, especially tachycardia and hypertension, may be detrimental for the high-risk cardiac patient. Rapid withdrawal from anticonvulsant drugs may trigger seizures, anxiety, and depression.

Addiction is a behavioral syndrome characterized by evidence of psychological dependence (craving), uncontrolled or compulsive drug use despite harmful side effects, and other drug-related aberrant behavior (e.g., altering prescriptions, manipulating health care providers, drug hoarding or sales, unsanctioned dose escalation).[72,204] The prevalence of opioid addiction is as high as 50% in patients with chronic nonmalignant pain and up to 8% in patients with cancer pain.[72,73] Many issues regarding patients with chronic pain who consume opioids also apply to patients who abuse or are addicted to opioids. The daily dose of opioids in abusing or addicted patients is typically larger, such patients often have coexisting psychiatric diseases (depression, anxiety, psychosis). In addition, the known history of abuse may lead to tempered use of opioids by health care providers, a practice that makes these patients particularly vulnerable to inadequate postoperative pain control.[61] Further special considerations in the management of the drug-addicted patient are discussed in the literature.[61,192,206]

Pseudoaddiction describes a situation in which medical personnel do not provide a sufficient dosage of medication, thereby provoking repetitive demands from the patient for analgesics. This may be interpreted as "drug-seeking behavior." Pseudoaddiction can be avoided with adequate algorithms and regular education of health care providers.[56]

MANAGEMENT AND PRACTICAL RECOMMENDATIONS

Perioperative management must address the risk of opioid withdrawal, the altered pain sensitivity, and the psychological alterations typical in the population

of patients with chronic pain. Most of the following recommendations must be considered "expert views" only.[192,207,208]

Preoperative Evaluation

Preanesthesia evaluation is necessary to educate patients, to organize resources for preoperative improvement of the patient's physical function, to choose optimal anesthetic techniques, and to formulate plans for postoperative recovery, including perioperative pain management[61] (see also Chapter 38). Misconceptions about the surgical procedure, the role of the anesthesiologist in perioperative care, and postoperative pain treatment are common among patients.[209] A thorough history must be obtained to identify all preoperative medications, including opioids, other analgesics, and adjuvants, as well as signs of psychiatric comorbidity and aberrant drug-related behavior. Patients with spinal cord stimulators should be instructed to turn off their devices.[210] Screening tools and thorough education of the patient are recommended.[186,211] Consultation of a pain specialist should always be considered. Pertinent issues and practical recommendations are summarized in Boxes 64-1 and 64-2.

BOX 64-2 ***Preoperative Considerations and Recommendations in Patients With Chronic Pain***

- Take a thorough history to identify all analgesic and adjuvant medications, risk factors, and comorbidity.
- Educate the patient about the perioperative procedures, the potential for aggravated pain, and increased opioid requirements.
- Communicate plans among the designated anesthesiologist in the operating room, the postanesthesia care unit, and the surgical and nursing personnel on the ward.
- Differentiate among addiction, pseudoaddiction, and physical dependence in patients receiving long-term opioid medication.
- Expect physical dependence in patients receiving long-term opioid medication.
- Continue previous long-acting opioid analgesics for short procedures.
- For major surgery, calculate and order the background infusion of an equianalgesic opioid dose to be started in the operating room for patients with NPO status for more than 8 hours.
- Order regular opioid medication on the morning of surgery.
- Maintain anticonvulsant drugs and benzodiazepines at preoperative doses.
- Discontinue all other adjuvants if NPO status lasts longer than 24 hours.
- Identify an untreated depressive disorder with screening questions for disturbed sleep, lowered mood, and reduced concentration, self-confidence, and motivation.
- Identify an untreated anxiety disorder with screening questions for restlessness, irritability, difficulties in controlling anxiousness, and worrying.
- Consider referral to a pain specialist for evaluation.
- Choose regional or general anesthesia based on individual considerations.

Data from Farrell C, McConaghy P: Perioperative management of patients taking treatment for chronic pain, BMJ *345:e4148, 2012; and Kopf A, Banzhaf A, Stein C: Perioperative management of the chronic pain patient,* Best Pract Res Clin Anaesthesiol *19:59-76, 2005.*
NPO, Nothing by mouth.

Perioperative Management

To avoid opioid withdrawal, the preoperative systemic dosage should be continued throughout the perioperative period, and mixed agonist-antagonists (buprenorphine, nalbuphine) must be avoided (see also Chapters 38 and 40). If a neuraxial catheter with opioid medication is used, the flow and concentration of the opioid should be continued throughout the perioperative period as background analgesia.[212] For minor surgery and for surgical procedures between minor and major surgery, oral slow-release opioid medication may be continued at its regular intervals. For major surgery with postoperative restriction of enteral intake, oral opioids should be discontinued and replaced by equivalent doses of intravenous opioids, which must be continued for the entire perioperative period. This applies to general and regional anesthesia. The anesthesia technique should be selected on an individual basis, considering the patient's expectations, because no data are available favoring general, regional, or combined anesthesia for this patient population.[208] The frequency and extent of monitoring techniques should be adapted to the patient's risk of instability.

Pain should be periodically assessed during emergence and recovery.[213] For thorough evaluation of pain relief, functional criteria (ability to cough, breathe deeply, perform physical therapy, ambulate) should be used in conjunction with patient-generated pain ratings to determine the end points for analgesic therapy. Pain acts as an antagonist to central nervous system depressants, and in particular to the respiratory depressant effects of opioids. Thus, any surgical procedure that removes a major nociceptive stimulus (e.g., an infiltrating tumor) may lead to unopposed opioid-mediated respiratory depression or somnolence in the postoperative period.

For patients without chronic pain, RCTs suggest that adequate postoperative analgesia by a multimodal approach may facilitate the return of gastrointestinal function, be cardioprotective, reduce pulmonary complications, and shorten the length of stay in the intensive care unit and the hospital.[214] Whether these findings are applicable to patients with chronic pain is unknown. Individually adapted regimens are usually superior to "conventional" analgesia, regardless of the specific analgesia technique used.[215] In minor surgery and in surgical procedures between minor and major surgery, an opioid-NSAID combination should always be considered to enhance opioid effects. Because pregabalin and gabapentin can reduce postoperative pain and opioid consumption[216] and have anxiolytic effects,[217] the patient with chronic pain and anxiety may benefit. A dose range for pregabalin of 150 mg twice daily until the second or third postoperative day has been recommended.[207] Ketamine may also be applied as an adjunctive therapy,[199] but no data encourage its routine use in the perioperative period for the patient with chronic pain. Support from a multimodal pain treatment facility should be requested. Apart from the choice of analgesia technique and adequate opioid medication, optimization of organizational structures is a key factor for improving perioperative analgesia.[218] If addiction is suspected, the patient should be reevaluated for weaning or rehabilitation only after recovery from surgery and

postoperative pain.[219] Specific risk factors in patients with chronic pain are summarized in Box 64-1.

Postoperative Regional Anesthesia

Although no strong evidence indicates the superiority of particular anesthetic techniques for postoperative analgesia in patients with chronic pain, individual considerations may favor regional anesthesia, particularly because these patients are prone to intensified postoperative pain experiences (see also Chapter 98). Patients who have been consuming opioids on a long-term basis need their daily systemic dosage by the intravenous or oral route to prevent withdrawal.[61] In addition, postoperative analgesia with an epidural or plexus catheter may be accomplished with a combination of local anesthetics and opioids, similar to patients without chronic pain (see Chapters 56 and 98). However, higher doses of epidural opioids are recommended because cross-tolerance between orally and epidurally administered opioids has been described. Epidural lipophilic opioids (fentanyl, sufentanil) may provide better postoperative pain relief than epidural morphine in patients who have been consuming opioids on a long-term basis; this effect has been attributed to the need for a lower receptor occupancy or incomplete cross-tolerance between morphine and sufentanil.[220]

Postoperative Intravenous Opioids

The total required opioid dose consists of the daily dose taken before and the dose made necessary by surgical stimulation (see also Chapter 98). A continuous perioperative intravenous opioid infusion equivalent to the regular daily dosage is recommended if the oral route is unavailable.[61,215] Additional bolus doses of opioid or nonopioid analgesics, or both, must be titrated to individual needs to achieve adequate pain control in the postanesthesia care unit. Depending on the local circumstances, this may be patient, nurse, or physician controlled. The bolus size should be equal to the hourly dose of the background infusion. Once the patient demands less than four extra bolus doses per day, the background infusion may be reduced in daily steps of approximately 20% to 30%. For calculation of opioid dose equivalents, the relative potency, half-life, bioavailability, and route of administration must be considered.[221] As soon as possible, oral medication should be resumed. Intravenous doses during the first 24 to 48 hours after surgery should be converted to oral dose equivalents. Half the total dosage may be delivered as long-acting and half as short-acting breakthrough medication.[61]

Perioperative Transdermal Opioids

Transdermal fentanyl patches are relatively reliable in administering controlled amounts of the drug to the circulation over long periods. However, during surgery the amount of drug delivered to the patient may significantly shift. Changes in intravascular volume, body temperature, and volatile anesthetics alter skin permeability and perfusion, thus resulting in relatively large fluctuations in transdermal fentanyl passage. In addition, forced-air warming blankets and heat packs applied onto the patch itself can lead to severalfold increases in fentanyl permeation through the skin.[57] Thus, in major surgery, removal of transdermal systems is advisable to avoid unforeseen decreases and increases of systemic opioid uptake. The transdermal opioid dose should be converted to intravenous morphine to be administered as a continuous background infusion.[221] Pertinent issues and practical recommendations are summarized in Box 64-3.

BOX 64-3 ***Intraoperative and Postoperative Management Issues and Practical Recommendations in Patients With Chronic Pain***

- Start the background opioid infusion immediately when the patient arrives in the operating room.
- Remove an opioid-patch when major surgery is planned; in minor surgery, a patch may be continued without a background infusion.
- Every patient with chronic pain must be seen postoperatively three times daily to evaluate pain at rest, pain with exercise (e.g., coughing), nausea, sedation, mobilization, and sleep quality.
- Monitor closely for signs of respiratory depression and of withdrawal (e.g., unexplained tachycardia, restlessness, sweating, confusion, hypertension).
- Integrate the patient into the acute pain service protocol if available.
- Titrate a short-acting opioid for acute pain with two to four times the usual starting dose needed for an opioid-naïve patient.
- Add COX inhibitors, anticonvulsants, and other adjuvants as needed.
- Evaluate the demand-delivery ratio of PCA frequently, and adapt the demand dose in relation to the background infusion (the demand dose equals the hourly dose of background infusion).
- Increase the background infusion in PCA in relation to the cumulative daily opioid demand dose (add 50% to 75% of the daily demand dose to background infusion).
- Change the technique of postoperative analgesia if inadequate use persists in spite of repeated patient education.
- In case of insufficient epidural analgesia with morphine, use epidural fentanyl or sufentanil.
- In case of IV opioid dose escalation, consider spinal or epidural opioid application or switch to an IV agonist.
- Reduce daily opioid doses after the second postoperative day stepwise to the preexisting dose.
- Switch back to an oral or transdermal medication as early as possible: use 50% to 75% of the last daily IV opioid dose as slow release oral or transdermal delivery plus the rest as a demand dose.
- When switching back to the transdermal route, consider 12- to 16-hour delayed effects, and supply the patient for this period with sufficient on-demand analgesia.
- Do not attempt to solve a chronic pain problem in the immediate postoperative period.
- Use nonpharmacologic techniques (distraction, relaxation) when appropriate, and offer counseling in the pain unit after postoperative recovery.

Data from Farrell C, McConaghy P: Perioperative management of patients taking treatment for chronic pain, BMJ *345:e4148, 2012; and Kopf A, Banzhaf A, Stein C: Perioperative management of the chronic pain patient,* Best Pract Res Clin Anaesthesiol *19:59-76, 2005.*

COX, Cyclooxygenase; *IV,* intravenous; *PCA,* patient-controlled analgesia

Chapter 65

Palliative Medicine

SARAH GEBAUER

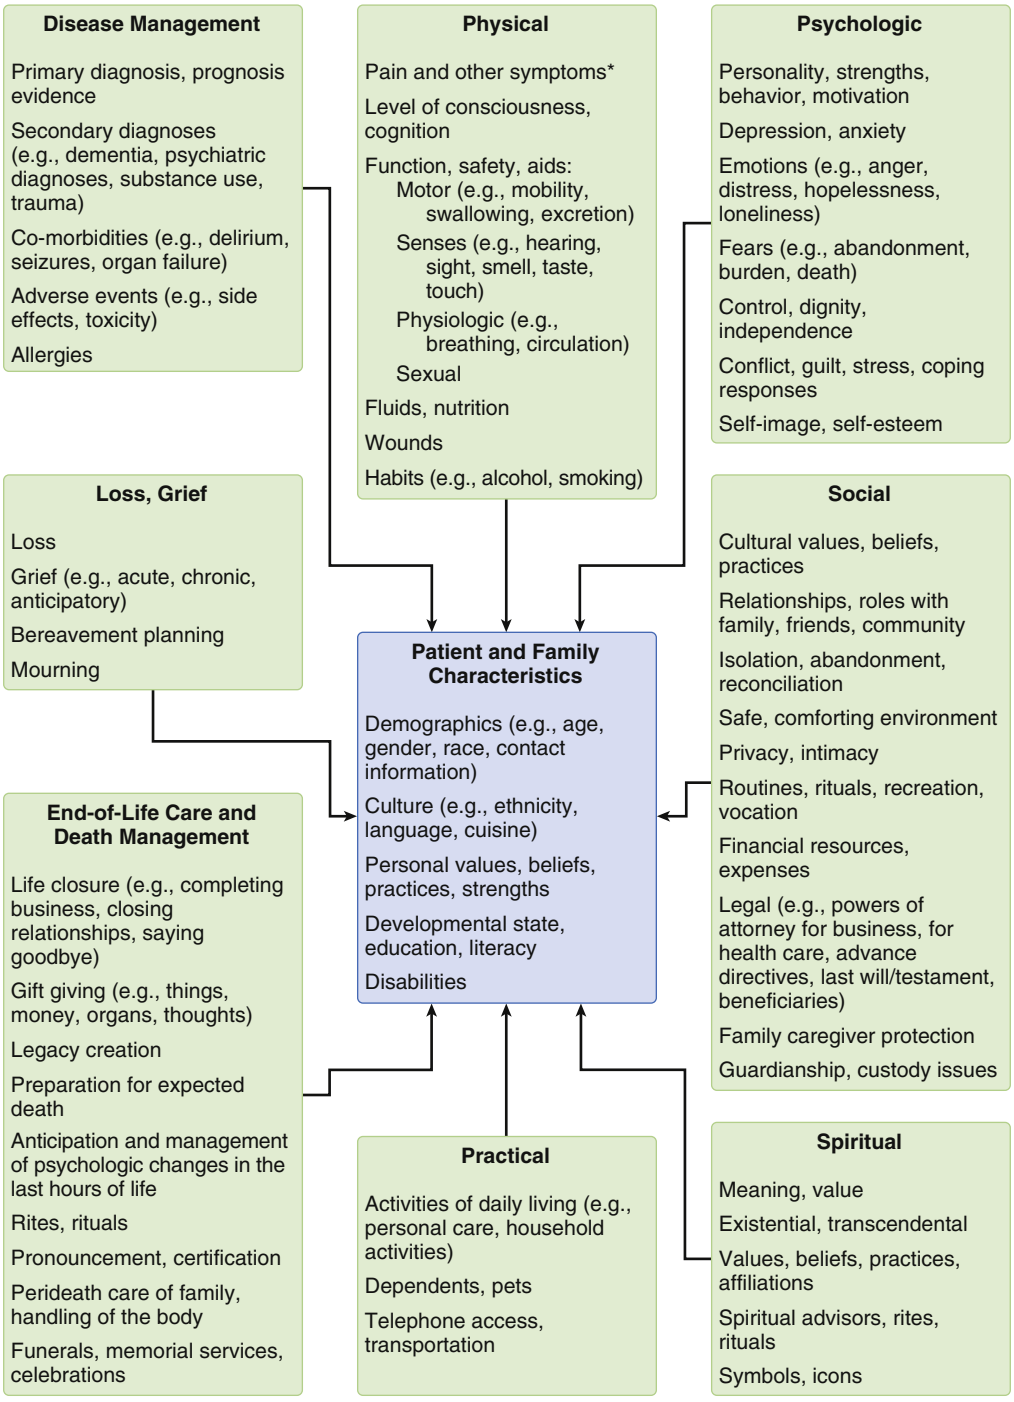
Key Points

- Palliative care is an interdisciplinary approach to symptom management and decision making in treating serious illnesses that are appropriate for patients with a wide range of illnesses and is not limited to patients who are imminently expected to die.
- Palliative care teams reduce costs and decrease the burden of symptoms for patients with serious illnesses.
- Physicians receive little training in discussing difficult topics and tend to focus on details and use medical jargon.
- Patients and families want physicians to be truthful and empathetic and to participate in shared decision making.
- Physicians have difficulty prognosticating the future for an individual patient. Patients and families understand and accept this reality.
- Opioids administered in small doses do not hasten death in patients receiving palliative care and are effective in treating dyspnea.
- Patients with perioperative limitations on treatment should prompt a thorough discussion of a perioperative plan with the patient and surgical team.

WHAT IS PALLIATIVE MEDICINE?

DEFINITION

The World Health Organization (WHO) defines palliative care as "an approach that improves the quality of life of patients and their families facing the problem associated with life-threatening illness, through the prevention and relief of suffering by means of early identification and impeccable assessment and treatment of pain and other problems, physical, psychosocial and spiritual."[1] Illness has many facets, and symptom management, family support, and aid in decision making are common areas of focus for palliative care teams[2] (Fig. 65-1). Palliative care refers to the work of an interdisciplinary team, whereas palliative medicine refers to the medical subspecialty focused on providing symptom relief and decision-making support for patients with serious illnesses.



PRIMARY VERSUS SPECIALIST PALLIATIVE MEDICINE

A distinction has been made among the levels of palliative care. This distinction facilitates the differentiation among the skills expected from all physicians and from those more suitable to a specialist service. Examples of primary palliative medicine include basic pain and symptom management, as well as discussions about prognosis, goals of treatment, and resuscitation status.[3] Specialty palliative medicine includes the management of refractory or complex symptoms, as well as the facilitation of conflict resolution among families, staff members, and treatment teams related to the goals of care.[4]

HISTORY OF PALLIATIVE MEDICINE

The word *palliative* comes from the Latin word *to clothe* and refers to the "covering up" of symptoms such as pain. Modern palliative medicine grew out of the hospice movement that was started by Dr. Cicely Saunders in the late 1960s.[5] Since that time, the field has broadened from a focus on patients at the end of life to include patients with serious illnesses, with the growing recognition that many hospice principles, such as the relief from suffering, also apply to patients regardless of prognosis[6] (Fig. 65-2). After its introduction to the United States in the 1970s, several academic medical centers developed palliative care teams in the 1990s to meet this growing need.[6]

Inpatient palliative care teams have rapidly grown over the past decade,[7] and currently 85% of hospitals with more than 300 beds and 63% of hospitals with 50 or more beds have palliative care teams.[8] Hospice and palliative medicine became a recognized subspecialty in 2006, with the first board examinations offered in 2008. Physicians from 10 medical specialties, including anesthesiology, are eligible to complete a fellowship and to take the board examination.[9] Currently, 129 anesthesiologists are board-certified or eligible to practice in hospice and palliative medicine, which represents 3% of the estimated 4400 hospice and palliative medicine physicians in the United States.[10]

* Other common symptoms include, but are not limited to:
Cardiorespiratory: breathlessness, cough, edema, hiccups, apnea, agonal breathing patterns
Gastrointestinal: nausea, vomiting, constipation, obstipation, bowel obstruction, diarrhea, bloating, dysphagia, dyspepsia
Oral conditions: dry mouth, mucositis
Skin conditions: dry skin, nodules, pruritus, rashes
General: agitation, anorexia, cachexia, fatigue, weakness, bleeding, drowsiness, effusions (pleural, peritoneal), fever/chills, incontinence, insomnia, lymphedema, myoclonus, odor, prolapse, sweats, syncope, vertigo

Figure 65-1. Aspects of illness. *(Modified from Ferris FD, Balfour HM, Bowen K, et al: A model to guide patient and family care: based on nationally accepted principles and norms of practice,* J Pain Symptom Manage *24:106-123, 2002.)*

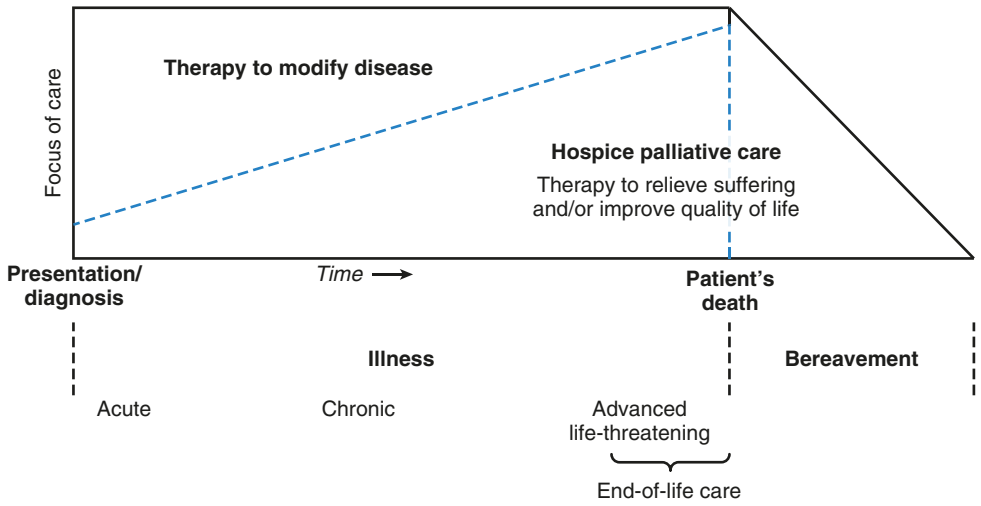


Figure 65-2. Schematic illustration depicting the role of hospice care and palliative care during illness and bereavement. *(From Ferris FD, Balfour HM, Bowen K, et al: A model to guide patient and family care: based on nationally accepted principles and norms of practice,* J Pain Symptom Manage *24:106-123, 2002.)*

WHY IS PALLIATIVE MEDICINE NEEDED?

The combination of an aging population and medical advancement has contributed to a growth in the number of patients with chronic illnesses. In the United States in 2011, Medicare spent $549 billion, with 55% of Medicare expenses going to the most expensive 10% of patients in 2008.[11] Many of these patients have multiple comorbidities, repeated or prolonged hospitalizations, or a life expectancy of less than 1 year, and many patients may be appropriate for hospice or palliative care services.[12]

Patients with serious illnesses have a significant symptom burden, most often involving pain, dyspnea, anxiety, and depression, and their family members report similar concerns.[13] Although the quality of pain control during a life-limiting illness is often a major concern of patients and their families, several surveys have found that they are often dissatisfied with the quality of pain control.[13,14] Patients and families also describe poor communication with health professionals, particularly in the setting of conversations regarding prognosis.[15] Palliative care, with its emphasis on symptom management and goal setting, attempts to address these concerns.

WHY IS PALLIATIVE MEDICINE IMPORTANT TO ANESTHESIOLOGISTS?

As patients who are older and more seriously ill undergo surgery,[16] anesthesiologists should develop an understanding of the concepts of palliative medicine. Anesthesiologists have specific skills in symptom management that may benefit the patient, and they have a unique perspective on the surgical process that can provide insight to palliative medicine and surgery teams.[17] As more patients and families interact with palliative care teams, anesthesiologists should be able to discuss related concerns and to develop an anesthetic plan that includes palliative concepts, including goals of care discussions and symptom management. Additionally, many pain and critical care anesthesiologists regularly care for patients who are seriously ill and have specific expertise to offer.

GLOBAL PALLIATIVE CARE

Approximately one half of the countries in the world have at least one hospice or palliative care service, although most exist in larger and more developed countries. The variation in availability is vast, from 1 physician for every 1000 inhabitants in the tiny country of Niue near New Zealand to 1 per 8.5 million inhabitants in China and 1 per 90 million in Pakistan.[18] In addition to the variation in physician availability, the access to appropriate medications is often restricted. An estimated 80% of people with pain worldwide are unable to access opioids, often attributable to concerns about addiction or restrictive national opioid policies.[19] The WHO has implemented a "Public Health Strategy for Palliative Care" that incorporates aspects of policy, drug availability, and education to customize and integrate palliative care throughout the globe.[20]

PALLIATIVE CARE TEAM

Guidelines suggest that professionals with skills to meet the patient and family's physical, psychological, social, and spiritual needs participate in the creation of a specialized care plan. Ideally, teams are interdisciplinary and include a nurse, physician, social worker, and chaplain, as well as other professionals, depending on the need.[21] Many professional disciplines have developed specialized certification or training in palliative care (Table 65-1).

WHERE IS PALLIATIVE CARE DELIVERED?

In the United States, palliative care is often a consult service in hospitals or in an inpatient unit.[6] Approximately two thirds of U.S. hospitals and 85% of middle-to-large hospitals have palliative teams, although access varies, depending on the geography and type of hospital.[22] Geography is an important factor in the availability of services. Seventy-three percent of Northeastern U.S. hospitals with 50 or more beds have palliative teams, whereas 51% of

TABLE 65-1 MEMBERS AND ROLES IN A PALLIATIVE CARE TEAM

Physician	• Diagnoses, treats, and manages a wide variety of medical issues for patients. • Provides expert symptom management and consultation. • Provides expert skills and consultation in communication with patients who are seriously ill, their families, and other providers.
Nurse	• Participates in the diagnosis, treatment, and management of acute and chronic serious illnesses within his or her scope of practice. • Assesses the patient's psychosocial and spiritual needs in the setting of a serious illness. • Participates in symptom management within his or her scope of practice. • Uses unique skillsets to communicate with the patient, family, health care team, and community.
Social worker	• Addresses the psychosocial needs of patients and their families affected by serious illness. • Participates in meetings with the medical team, patients, and families. • Assists in complex discharge needs, and communicates with community resources.
Spiritual advocate	• Assists patients and families in identifying and addressing spiritual distress related to serious illness. • Provides or facilitates appropriate spiritual or religious rituals. • Provides liaison services to community spiritual resources.
Additional professionals who provide expertise to the palliative care team	• Anesthesia pain experts • Pharmacists • Rehabilitation therapists • Psychiatrists

Note: Roles and competencies may vary by region and training.

Southern U.S. hospitals have palliative teams.[8] Patients admitted to the hospital are actively dying or often have symptoms that are difficult to manage, although only 20% to 26% of U.S. cancer centers offer dedicated palliative care inpatient beds.[6,23] Palliative care clinics are increasingly available, although home palliative care for patients who do not meet hospice eligibility criteria is rare in the United States, likely attributable to the reimbursement model.[6] Methods and locations of palliative care delivery are widely variable throughout the world, depending on the country's infrastructure.

INPATIENT PALLIATIVE CARE TEAMS

Outcomes With Palliative Care Teams

Inpatient palliative care teams reduce hospital costs. A retrospective study of six hospitals with well-established palliative care teams showed a decrease of $1700 per admission for patients discharged alive and $5000 for patients who died.[7] A study of Medicaid beneficiaries showed hospital costs decreased by an average of $6900 during an admission once palliative care teams became involved, with a reduced length of stay in the intensive care unit (ICU)[24] and fewer deaths in the ICU[25] (also see Chapters 101 and102). Making decisions about hospital length of stay is not clearcut.[24,26] Inpatient palliative care teams increase patient quality of life[27] and patient and caregiver satisfaction.[27] Data on symptom improvement is sparse but suggests improvement in some areas.[28,29] Importantly, palliative care teams do not increase in-hospital mortality.[24,30] This fact may be important for families and patients who incorrectly view palliative care as hastening death.

When to Consult Palliative Care Teams

A variety of indicators have been developed to help physicians decide when a palliative care assessment should be performed. Patients' palliative care needs can be assessed by the treating physician, and a consultation with a palliative medicine specialist should be made on the basis of that assessment. The first screening criterion is generally considered to be whether a patient has a condition that is potentially life-limiting or life-threatening.[31] These terms, although open to interpretation, are not meant to include patients who routinely return to their baseline status, such as a previously healthy patient with community-acquired pneumonia.[31] Rather, these terms are meant to describe patients with a condition known to be life-threatening (e.g., metastatic cancer, cirrhosis, chronic renal failure)[31] or with conditions that have a high likelihood of leading to death (e.g., multiorgan failure, major trauma, sepsis).[31] Additionally, the patient should fit at least one additional criterion, including frequent hospital admissions for the same condition, functional decline, and an ICU stay of 7 days or longer. In general, consultation is often requested for assistance with symptoms that are difficult to control, complex decision making, and provider or family support.

Palliative Care in the Surgical Intensive Care Unit

The two main models of palliative care integration in the ICU are the consultative model and the integrative model.[32] In the consultative model, a specialist palliative care team makes recommendations to the primary physician regarding the care of the patient; in the integrative model, the surgeon or intensivist identifies and addresses

issues related to palliative care without specialist input. The most effective model is not clear at this point and is often determined by hospital resources and culture (also see Chapters 101 and 102).

Although initial palliative care efforts and research have focused on medical intensive care units (MICUs), increased attention is being focused on providing palliative care to appropriate patients in the surgical intensive care unit (SICU) to improve symptom management, to communicate the goals of treatment, and to provide family support.[32] One study of patients in a trauma ICU showed early assessment of patient and family preferences and interdisciplinary meetings led to unchanged mortality, do not resuscitate (DNR) orders, and the withdrawal of life support; however, the DNR and withdrawal orders were completed early in the hospital stay, and the ICU length of stay decreased in patients who died.[26]

Trigger Criteria in the Surgical Intensive Care Unit

Identifying appropriate palliative care consultations early in the hospital course is increasingly the focus. Trigger criteria, in which a predefined list of patient factors results in automatic notification of a member of the critical care or palliative care team, are sometimes used to identify ICU consultations earlier and have shown encouraging results.[24] However, the most effective trigger criteria for surgical ICUs have not been defined.[32] Many proposals include some combination of the lengths of stay in the ICU, the lack of improvement during the ICU stay, patient age, and the patient's illness.[32] One study, specifically in the SICU, used 10 triggers based on expert opinion; these included multiorgan system failure, SICU stay longer than 1 month, greater than three SICU admissions during one hospitalization, and death expected during a current SICU admission, among other triggers.[33] This study showed no benefit with palliative care, but its applicability may have been limited. Only 6% of the patients in this study met the trigger criteria, and although the attending physician was notified when a patient met the criteria, a palliative care consultation was left to the judgment of the attending physician.[33] A more inclusive screening process or a mandated palliative care referral, as observed in some of the successful medical ICU studies,[24] may have altered these results.

OUTPATIENT PALLIATIVE CARE

Increasingly, palliative care clinics exist that can follow patients after discharge or see patients for outpatient symptom management and psychosocial support.[34] The providers, availability, and focus vary widely.[34] A landmark study by Temel in 2010 randomized 151 patients with metastatic non–small-cell lung cancer to early outpatient palliative care plus the standard oncologic care or standard oncologic care alone. Patients in the palliative care group had higher quality-of-life scores, as well as fewer symptoms of depression.[35] Perhaps most surprisingly to some, the patients in the palliative care group lived a median of 2.7 months longer than those with standard care, despite receiving less aggressive care.[35] These results and others have led to a recommendation by the American College of Chest Physicians that palliative care be introduced early in the course of disease for patients with stage IV lung cancer or a high symptom burden.[36] Smaller studies have shown positive but variable improvement in symptoms.[37,38]

Palliative Care and Hospice Care

Continuous Features

- Multidisciplinary team
- Symptom management: pain, dyspnea, psychosocial
- Focus on quality-oriented care
- Family support
- Attempts to minimize suffering

Early Palliative Care	Hospice Care
• Appropriate at any stage of serious illness	• Prognosis <6 months (can be renewed every 60 days)
• Often provided in hospitals or outpatient clinics	• Focus on home-based care
• Can be used in conjunction with "aggressive" care	• Patient usually agrees to focus on comfort rather than life-prolonging treatments
• Free-for-service model	• Throuh Medicare, billed on a per-diem rate

Figure 65-3. Features of palliative care and hospice care in the United States.

DIFFERENCES BETWEEN HOSPICE CARE AND PALLIATIVE CARE

In contrast to palliative care, the definition of hospice care varies among countries as it applies to the type of patient, the involvement of the medical team, and the setting.[39] In some countries, such as the United States, hospice care refers to a benefit provided by the governmental health care system, whereas in other countries, hospice care and palliative care are interchangeably used. In general, hospice services tend to focus on later-stage illnesses. Despite the logistic differences, the philosophy of hospice care generally focuses on reducing suffering, enhancing the quality of life, and supporting the patient and family. The available services, as well as the concerns for the patients, caregivers, and physicians, may be different, depending on the country's health care framework and culture. In the United States, palliative services are provided on a continuum, whereas hospice care is only available to patients with a life expectancy of less than 6 months (Fig. 65-3).

HOSPICE CARE IN THE UNITED STATES

In the United States, hospice is a per-diem capitated payment system for a defined set of services for patients with a life expectancy of 6 months or less, as agreed on by two physicians.[40] Medicare pays for approximately 80% of hospice care in the United States, and many private insurers have established similar guidelines. These services include visits to a patient's residence by a nurse (the main provider of clinical care[41]), aide, social worker, and chaplain.[40] Family members are also eligible to receive a year of bereavement counseling.[40] Continuous care and short-term hospital admission are available for patients with uncontrolled symptoms. A core set of requirements for the hospice benefit exists (Fig. 65-4). However, beyond these requirements, each hospice unit can decide which

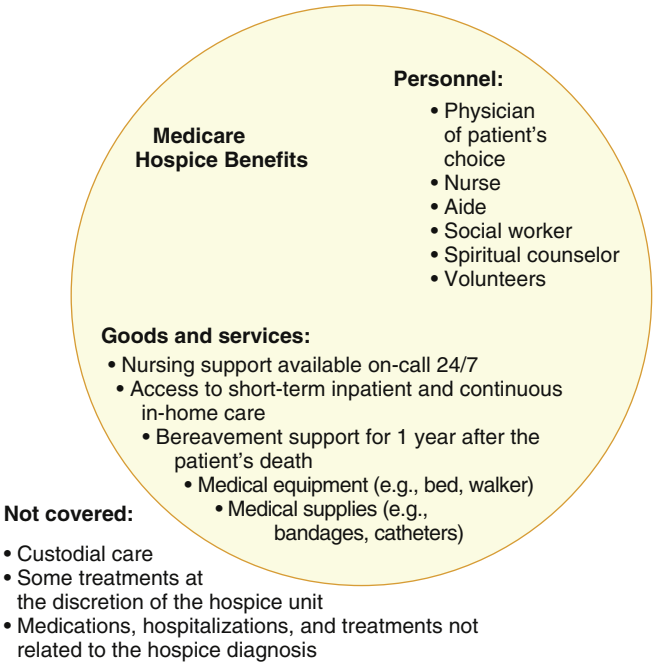

Figure 65-4. Aspects of the Medicare hospice benefits.

treatments to cover, and this coverage can vary widely. For example, some hospice organizations may cover palliative radiation treatments, whereas others may not. Patients who outlive their 6-month prognoses may have their benefits extended in 60-day increments after a face-to-face visit with a physician, recertifying that the patient continues to meet hospice criteria.

Who Is Eligible for Hospice Care?

To qualify for hospice, an attending physician and a hospice medical director must certify that the patient's prognosis is less than 6 months if the disease runs its normal course.[40] Medicare has created guidelines that describe eligibility criteria for hospice services, although the opportunity for interpretation does exist. For example, the criteria for a patient with chronic lung disease include disabling dyspnea at rest, poor response to bronchodilators, hypoxemia at rest, and repeated hospitalizations for emergency department visits.[41] As a result of the subjectivity of some of the guidelines, some hospices may accept patients that other hospices deem ineligible. Patients are not required to have a DNR order to be enrolled in hospice.

Recipients of Hospice Care

Although patients with cancer were previously the primary recipients of hospice care, the proportion of patients receiving hospice care with noncancerous diagnoses such as dementia, chronic obstructive pulmonary disease (COPD), and congestive heart failure (CHF) has increased from 16% in 1990 to 69% in 2010.[42] During this same period, the percentage of patients with Medicare who died while receiving hospice care increased from 5.5% to 44%.[42] This increase is particularly problematic, considering the lack of good prognostic criteria for a 6-month life expectancy in these disorders, which can complicate hospice referral timing.[43] The median length of stay in hospice was 18 days in 2010,[42] and approximately one third of all hospice patients live for less than 1 week after admission to hospice care.[41] This trend toward late admission suggests that many patients are referred to hospice well after they are eligible.

Outcomes with Hospice Care

Hospice care decreases patient symptom burden[44] and increases caregiver satisfaction, with 98% of family members recommending hospice care to others.[41] A survey of over 1500 bereaved family members showed that 70% of respondents whose family member received hospice services considered the care "excellent" with less than 50% of those with decedents in hospitals, nursing homes, or home with home health services considering the care received at the same level.[45] Studies related to cost-effectiveness vary in their conclusions. Yet, a few studies suggest that the length of hospice use is correlated with cost savings.[44,46] A 2007 study by Taylor suggested cost savings only with a hospice stay of 53 to 107 days,[46] whereas a 2013 study by Kelley showed cost savings with shorter hospice stays as well.[44]

HOSPICE CARE AND ANESTHESIOLOGISTS

Surgical anesthesiologists, as well as pain and critical care medicine anesthesiologists, are likely to interact with patients who are enrolled in hospice care. Awareness of the goals of care in the hospice setting and what services are provided will help the anesthesiologist develop an appropriate plan based on the individual patient's goals. Pain medicine physicians (also see Chapters 64 and 98) may be providing care as part of a hospice benefit. Critical care anesthesiologists are often called on to aid in the determination of hospice eligibility and to help families discuss care plans that may involve hospice (also see Chapters 101 and 102).

PEDIATRIC HOSPICE CARE AND PALLIATIVE CARE

Pediatric palliative care is appropriate for many children with chronic serious illnesses, and the WHO states that pediatric palliative care can be successfully delivered even in resource-limited settings.[1] Pediatric hospice and palliative care are similar to their adult counterparts, but the patient's development stage is incorporated into the pediatric care plan. Explanations of illness and death depend on the child's developmental stage; a child younger than 2 years of age has no concept of death, whereas a 10-year-old child may be interested in the details of the death process[47] (also see Chapters 93 and 95).

Characteristics of the Pediatric Palliative Care Population

The variety of diagnoses for patients in pediatric palliative care are wider than those for adults[48] with the most common disorders being congenital and neuromuscular in origin.[48] In the largest observational study to date, over one third of pediatric patients referred for palliative care consultation services were 1 to 9 years of age, one third were 10 to 18 years old, and less than 20% were

younger than 1 year of age.[48] Children often have prolonged survival after the initial palliative care consultation, compared with adults.[48] Some disorders, including chromosomal or severe developmental abnormalities, are rarely seen by adult palliative care physicians and pose additional difficulties for adult palliative care teams. The decision to forgo treatment with curative intent is generally difficult for families, and prognostication is similarly difficult for providers.[47] Moreover, multiple legal issues related to declining medical treatment exist that differ from the regulations that concern adults.[49]

Symptom Management in Pediatric Palliative Care

Historically, symptoms in children with serious illnesses have been poorly managed. In a retrospective survey of parents of deceased children in 2000, parents noted that their children suffered "a lot" or "a great deal," mostly from pain, fatigue, and dyspnea.[49] In contrast to most studies of adults near the end of life, a 2011 study noted neurologic symptoms being more prevalent than pain in children,[48] suggesting a need for a better understanding and treatment of these symptoms in the pediatric population. Regional anesthesia has been reported as being of benefit to pediatric patients with pain that is difficult to manage with systemic treatment.[50] Data on specific therapies for children are limited, and many practitioners use medications based on adult studies.

PALLIATIVE SURGERY

Palliative surgery has been defined as "the deliberate use of a procedure in a patient with an incurable disease with the intention of relieving symptoms, minimizing patient distress, and improving the quality of life."[51] Although a diagnosis may not be specifically cancer, the few studies on palliative surgery focus on oncology patients. Palliative surgery for patients with cancer is most often for bowel obstruction, with wound management also common.[52] A 2004 study of over 1000 patients with advanced cancer showed a 30-day morbidity of 29% and mortality of 11%, with 80% of patients experiencing improved symptoms at 30 days. A similar study by the same author in 2011 of 227 patients showed a morbidity of 20% and mortality of 4%, with 90% experiencing symptom resolution, a significant improvement from the similar study in 2004.[51,53] The study authors attribute at least some of this change to better patient selection through shared decision making with patients and families.[51] Poor functional status was associated with decreased survival in both studies.

COMMUNICATION

ADVANCE CARE PLANNING

The Patient Self-Determination Act took effect in 1991 in the United States and requires health care providers and institutions to advise patients of their right to an advance directive and to develop institutional policies and education regarding advance directives.[54] However, since the introduction of advance directives, multiple issues have been identified, such as changing preferences as the illness changes and the inherent difficulty in predicting future desires as circumstances change.[55-57] Because the outcomes of studies on advance directives have been disappointing, many experts believe a patient discussing preferences with and naming a surrogate decision maker may be the most crucial part of the process,[58,59] although the decisions made by the surrogate may not always be in accordance with the patient's wishes.[60] Understanding a patient's goals requires open communication with the patient and physician and sometimes repeated conversations to clarify and update the goals of treatment as the patient's condition changes. More information on advance directives and decision-making surrogates can be found in Chapter 10.

OUTCOMES OF ADVANCE CARE PLANNING

The landmark 1995 Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatments (SUPPORT) was a 2-year prospective observational study, followed by a 2-year randomized trial of 9105 patients in five U.S. teaching hospitals, with the goal of improving end-of-life decision making.[14] The study enrolled patients with advanced stages of nine illnesses and a 6-month mortality of 45% to 48%; patients with trauma were notably excluded.[14] The observation period showed that 49% of patients who did not want cardiopulmonary resuscitation (CPR) did not have a written DNR order, and that the physicians were often not aware of the patients' wishes.[14] In the intervention, prognostic data were made available to physicians, and a nurse was available to facilitate information sharing, advance care planning, and pain assessment. In the intervention phase, no differences in physician communication, pain, use of hospital resources, or other measured outcomes were documented[21] (also see Chapter 102).

Based on the data from the SUPPORT trial, a study that examined the rates of advance directive completion showed that although more advance directives were documented, only 14% of the patients spoke with a physician when completing their advance directive, and only approximately 25% of the physicians were aware of their patients' advance directives a week after hospital admission.[61] Similar studies did not demonstrate that advance directives influenced the types of care or the resources used.[62,63]

PHYSICIAN COMMUNICATION SKILLS TRAINING

How physicians communicate about difficult issues can affect how patients and families perceive illness, death, and treatment options. Many of these skills have not traditionally been taught as part of the medical school curriculum, and most physicians are less comfortable discussing code status than they are with other topics, such as consent for procedures[64]; between 40% and 75% of physicians, depending on their level of training, assess their own knowledge of delivering "bad news" as inadequate.[65] In one survey of surgical residents, only 9% believed they "received adequate training in palliation"

during residency,[66] and as many as 90% of internal medicine residents expressed a desire for additional training in discussing topics such as DNR orders.[67] Despite this lack of training, residents often talk about these issues with patients,[68] highlighting the importance of education in this area.

PHYSICIAN COMMUNICATION SKILLS

Physicians often favorably rate themselves in terms of patient communication, but surveys of other practitioners and of patients suggest that physicians may not be able to self-assess accurately. One study in an ICU showed 90% of surgeons were satisfied with their communication skill concerning prognosis, but only 23% of intensivists and 3% of nurses rated it as such.[69] Similarly, patients' perceptions of their cancer stage and prognosis were often incorrect in one study, although oncologists thought they were clear in their explanations of the illness.[70] Recordings of physician discussions with patients and families show that physicians focus on technical detail, avoid emotional topics, and tend to dominate the conversations,[71] despite increased family satisfaction when the family spoke more and physicians exhibited more supportive behaviors.[71] Even when a conversation takes place between a physician and patient, the physician and patient may not agree on the outcome. One study of patients with metastatic cancer showed that physicians misunderstood their patients' preferences for CPR 30% of the time.[72] Currently, no comparable studies regarding anesthesiologists have been conducted. These findings highlight the importance of the anesthesiologist's role in assessing a patient's understanding of his or her disease process before a procedure is performed or during an ICU stay.

WHAT DO FAMILIES CONSIDER IMPORTANT IN END-OF-LIFE COMMUNICATION?

A majority of family members consider trust in the treating physician and truthful communication about the patient's illness as two of the most important factors in receiving quality end-of-life care.[73] In addition, families have greater satisfaction when a higher level of decision making is shared.[74] Family satisfaction increases with the number of empathetic statements made by a physician during a meeting.[75] A variety of patient and family preferences are available that address how much information is desired and how to receive it. A combination of personal, cultural, and family reasons influence these preferences, and physicians should not assume a preference based on a patient's race or ethnicity.[76] Many practitioners use a question such as, "How much would you like to know?"[77] although no studies of patient perceptions of that approach have been conducted. One study of patients with cancer indicated that some patients' preferences for involvement in decision making changed over the course of the illness.[78] A few studies have noted that caregivers wanted more information than the patients.[79] Some patients may indicate that they do not want to know about their condition and name a surrogate decision maker instead (also see Chapter 10). Sometimes these interactions do not work out well. Another type of conflict was nationally illustrated in Oakland, California, early in 2014. A patient in her teens had a postoperative hemorrhage after a tonsillectomy. She was resuscitated, but she did not have a return of brain function. The disagreement between the parents and the medical establishment was substantial and has never been publically resolved.

SPIRITUALITY AT THE END OF LIFE

Serious illness and the prospect of death can bring a number of spiritual issues to the foreground for patients and families, from questioning the meaning of one's life to a religion's teaching on specific medical interventions.[80] Patients typically want physicians to ask about their spiritual preferences[81] but often describe their spiritual needs as frequently not being met.[82] A simple screening question such as, "Is religion or spirituality important in your life?" has been proposed and may help identify patients in whom a spiritual need remains unmet. Asking about religion and spirituality may provide a context for the health care team, since many patients and families make decisions based on their religious and spiritual beliefs.[83] Physician understanding of the reasoning behind their patients' decisions is likely to improve end-of-life care. A spiritual counselor or chaplain can help patients and families with issues of spiritual suffering,[84] as well as identify and facilitate specific rituals related to illness or burial.

COMMUNICATION FRAMEWORKS

The aforementioned studies, which demonstrate frequent misunderstandings and poor communication, emphasize the need for an understanding of the importance of effective communication among physicians, patients, and families.[85] A number of frameworks have been developed to aid physicians in discussions with patients and families.[86-88] No study has compared their relative effectiveness on patient or family outcomes, and very few are assessing the effect of a specific communication framework on patient or family outcomes.[77] Commonalities in the approaches include active listening, validating patient concerns, and assessing understanding.

Family Meetings

Family conferences in the ICU have increasingly been used to facilitate information sharing between families and providers. In the ICU setting, meetings held within 72 hours of admission have shown decreased lengths of stay without increased mortality.[89] One of the few studies that evaluated a standardized communication approach was a single-site study of families of patients who were seriously ill and randomized to either a standardized communication template with a bereavement brochure or the standard care.[87] The communication intervention emphasized empathy, understanding of the patient as a person, and allowed family members to ask questions with the mnemonic of VALUE (value, acknowledge, listen, understand, elicit questions).[87] Family members in the study arm had decreased symptoms of psychological distress in a survey 3 months later[87] (Box 65-1).

BOX 65-1 ***VALUE: Framework for End-of-Life Conferences***

Value: Value and appreciate what the family member says. "Thank you for helping me understand how your husband's condition has changed over the past year."

Acknowledge: Acknowledge emotions. "This is often a sad time for families."

Listen: Actively listen. Remember to be silent and to give the family member time to speak.

Understand: Gain an understanding of the patient. Ask who the patient is as a person. "Can you tell me about your father, what kind of person he is and what's important to him?"

Elicit questions: Ask family members if they have questions. "We have discussed a lot of information. Do you have any questions?"

Data from Lautrette A, Darmon M, Megarbane B, et al: A communication strategy and brochure for relatives of patients dying in the ICU, N Engl J Med *356:469-478, 2007.*

BOX 65-2 ***SPIKES: Framework for Breaking Bad News***

Setting: Arrange for a quiet, private space large enough for all participants.

Perception: Assess the participants' understanding. "What have the doctors told you about your wife's illness?"

Invitation: Ask how much information is desired. "Some people like all the details, others just like the big picture. What would you like?"

Knowledge: Tell the participants what is known, using language that is easy to understand and avoiding the use of complex medical phrases.

Empathy: Acknowledge emotions. "I wish things were different."

Sequelae: Agree on the next steps. "Let's meet tomorrow afternoon so I can update you on her condition."

Data from Baile WF, Buckman R, Lenzi R, et al: SPIKES–A six-step protocol for delivering bad news: application to the patient with cancer, Oncologist *5:302-311, 2000.*

BOX 65-3 ***NURSE: Framework for Dealing With Emotion***

Name: State the emotion you believe the patient or caregiver is exhibiting. "It seems like you are angry."

Understand: Empathize with and legitimize the emotion. "I can't imagine how hard this must be for you."

Respect: Praise the patient or caregiver for his or her strength. "You've done so much for your mother during this difficult time."

Support: Show support. "I want to help."

Explore: Ask the patient or caregiver to elaborate on the emotion. "Can you help me understand what was so frustrating today?"

Data from Back AL, Arnold RM, Baile WF, et al: Approaching difficult communication tasks in oncology, CA Cancer J Clin *55:164-177, 2005.*

Many physicians struggle with how to begin family meetings. Although no study specifically addresses this concern, common approaches include introducing the family and team members; a brief summary is given by the physician that explains why he or she is holding the meeting; and the physician asks the family members to tell him or her what they understand. For example, "What have you been told about what's going on with your dad?"

Breaking Bad News

The six-step SPIKES (setting, perception, invitation, knowledge, empathy, sequelae) protocol is a framework for breaking bad news. Several of the elements, such as finding a quiet meeting space, asking what the patient or family understands, and making a plan for the future, apply in many situations[86] (Box 65-2).

Responding to Emotion

The NURSE (name, understand, respect, support, explore) protocol is a framework for responding to emotion, including anger. Patient and family anger directed toward health care providers is common in the setting of serious illness.[90] Crucial concepts in responding to anger include not becoming defensive or personalizing the anger, respectfully listening, and setting appropriate boundaries for safety.[90] Although difficult to accomplish in the moment, viewing anger as a coping mechanism in the grieving process is often helpful[91] (Box 65-3).

Requests for Nondisclosure

Family members may ask physicians to withhold a diagnosis from the patient. The cultural norms for disclosing a patient's diagnosis may vary widely among cultures and countries. In the United States, the culture of disclosure has rapidly changed, and now most physicians expect to disclose the prognosis to the patient.[92] No evidence is available that recommends how to deal with requests for nondisclosure, but expert opinions recommend empathetically responding to the family member, trying to understand the family's concerns about disclosing the prognosis, and asking the patient how and if he wants to be involved. For example, "Some people want to be told about any health issues and make their own decisions, and yet others prefer for a family member to be told the medical information and to make the decisions. What would you like?"[93]

Time-Limited Trials

In cases where the benefit of a clinical intervention is unclear for a specific patient, such as mechanical ventilation for ischemic encephalopathy, a time-limited trial, in which the physician and patient or family agree to reevaluate the benefit after a specified period, may be helpful.[94] Time-limited trials give families a sense of when the health care team expects to know whether an intervention is helping and creates the expectation that the issue will be readdressed.

RESUSCITATION STATUS

Outcomes of Cardiopulmonary Resuscitation

Resuscitation status is another conversation that some providers consider challenging[64] and that anesthesiologists may have with patients in the ICU or in the

perioperative period. CPR was introduced around 1960, initially as a treatment for intraoperative events[95] and then introduced outside the surgical unit. Outcomes of CPR have improved, with over one half of patients surviving the initial resuscitation and nearly one quarter surviving to discharge.[96] In surgical patients, approximately 85% of cardiac arrests occur postoperatively, and surgical patients may have a higher likelihood of survival than other groups of patients.[97,98] In one large study of older patients who survived to discharge after in-hospital CPR, approximately one half had moderate-to-severe neurologic defects[99] and 60% were alive 1 year later[99] (also see Chapters 101 and 102).

Resuscitation Status Discussions

Few studies examine the best way to approach discussions regarding resuscitation.[95] Ideally, the discussion about code status takes place in the context of a conversation about the patient's overall condition and goals. For example, one patient might decide on life prolongation as a goal, in which case a physician might recommend resuscitation attempts even if unlikely to succeed, whereas another patient with the same illness might prioritize physical independence as a goal, in which case the physician might recommend a DNR order to decrease the likelihood of prolonged ICU time or an unacceptable physical status. Some physicians advocate for making a recommendation about resuscitation status based on the patient's goals. The impact of this approach is unknown; a small simulated study that played a standardized video of a code status discussion to patients with cancer showed no difference between asking the patient his or her desired resuscitation status or making a suggestion for DNR order.[100]

Perioperative Limitations on Treatment

The American Society of Anesthesiologists (ASA) has published guidelines related to orders for the limitation of treatment in the perioperative setting.[101] The ethics of perioperative DNR orders are discussed in Chapter 10.

WITHDRAWAL OF LIFE SUPPORT

Some patients or family members may wish to discontinue ventilation or other forms of life support. Withdrawal of life support is ethically acceptable and respects patient autonomy (also see Chapter 10). Anesthesiologists can add expert skills in medication titration and the management of pain and anxiety to the withdrawal of ventilation. Multiple protocols for withdrawal of ventilatory support are available in the ICU, most using a narcotic for pain or dyspnea and a benzodiazepine for agitation or anxiety that are rapidly titrated to patient comfort.[102] Studies of the protocol use for the withdrawal of life support have not demonstrated an improvement in provider perception of the quality of death.[103,104] Specific concerns include making arrangements for rituals and family support, preparing the family, and discontinuing unnecessary tubes, treatments, and monitors.[102] Involving a spiritual advisor may be appropriate for some families.

Outcomes of Withdrawal of Life Support

One study of 74 medical patients in an ICU who were expected to die shortly after extubation showed a mean morphine dose of 5.3 mg/hr in the last hour of mechanical ventilation, followed by 10.6 mg/hr during the hour before death.[105] The average time to death was 153 minutes after extubation, with a range of 4 to 934 minutes. Somewhat surprisingly, each 1 mg/hr increase of morphine corresponded to an 8-minute delay in death.[105] This response is similar to an earlier study that showed a 13-minute increase in the time to death with each 1 mg/hr increase of benzodiazepine.[106]

Paralytic Drugs in the Withdrawal of Life Support

As noted in Chapter 10, patients should not be paralyzed before extubation of the trachea; it obscures symptom assessment and may lead to patient suffering. Patients already on paralytic medications should await the return of neuromuscular function before extubation unless doing so causes undue burden on the patient.[107]

PROGNOSIS

Multiple studies have examined the ability of physicians to prognosticate survival for a given patient. In a meta-analysis of eight studies in patients with a median survival of 4 weeks, physicians overestimated the prognosis by approximately 30%, with predictions more accurate in patients with poorer performance status.[108] In a prospective cohort study of 365 physicians and 504 patients receiving hospice care, the physicians overestimated survival by a factor of five, and 63% of their predictions were overestimates.[109] The longer a physician knew a patient, the more difficult it was for that physician to prognosticate.[109] Physicians in the ICU tend to be overly pessimistic; in a study of 851 patients on ventilation, only 71% of patients for whom a physician estimated a likelihood of survival of less than 10% at some point during their stay in the ICU died in the ICU.[110] A meta-analysis suggested that physicians are more accurate than algorithmic scoring systems (described in the Prognostic Tools section) in the first 24 hours after ICU admission; however, neither physicians nor scoring systems are reliably accurate for individual patients.[111] Overall, physician estimates do correlate with survival.[112] However, a study of 521 patients in a medical ICU found that physicians and nurses were unable to predict satisfaction with the quality of life 6 months after admission. In general, nurses tended to be more pessimistic than physicians and suggested withdrawal of therapy more often in patients who ultimately survived[113] (Figs. 65-5 and 65-6).

Difficulty with prognostication has led some physicians to avoid giving any kind of timeframe to eliminate the possibility of being wrong.[114,115] However, 87% of 179 surrogate decision makers wanted the physician to give a prognosis, even if it was uncertain.[116] Most understood the inherent unpredictability of prognostication and preferred that physicians make the prognostic uncertainty clear during the discussion.[116] Prognosis, even in the face of uncertainty, can help families prepare for bereavement

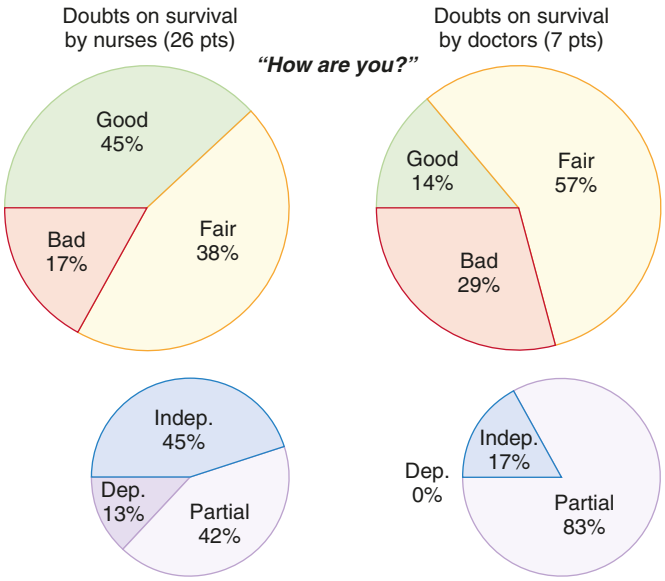

Figure 65-5. Answers of survivors 6 months after being discharged from the intensive care unit for whom treatment had been considered futile or questionable by nurses or physicians to improve survival. *Dep.,* Dependent; *Indep.,* independent. *(From Frick S, Uehlinger DE, Zuercher Zenklusen RM: Medical futility: predicting outcome of intensive care unit patients by nurses and doctors—a prospective comparative study,* Crit Care Med *31:456-461, 2003.)*

Figure 65-6. and make important decisions about coordinating work, visitors, and finances.[116] Good data suggesting how to present prognoses to patients are not available. One approach to prognostication involves giving ranges such as hours to days, days to weeks, weeks to months, and months to years, with those categories roughly tracking with functional status. These ranges, along with an explanation from the physician about the difficulty of prognosticating, can often give families sufficient guidance with which to make important decisions. However, interpretation of a given prognosis may vary with the patient and family. One study that gave surrogate decision makers in the ICU hypothetical physician statements about prognosis and asked them to interpret them showed that surrogates tended to be optimistic, especially with worse prognoses.[117] These findings are similar to a study of patients with cancer in phase I and II clinical trials.[118]

DISEASE TRAJECTORIES

Multiple disease trajectories exist, although most can be included in one of the following functional categories: sudden extreme disability or near death; a period of good functionality, followed by a rapid, steady decline; a waxing and waning course with periods of decompensation followed by improvements; and a slow decline, starting at a low functional level[119] (Fig. 65-7). These frameworks can be useful when discussing prognoses with patients, particularly in talking to patients with conditions that are difficult to predict such as COPD and CHF.

PROGNOSTIC TOOLS

Cancer

Multiple Web-based cancer prognostic tools exist but none that are useful for every type of cancer. An important consideration is that the type of cancer is less important than a variety of patient factors, such as functional status and laboratory values as the disease becomes more advanced[120] (Fig. 65-8). In general, a patient with cancer who spends more than one half of the day in bed has a median survival of 6 months[121] (Box 65-4).

Intensive Care Unit

Multiple tools have been proposed to help the clinician predict mortality in the ICU, which are covered in depth in Chapter 101.

Other Selected Conditions

Many conditions have courses that are difficult to predict. The tables give characteristics associated with patients with a median survival of 6 months or less,[122] although it should be noted that the prognostic accuracy of these factors is not known. Table 65-2 offers a general sense of where the patient might be in the illness trajectory.

Congestive Heart Failure. CHF often has a waxing and waning course. The Seattle Heart Failure Model estimates mean 1- to 3-year survival but does not appear to be able to predict whether individual patients are in the last year of life.[123] Factors associated with a poor prognosis include hospitalization, tachycardia, hypotension, decreased ejection fraction, and increased creatinine level.[124] In patients hospitalized for acute decompensation of heart failure, older age and COPD were associated with decreased 1-year survival.[125]

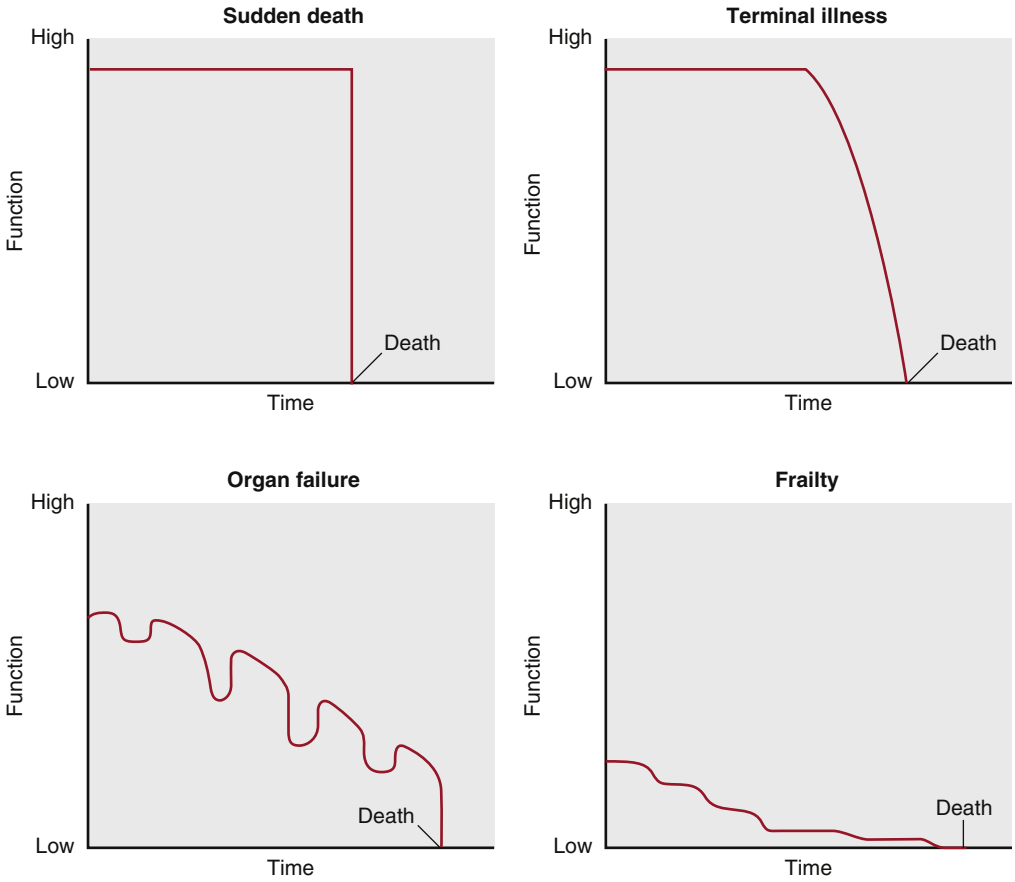

Figure 65-7. Trajectories of dying. *(From Lunney JR, Lynn J, Hogan C: Profiles of older Medicare decedents,* J Am Geriatr Soc *50:1108-1112, 2002.)*

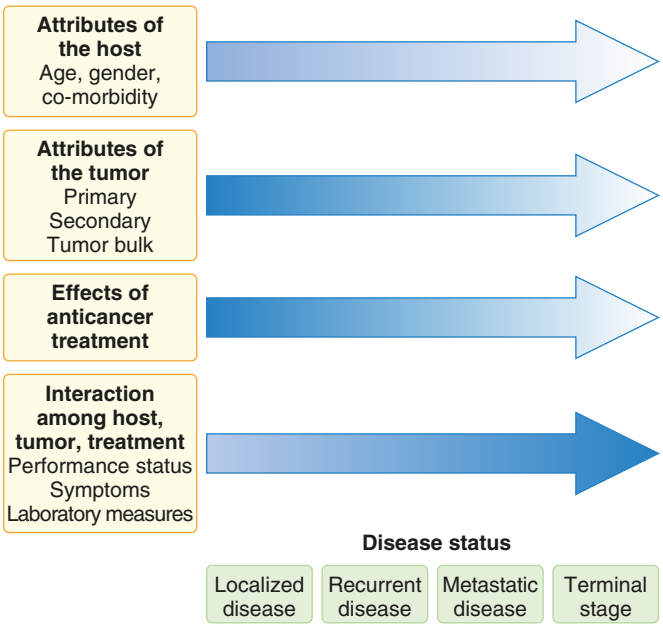

Figure 65-8. Factors associated with the length of survival in patients with cancer. Depth of shading represents relative importance of the factor as a predictor of subsequent survival. *(From Hauser CA, Stockler MR, Tattersall MH: Prognostic factors in patients with recently diagnosed incurable cancer: a systematic review,* Support Care Cancer *14:999-1011, 2006.)*

BOX 65-4 *Cancer Presentations With a Median Survival of 6 Months or Less*

Solid Cancers in General

Any locally advanced or metastatic solid cancer with one or more of the following presentations:

- Patient spends more than one half of the day in bed
- Serum calcium >11.2 mg/dL
- Episode of extremity venous thromboembolism or pulmonary embolism
- Two or more brain metastases plus intracranial metastases
- Spinal cord compression with decreased ability to walk
- Malignant pericardial effusion

Carcinoma of Unknown Primary Origin

Any metastatic adenocarcinoma or undifferentiated carcinoma of unknown primary origin with one or more of the following presentations:

- Patient is ambulatory and can care for him or herself but cannot work
- Hepatic, bone, or adrenal metastases
- Recurrence of disease after chemotherapy
- Serum albumin <3.5 mg/dL or weight loss of ≥10% in 6 months

Modified from Salpeter SR, Malter DS, Luo EJ, et al: Systematic review of cancer presentations with a median survival of six months or less, J Palliat Med *15:175-185, 2012.*

TABLE 65-2 **PRESENTATIONS OF NONCANCER DIAGNOSES WITH A MEDIAN SURVIVAL OF 6 MONTHS OR LESS**

Diagnosis	Presentation
Heart failure	
Hospitalization for moderate-to-severe symptomatic heart failure, NYHA Class III or IV, with three or more of the presentations listed.	• Age >70 years • LVEF ≤20% • Serum BNP >950 pg/mL • Cardiac troponin I >0.4 ng/mL • CRP >3.5 mg/L • Fourth hospitalization for heart failure or repeat hospitalization within 2 months • Dependency for two or more activities of daily living or need for home care after hospital discharge • Weight loss ≥2.3 kg within 2 months, or serum albumin <2.5 g/dL • History of cardiogenic shock, ventricular or supraventricular arrhythmia, cardiac arrest, CPR, or mechanical ventilation • Systolic blood pressure <110 mm Hg • Serum creatinine >2 mg/dL or BUN >40 mg/dL • Serum sodium <135 mEq/L • Peripheral vascular disease or cerebrovascular disease • Other comorbid illness, such as diabetes mellitus, dementia, COPD, cirrhosis, and cancer, among others
Dementia	
Advanced dementia with dependency in all activities of daily living, bedbound status, urinary and bowel incontinence, decreased ability to communicate verbally, and admission to a hospital or skilled nursing facility with one or more of the presentations listed.	• BMI <18.5 kg/m^2, decreased oral intake, or significant weight loss • Presence of at least one pressure ulcer • Evidence of at least one comorbid illness • Male sex plus >90 years of age • Placement of a feeding tube attributable to inability to eat or history of aspiration
Hepatic cirrhosis	
Decompensated hepatic cirrhosis and one or more of the presentations listed.	• MELD score ≥21
Decompensated hepatic cirrhosis with hospitalization for an acute illness related to liver disease and one or more of the presentations listed.	• MELD score ≥18 • Hospitalization in an intensive care unit related to severe decompensation of liver disease with hypotension requiring the use of pressors, serum creatinine >1.5 mg/dL, or evidence of jaundice • Evidence of hepatopulmonary syndrome or rapidly progressive hepatorenal syndrome
Chronic obstructive pulmonary disease	
Hospitalization for a severe COPD exacerbation, with Pao_2 ≤55 mm Hg, $Paco_2$ ≥50 mm Hg, and supplemental oxygen dependence, with three or more of the presentations listed.	• Age >70 years • Evidence of right-sided heart failure • Repeat hospitalization for COPD within 2 months • History of intubation and mechanical ventilation • Required considerable assistance and frequent medical care and/or dependence for three or more activities of daily living before hospitalization • Need for home care after hospital discharge • Malnutrition (weight loss of ≥2.3 kg, serum albumin <2.5 g/dL or BMI <18 kg/m^2 • Serum creatinine >2 mg/dL

Modified from Salpeter SR, Luo EJ, Malter DS, Stuart B: Systematic review of noncancer presentations with a median survival of 6 months or less, Am J Med *125:512 e1-6, 2012.*

BMI, Body mass index; *BNP,* brain natriuretic peptide; *BUN*, blood urea nitrogen; *COPD,* chronic obstructive pulmonary disease; *CPR*, cardiopulmonary resuscitation; *CRP,* C-reactive protein; *LVEF,* left ventricular ejection fraction; *MELD,* Model for End-Stage Liver Disease; *NYHA,* New York Heart Association; *$Paco_2$*, partial arterial pressure of carbon dioxide; *Pao_2,* partial arterial pressure of oxygen.

Dementia. The course of dementia is difficult to predict, and a patient's 6-month mortality is higher once the patient develops the common problems of infection and an inability to eat.[126] Probability of death within 6 months increases with advancing age, shortness of breath, immobility, and insufficient oral intake, among other presentations.[127]

Chronic Obstructive Pulmonary Disease. The BODE Index measures **b**ody mass index (BMI), airflow **o**bstruction, **d**yspnea, and **e**xercise capacity and is used to predict the risk of death in COPD,[128] although its use of a 6-minute exercise capacity test makes it impractical for the bedside anesthesiologist. More than 3 days of mechanical ventilation and an inability to extubate the trachea successfully suggest a poor prognosis.[129]

Liver Disease. In decompensated liver disease, the Model for End-Stage Liver Disease (MELD) score (see Chapter 101)

is often used to predict a prognosis.[130] Hepatic encephalopathy and hepatorenal syndrome are also predictors of a poor prognosis.[130,131]

Renal Disease. Patients with stage 5 chronic kidney disease (CKD; patients on dialysis) will live 16% to 33% as long as age- and sex-matched patients who are not on dialysis.[132] For patients on dialysis who are older than 65 years of age, their probability of survival at 10 years is 3.1%.[132] Poor functional and nutritional status, as well as comorbid conditions, suggest a poor prognosis.[132] Withdrawal of dialysis makes up 20% of deaths in patients on dialysis each year, and the average patient lives 8 to 12 days after dialysis withdrawal.[133]

DYING PROCESS

Most physicians have observed people die but may not have witnessed the dying process. Over 500,000 people die in the ICU every year in the United States alone, and more die after an ICU stay.[134] Understanding the dying process is important because family members may ask physicians what the dying process will be like for the patient; anesthesiologists need to be able to recognize the signs that a patient is imminently dying. The individual variation in the timing with which a patient develops many symptoms is substantial, with 84% of patients being drowsy or comatose 24 hours before death, and acrocyanosis and the loss of a radial pulse occurring a median of 1 hour before death[135] (Table 65-3).

SYMPTOM MANAGEMENT

Alternative Routes of Drug Delivery

Many patients near the end of life may be unable to swallow oral medications as a result of oral lesions, nausea, the dying process, or other reasons. Many patients in palliative and hospice care have difficult intravenous access as a result of frequent medical care, dehydration, or other issues. To avoid multiple attempts at intravenous cannulation, many palliative medicine practitioners and most hospices use subcutaneous infusions for the delivery of medications, especially opioids.[136,137] An assumption of safety is based, in part, on studies showing that many intramuscular injections are actually administered into the subcutaneous tissue,[138] although often off-label use. The subcutaneous administration of opioids is safe, although the optimal conversion ratio from one route to another is a subject of debate.[139] Opioids can be subcutaneously given as boluses or continuous infusions. Notably, methadone can cause skin irritation when administered via this route.[140] Other studies support the transmucosal, sublingual, and rectal administration of opioids,[139] with emerging literature supporting transnasal application. This method of delivery has been used for other medications, including ketorolac, as well as ketamine and lidocaine infusions.[141,142] Of note, other types of drugs such as benzodiazepines, some antiemetic medications, antibiotics, neuroleptics, and even fluids are subcutaneously administered in the palliative care setting.[136,137,143]

Pain

Management of pain in patients who are seriously ill can be quite different from other patients with pain. Some of these patients have pain that is best managed by a pain expert (also see Chapter 64), and some patients will need adjuvant medications (Table 65-4). Major differences in the care of patients with life-limiting diseases are discussed in this text.

Of those patients with cancer, 15% to 90% with solid tumors have pain, depending on the type and stage of cancer, as well as the age, race, and sex of the patient.[144] Most cancer pain is due to the cancer itself, whereas approximately one fifth of patients develop pain related to the cancer treatment.[145] The majority of cancer pain can be managed with the WHO "Cancer Pain Stepladder."[146] Zech published a prospective study of 2118 patients with cancer in 1995 during which 76% of the patients received pain relief[146] with minimal side effects with this approach. Psychological issues may also contribute to pain in this population.[147] Palliative chemotherapy is a treatment that is not expected to cure the patient, but it may improve symptoms, especially pain related to tumor burden; sometimes palliative chemotherapy may prolong life and may be a useful option for pain control in carefully selected patients.

Bone Pain

Breast, lung, kidney, and prostate cancers frequently metastasize to the bones.[148] These metastases may have osteolytic or osteoblastic components, and many patients have both osteoblastic and osteolytic bony lesions.[149] Multiple targets for bone pain are possible, but no clear consensus has been reached on the best treatment methods.[150] Sometimes the pain is extremely intense. Hormonal therapy is effective in breast, prostate, and endometrial cancers. Interventional techniques such as intrathecal catheters may be appropriate in some patients[151] (also see Chapter 64). Palliative radiotherapy can be helpful for patients with bone metastases, although pain relief may take several weeks.[152] According to guidelines from the American Society for Radiation Oncology, pain relief from single-fraction radiotherapy for bone metastases is as effective as multifraction radiation and has the benefit of decreased visits for the patient. However, the retreatment rate is 20% for single-fraction radiation versus 8% for multifraction dosing.[153] Dexamethasone orally, subcutaneously, or intravenously is commonly recommended for bone pain by expert consensus, although only a few, small studies support its use.[154] Bone-modifying agents, such as zoledronic acid or pamidronate have shown benefit for bony pain in some cancers and should be initiated when pain begins or when appropriate from an oncology standpoint.[148,155] Nonsteroidal antiinflammatory drugs (NSAIDs) are helpful in alleviating cancer pain, although their advantage when combined with opioids is less clear.[156] More advanced interventions such as vertebroplasty or surgery may be indicated in some bony metastases.

TABLE 65-3 **CHANGES DURING THE DYING PROCESS**

Changes	Exhibited Signs
Fatigue, weakness	Decreasing function
	Decreasing attention to hygiene
	Inability to move around the bed
	Inability to lift head off the pillow
Cutaneous ischemia	Erythema over bony prominences
	Skin breakdown
	Wounds
Pain	Facial grimacing
	Tension in forehead and between eyebrows
Decreasing food intake, wasting	Anorexia
	Poor intake
	Aspiration, asphyxiation
	Weight loss, muscle and fat loss notable in temples
Loss of ability to close eyes	Eyelids not closed
	Whites of eyes show (with or without pupils visible)
Decreasing fluid intake, dehydration	Poor intake
	Aspiration
	Peripheral edema attributable to hypoalbuminemia
	Dehydration, dry mucous membranes or conjunctivae
Cardiac dysfunction, renal failure	Tachycardia
	Hypertension followed by hypotension
	Peripheral cooling
	Peripheral and central cyanosis (bluing of extremities)
	Mottling of the skin (livedo reticularis)
	Venous pooling along dependent skin surfaces
	Dark urine
	Oliguria, anuria
Neurologic dysfunction, including:	
Decreased level of consciousness	Increased drowsiness
	Difficulty awakening
	Nonresponsive to verbal or tactile stimuli
Decreased ability to communicate	Difficulty finding words
	Monosyllabic words, short sentences
	Delayed or inappropriate responses
	Not verbally responsive
Respiratory dysfunction	Change in ventilatory rate—increasing first, then slowing
	Decreasing tidal volume
	Abnormal breathing patterns—apnea, Cheyne-Stokes respirations, agonal breaths
	Loss of ability to swallow
	Dysphagia
	Coughing, choking
	Loss of gag reflex
	Buildup of oral and tracheal secretions
	Gurgling
Loss of sphincter control	Incontinence of urine or bowels
	Maceration of skin
	Perineal candidiasis
	Terminal delirium
	Early signs of cognitive failure, (e.g., day-night reversal)
	Agitation, restlessness
	Purposeless, repetitious movements
	Moaning, groaning
Rare, unexpected events	Bursts of energy just before death occurs, the "golden glow"
	Aspiration, asphyxiation

TABLE 65-4 **ADJUVANT ANALGESICS IN THE MANAGEMENT OF CANCER PAIN**

	Examples	Comment
Multipurpose analgesics		
Glucocorticoids	Dexamethasone, prednisone	Are used for bone pain, neuropathic pain, lymphedema pain, headache, and bowel obstruction.
Antidepressants		
TCAs	Desipramine, amitriptyline	Are used for opioid-refractory neuropathic pain; often used with comorbid depression; secondary amine compounds (e.g., desipramine) have fewer side effects and might be preferred.
SNRIs	Duloxetine, milnacipran	Good evidence exists for their use in some conditions but are overall less effective than TCAs; better side-effect profile than TCAs and are often tried first.
SSRIs	Paroxetine, citalopram	Evidence for their use is scarce; if pain is the target, then other subclasses are preferred.
Other	Bupropion	Little evidence exists for its effectiveness but less sedating than other antidepressants; is often tried early when fatigue or somnolence is a problem.
α_2-Adrenergic agonists	Tizanidine, clonidine	Are seldom used systemically because of side effects, but tizanidine is preferred for a trial; clonidine is used in neuraxial analgesia.
Cannabinoid	THC/cannabidiol, nabilone, THC	Good evidence exists for THC/cannabidiol when used in cancer pain; evidence is scarce for other commercially available compounds.
Topical agents		
Anesthetic	Lidocaine patch, local anesthetic creams	Sometimes used in localized pain.
Capsaicin	8% patch; 0.25%-0.75% creams	High concentration patch is indicated for postherpetic neuralgia.
NSAIDs	Diclofenac and others	Evidence exists for their use in focal musculoskeletal pains.
TCA	Doxepin cream	Is used in treating itching; can be tried for pain.
Others		Compounding creams with various drugs have been empirically tried, but no evidence exists for effectiveness.
Used for neuropathic pain		
Multipurpose drugs	As above	As above
Anticonvulsants		
Gabapentinoids	Gabapentin, pregabalin	Are used first for opioid-refractory neuropathic pain unless comorbid depression; may have multipurpose uses in view of the evidence in postsurgical pain; both drugs act as N-type calcium channel blockers in the CNS, but individuals vary in response to one or the other.
Others	Oxcarbazepine, lamotrigine, topiramate, lacosamide, valproate, carbamazepine, phenytoin	Evidence is scarce for all drugs listed; newer drugs are preferred because of reduced side-effect liability, but individual variation is great; all drugs are considered for opioid-refractory neuropathic pain if antidepressants and gabapentinoids are ineffective.
Sodium-channel drugs		
Sodium-channel blockers	Mexiletine, intravenous lidocaine	Good evidence exists for intravenous lidocaine.
Sodium-channel modulator	Lacosamide	New anticonvulsant with very scarce evidence of analgesic effects.
GABA agonists		
$GABA_A$ agonist	Clonazepam	Evidence is scarce but used for neuropathic pain with anxiety.
$GABA_B$ agonist	Baclofen	Evidence for the treatment of trigeminal neuralgia is the basis for trials in other types of neuropathic pain.
N-methyl-D-aspartate inhibitors	Ketamine, memantine, and others	Evidence is scarce for ketamine, but experience is positive with intravenous use in advanced illness or pain crisis; little evidence exists for oral drugs.
Used for bone pain		
Bisphosphonates	Pamidronate, ibandronate, clodronate	Good evidence exists for its use; similar to NSAIDs or glucocorticoids, usually considered first-line treatment; also reduces other adverse skeletal-related events; concern about osteonecrosis of the jaw and renal insuffciency might restrict its use.
Calcitonin		Evidence is scarce but is usually well tolerated.
Radiopharmaceuticals	Strontium-89, samarium-153	Evidence is good, but its use is restricted because of bone-marrow effects and the need for expertise.
Used for bowel obstruction		
Anticholinergic drugs	Hyoscine compounds, glycopyrronium	Along with a glucocorticoid, are considered first-line adjuvant treatments for nonsurgical bowel obstruction.
Somatostatin analog	Octreotide	Along with a glucocorticoid, is considered a first-line adjuvant treatment for nonsurgical bowel obstruction.

Neuropathic Pain

Between 17% and 28% of patients with advanced cancer have neuropathic pain.[157] More information on neuropathic pain, the use of lidocaine and ketamine, and other adjuvant medications is available in Chapters 32 and 64. As always, a patient's life expectancy should be considered; some medications may be difficult to titrate in a short period. More information on neurolytic techniques is available in Chapter 64.

Pain in the Intensive Care Unit

In the ICU, pain is also common and attributable to many factors such as surgical or traumatic wounds, placement of invasive monitoring devices, and immobility.[158] In addition, pain can be difficult to assess because the trachea is intubated or otherwise the patient is unable to speak. The Behavioral Pain Scale[159] and the Critical Care Pain Observation Tool[160] are validated methods of assessing pain in the ICU population.[161] Commonalities among the tools include assessment of facial expression, body movement, and compliance with ventilation. In the SUPPORT trial, pain was also poorly controlled among those who died in the hospital, with one half of the surrogates indicating that their family member had moderate-to-severe pain for at least one half of the time in the 3 days before death.[14] However, a more recent study has demonstrated improvement in pain assessment and treatment in the ICU[162] (also see Chapter 101).

OPIOID USE

Opioid use at the end of life is common, although consumption dramatically varies throughout the world.[19] In a 2012 study of 1068 patients at six U.S. medical centers, 70% of patients received an opioid in the last week of life, and 47% received opioids in the last 24 hours.[163] Some physicians are hesitant to use opioids at the end of life for fear of hastening a patient's death. A study by Morita in 2001 retrospectively analyzed opioid and sedative consumption of 209 patients in the 48 hours before death and found no difference in survival based on opiate or sedative dose.[164] A small study on the rate of increase of opioids found no correlation with time to death, although total morphine doses were relatively low.[165] A larger study by Portenoy in 2006 showed a weak association with absolute narcotic dose and time to death, but this association appeared to account for less than 10% of the variance even when combined with other variables.[166] Narcotics should be titrated based on the clinician's assessment of the pain. Most experts believe that appropriately administered opiates do not hasten death, can be safely used, and generally do not require invoking the doctrine of double effect[167] (also see Chapter 10). Some authors have urged caution with the use of opioids in patients with cancer and uncertain prognoses to decrease the risk of narcotic dependence and abuse in patients with the possibility of a long life after treatment.[168]

NAUSEA AND VOMITING

Nausea and vomiting are common complaints in the palliative care and hospice populations and cause significant distress for patients and families.[169] Many techniques and medications used in the treatment of nausea and vomiting in the patient who is seriously ill are similar to those used in the patient after surgery. As with every patient, the first step in treating nausea and vomiting is a thorough evaluation of possible causes (Fig. 65-9). This section highlights issues specific to patients with life-limiting diseases (also see Chapter 97).

Nausea and Vomiting Related to Chemotherapy and Radiation Therapy

Many patients undergoing chemotherapy experience anticipatory nausea and vomiting, and the 2011 American Society of Clinical Oncology Practice Guidelines for chemotherapy and radiation therapy include the prescription of a 5-hydroxytryptamine-3 antagonist, such as ondansetron, often with dexamethasone, and the

addition of a neurokinin-1 antagonist, such as aprepitant, for the most emetogenic chemotherapy regimens.[170] For nonchemotherapy-related or radiation therapy–related nausea and vomiting, no Level 1a or 1b evidence is currently available to guide decisions on the choice of an antiemetic agent in the palliative care population.

BOWEL OBSTRUCTION

Some patients with abdominal tumors may develop partial or complete bowel obstruction. First-line therapy consists of medical management, often with steroids and octreotide.[171] Surgical outcomes for patients with bowel obstruction and a life expectancy of less than 2 months are poor,[172] and gastrointestinal stents should be considered. Placement of a nasogastric tube should be considered for immediate relief while other options are sought. A venting gastrostomy tube is an option in patients who are refractory to treatment and can allow the patients to enjoy the taste of food while allowing the stomach contents to be drained.

ARTIFICIAL HYDRATION AND NUTRITION

Many patients receiving palliative care are unable to take in food or fluids because of nausea, dysphagia, or obstruction. The decision of whether to administer artificial hydration and nutrition is often a difficult one for patients and physicians. Both parties may hold strong cultural or religious views, and many describe a fear of "starving" the patient.[173] Symptoms of hunger are less common in advanced disease, and thirst can be treated with ice chips or mouth swabs.[174] The administration of artificial hydration and nutrition is associated with risks of fluid overload leading to choking or edema, as well as diarrhea and nausea.[175] Additional risks associated with the gastrostomy tube, such as dislodgement and the increased need for restraints attributable to agitation, are present.[175] The administration of enteral or parenteral nutrition and hydration is considered a medical intervention, and, as such, the risks and benefits should be discussed with patients and families.[173] The benefit of artificial hydration and nutrition has been established for patients in a persistent vegetative state or those with acute stroke or head injury, short-term critical illness, oropharyngeal cancers, and possibly bulbar amyotrophic lateral sclerosis.[176] Additionally, artificial hydration may improve symptoms of delirium in patients with cancer, although it does not influence survival in most advanced cancers.[177] The use of percutaneous feeding tubes in patients with advanced dementia does not prevent pneumonia or improve survival and is not recommended.[178,179] For some patients, a time-limited trial of artificial hydration or nutrition may be appropriate to evaluate for benefit, such as improvement in delirium, while monitoring for side effects, such as dyspnea from pulmonary edema.

DYSPNEA

Dyspnea is "a subjective experience of breathing discomfort that consists of qualitatively distinct sensations that vary in intensity,"[180] as differentiated from breathing that appears labored or fast to an observer. Dyspnea in patients receiving palliative care has many causes, including dyspnea of physical and psychological origins.[181] Dyspnea is common in patients with a high risk of death[182,183] and was identified as the most distressing symptom by patients who could self-report in the ICU, regardless of their mechanical ventilation status.[184] Dyspnea increases closer to the time of death, even in patients without known cardiopulmonary disease.[185] Treatment is either aimed at reversing the cause of dyspnea, for example with a thoracentesis for an effusion, or at symptomatic management. Nonpharmacologic therapy such as a fan or pulmonary rehabilitation may be helpful.[186] Studies of low-dose opioids in refractory dyspnea in this population support their safety and efficacy.[187,188] In a randomized, double-blind, crossover study of 48 mostly older patients with COPD who were taking 20 mg of sustained-release morphine daily, a significant improvement in dyspnea was observed with minimal side effects.[189] Studies of the effect of benzodiazepines with and without opioids for dyspnea are small and mixed, with a trend toward possible benefit as a second- or third-line treatment.[190-192] Forced air through a nasal cannula generally gives the same benefit as oxygen unless the patient is hypoxic.[193]

NOISY BREATHING AT THE END OF LIFE

Approximately one half of patients experience noisy breathing, sometimes referred to as the *death rattle*, usually 1 to 2 days before death.[194,195] Terminal secretions are thought be secretions from the airway or oropharynx that cannot be cleared because of the inability to cough or swallow.[195] Despite widespread clinical use of antimuscarinic drugs for terminal secretions, strikingly few studies support this practice. A large study comparing atropine, hyoscine butylbromide, and scopolamine infusions showed improvement in symptoms and no difference among those agents, but this study lacked a placebo arm. A study of a one-time dose of sublingual atropine versus placebo showed no difference.[196] Of note, many of these earlier, small studies have multiple methodologic limitations. Family members differ in their interpretations of the sound, with some but not all finding it unsettling.[197] Many clinicians believe the noisy breathing, itself, is not bothersome to patients because most are generally unconscious, although evidence to support this view is lacking.

DEPRESSION AND ANXIETY IN THE PATIENT RECEIVING PALLIATIVE CARE

Depression and anxiety are common at the end of life, with estimates ranging from 5% to 30% and 7% to 13%, respectively.[198] Many factors contribute to psychological distress, including social, economic, spiritual, and physical stressors associated with serious illness.[199] A screening test for depression consisting of two parts, "Are you depressed?" and "Have you experienced a loss of interest in things or activities you would normally enjoy?" has a sensitivity of 91% and a specificity of 68% and has been validated in the palliative care

TABLE 65-5 DISTINGUISHING CHARACTERISTICS OF GRIEF AND DEPRESSION IN PATIENTS WHO ARE TERMINALLY ILL

Characteristic	Normal Grief	Depression
Nature of response	Adaptive	Maladaptive
Focus of distress	In response to a particular loss; not affecting all aspects of life	Pervasive; affecting all aspects of life
Symptom fluctuations	Symptoms coming in waves, generally improving with time	Constant
Mood	Sadness and dysphoria	Protracted and constant depression or flat affect
Interests and capacity for pleasure	Interests and capacity for pleasure remaining intact; diminishing engagement in activities because of functional decline	Anhedonia with significant diminished interest or pleasure in all activities
Hope	Episodic and focal loss of hope; hopes possibly changing over time; giving positive orientation toward the future	Persistent and pervasive hopelessness
Self-worth	Maintaining self-worth, although with feelings of helplessness	Worthlessness with the belief that one's life has no value
Guilt	Regrets and guilt over specific events	Excessive feelings of guilt
Suicidal ideation	Passive and fleeting desire for a hastened death	Preoccupation with a desire to die

From Widera EW, Block SD: Managing grief and depression at the end of life, Am Fam Physician *86:259-264, 2012.*

population.[200] Referral should be made to a psychiatrist or other experienced provider for patients who screen positive or for patients who have suicidal or homicidal ideations. Depression must be distinguished from delirium and normal grief, which can be a difficult distinction[200,201] (Table 65-5). For the anesthesiologist, recognizing depression and making appropriate referrals is important; depression may affect pain management, quality of life, and treatment decisions. Treatments for depression vary by life expectancy. Selective serotonin reuptake inhibitors (SSRIs) and monoamine oxidase inhibitors (MAOIs) may be appropriate for patients with a longer life expectancy; the time to onset of action is 1 to 2 months. For patients with a life expectancy of weeks to a few months, methylphenidate has been well studied in the cancer population. The onset of action is 1 to 3 days and is generally effective and well-tolerated for depression and fatigue.[202,203]

DELIRIUM AT THE END OF LIFE

Delirium is covered in depth in Chapter 80. It affects 28% to 88% of patients who are terminally ill, with incidence increasing closer to the time of death.[204,205] The Confusion Assessment Method has been validated in the palliative care population[206,207] (also see Chapter 80). Some patients may have more than one possible cause of delirium (Box 65-5). Delirium can have a major impact on a patient's ability to make a well-informed decision about treatment options, including surgery, which may have ethical and legal implications. Most patients who recover remember being delirious, and those who do find it very distressing.[208]

As much as one half of delirium near the end of life may be reversible.[205] Knowing which cases of delirium could be reversible can be difficult, although a younger age, less severe impairment, and lack of organ failure appear to correspond to a greater likelihood of reversibility.[209] Patients with true terminal delirium have a very short life expectancy.[204] The pursuit of the workup should be based on the patient's goals of care (Box 65-6). For example, the family of a patient with cancer who develops delirium but previously had an acceptable quality of life may desire a workup for potential causes

BOX 65-5 *Causes of Delirium*

- Metabolic disturbance
  - Hypercalcemia
  - Hyponatremia
  - Hypernatremia
  - Dehydration
  - Glycemic derangements
- Organ failure
  - Renal failure
  - Liver failure
  - Respiratory failure
- Medications
  - Opioids
  - Benzodiazepines
  - Anticholinergic agents
  - Steroids
- Sepsis
  - Pneumonia
  - Urinary tract infection
- Brain pathologic conditions
  - Tumor
  - Metastases
  - Leptomeningeal disease
  - Nonconvulsive status epilepticus
- Hypoxia
- Withdrawal
  - Alcohol
  - Benzodiazepines
- Hematologic conditions
  - Disseminated intravascular coagulation
  - Anemia

From LeGrand SB: Delirium in palliative medicine: a review, J Pain Symptom Manage *44:583-594, 2012.*

including a urinalysis and chest x-ray study, whereas the family of a patient who had previously been nearly comatose and expected to die in hours to days may not want to subject their family member to a bladder catheterization for a urinalysis.

Although delirium is often associated with agitation, hypoactive delirium, during which a patient may have decreased interaction with the environment and exhibit inattention, is likely more common than most clinicians appreciate.[210] Hypoactive delirium is considered disturbing by patients who experience it, but no consensus has been reached on whether or how to treat hypoactive delirium.[211]

BOX 65-6 *Evaluation of Delirium*

- Determining the goals of care
- Reviewing medications
- Considering the possibility of withdrawal
- Identifying any hematologic or metabolic abnormalities or organ failure
  - Complete metabolic panel
  - Complete blood count
- Evaluating oxygen levels
  - Oxygen saturation
- Identifying infections
  - Urine culture
  - Blood cultures
  - Chest x-ray imaging
- Performing specialized testing, if appropriate
  - Electroencephalogram
  - Arterial blood gas
  - Tests for disseminated intravascular coagulation
  - Test for thyroid-stimulating hormone
  - Computed tomography scan or magnetic resonance imaging scan of the brain
  - Lumbar puncture

From LeGrand SB: Delirium in palliative medicine: a review, J Pain Symptom Manage *44:583-594, 2012.*

BLEEDING IN THE PATIENT RECEIVING PALLIATIVE CARE

Bleeding can be caused by a number of pathologic conditions, including coagulation disorders and cancers. In addition to dressings and radiation therapy, fibrinolytic inhibitors such as tranexamic acid, interventional radiologic procedures such as embolization, and surgery have been suggested for patients with compatible goals and life expectancy.[212] Exsanguination in patients receiving palliative care is uncommon but can be upsetting to patients, families, and providers. No randomized trials of best treatments have been conducted. Some practical suggestions include the use of dark towels, suction, using pressure, and staying with the patient. Medications are frequently suggested during exsanguination to provide sedation and amnesia. The use of medications varies, but often benzodiazepines, opioids, and sometimes ketamine are used, with midazolam 5 to 10 mg being the most common[213] (also see Chapter 62).

ANESTHETIC CONCERNS IN THE PATIENT RECEIVING PALLIATIVE CARE

PREOPERATIVE CONSIDERATIONS

A patient's decisional capacity may change during hospitalization or over time and should be assessed before seeking consent from the patient for anesthesia. As noted in Chapter 10, patients awaiting surgery with a standing DNR order should prompt a discussion of the patient's goals and the creation of a plan for intraoperative and postoperative management that meets a patient's goals. In the case of the reversal of a DNR order, a plan for when that order would be reinstituted should be developed.[101] The anesthesiologist should also discuss the patient's preferences with the surgeon and nurse as appropriate.

TABLE 65-6 **ANESTHETIC DRUGS AND HOST DEFENSES**

Drug	Potential Effect on Antitumor Host Defenses
Ketamine	Reduces natural killer (NK) cell activity and the number in animal models.
Thiopental	Reduces NK cell activity and the number in animal models.
Propofol	Reduces NK cell number in animal models.
Volatile agents	Inhibits interferon stimulation of NK cell cytotoxicity in animal models. Reduces NK cell number in humans; is associated with worse outcomes when compared with local anesthesia for melanoma excision.
Nitrous oxide	Associated with acceleration in the development of lung and liver metastases in animal models. No effect on cancer outcomes after surgery for colorectal carcinoma in humans. Inhibits the formation of hematopoietic cells that may be important for tumor cells.
Local anesthetic drugs	Lidocaine inhibits epidermal growth factor (EGF) receptor and tumor cell proliferation *in vitro*; ropivacaine inhibits growth of cancer cells.
Morphine	Inhibits cellular immunity including NK cell activity in animal models Inhibits NK cell activity in humans.
Fentanyl	Inhibits NK cell activity in humans.
Tramadol	Stimulates NK cell activity in animal models. Stimulates NK cell activity in humans.
Cyclooxygenase-2 (COX-2) inhibitors	Display antiangiogenesis and antitumor effects in animal models

From Snyder GL, Greenberg S: Effect of anaesthetic technique and other perioperative factors on cancer recurrence, Br J Anaesth *105:106-115, 2010.*

BOX 65-7 *Perioperative Considerations in the Patient in Palliative Care*

Preoperative Considerations

Review the chart for advance directive or documentation of code status.

If a Do Not Resuscitate (DNR) order or other limits on treatment are listed, then clarify the patient's desires based on the American Society of Anesthesiologists (ASA) guidelines.[101]

- Full attempt at resuscitation is defined.
- Limited attempt at resuscitation is defined with regard to specific procedures.
  - Patient or surrogate decision maker should be informed about which procedures are essential to providing anesthesia (e.g., endotracheal tube) and which are not (e.g., chest compressions).
  - Example: Patient with extensive rib metastases declines chest compressions but desires other medications and procedures as appropriate
- Limited attempt at resuscitation is defined with regard to the patient's goals and values.
  - Patient or surrogate decision maker allows the medical team to decide which procedures are appropriate.
  - Example: Patient wants to have treatments that seem easily reversible (e.g., respiratory depression in the postanesthesia care unit [PACU] after accidental narcotic overdose) but does not want treatment that may to lead to neurologic compromise (e.g., prolonged cardiopulmonary resuscitation [CPR])
- Clearly document any changes in treatment limitation in the chart.
  - Include the people present during the discussion.
  - Document when the original advance directive will be reinstated.
  - Per ASA guidelines, "…when the patient leaves the postanesthesia care unit or when the patient has recovered from the acute effects of anesthesia and surgery."
- Discuss any changes in treatment limitation with the surgeon, nurse, or other appropriate health care providers.
- Ensure that the patient preoperatively receives any scheduled pain medications.
- Consider involving spiritual care to perform appropriate rituals if the risk of death is high.
- Review past medications for agents such as adriamycin and bleomycin.
- Review records for sites of metastases including the lung or brain that may affect the physiologic mechanisms.
- Assess decision-making ability of the patient with brain metastases or suspected cognitive impairment.
- Consider preoperative epidural placement for the appropriate patient.
- Assess baseline functional status and general prognosis.

Intraoperative Considerations

- Take special care in positioning patients with cachexia and those with poor skin integrity.
- Consider postoperative nausea and vomiting (PONV) prophylaxis for at-risk patients.
- Communicate any limitations in treatment to on-coming providers.

Postoperative Considerations

- Consider possibly increased postoperative pain requirements in the context of baseline opioid use.
- Ensure the availability of a rescue antiemetic therapy for at-risk patients.
- Communicate any limitations in treatment to PACU providers.

Data from Ethical Guidelines for the Anesthesia Care of Patients with Do-Not-Resuscitate Orders or Other Directives that Limit Treatment, 2008. Accessed June 20, 2013. <http://www.asahq.org/For-Members/Standards-Guidelines-and-Statements.aspx>

A thorough preoperative evaluation of the patient's disease should also take place with attention to the patient's cognitive status, recent medications (including chemotherapy), presence of metastases, and wounds. Knowledge of the patient's preoperative functional status and prognosis may impact the anesthetic plan, in addition to giving the patient an accurate assessment of risks and benefits. Details on special considerations in specific disease states such as cancer, COPD, and others are included in Chapter 39. Considering the number of patients receiving palliative care who will be given be given pain medication perioperatively, anesthesiologists are advised to follow the guidelines in Chapter 64 regarding perioperative pain management.

INTRAOPERATIVE CONCERNS

Resuscitation status should be communicated to any providers caring for the patient intraoperatively or postoperatively. Consideration should be given to postoperative nausea and vomiting (PONV) prophylaxis (also see Chapter 97), and the care of fragile skin in this population.

ANESTHETIC CHOICE AND CANCER

Recent studies have attempted to clarify the role of anesthesia in cancer progression and recurrence. Studies of the effect of regional anesthesia on those with cancer are mixed but suggest a possible benefit; additional discussion is available in Chapter 56. Studies that examine the choice of specific systemic anesthetics on cancer are mostly in vivo or in vitro but also suggest differences in responses to tumor cells among the different drugs[214] (Table 65-6).

POSTOPERATIVE COURSE

Standard postoperative care is sufficient for most patients in palliative care. Risks for postoperative pain, delirium, and nausea and vomiting may be increased, depending on the individual patient. Some patients may need increased dosages of pain medication, depending on baseline use. Providers should communicate any limitations in care and when limitations revert to their preoperative status (Box 65-7).

Chapter 66

Anesthesia for Thoracic Surgery

PETER D. SLINGER • JAVIER H. CAMPOS

Key Points

- Patients undergoing pulmonary resection should have a preoperative assessment (see Chapter 38) of their respiratory function in three areas: lung mechanical function, pulmonary parenchymal function, and cardiopulmonary reserve (the "three-legged stool" of respiratory assessment).
- Patients with underlying lung disease have a decreased risk of respiratory complications when pulmonary resections are performed with video-assisted thoracoscopic surgery (VATS).
- After lung resection surgery and proper weaning, the trachea can usually be extubated in patients who had adequate predicted postoperative respiratory function in the operating room. In addition, they must be "AWaC" (alert, warm, and comfortable).
- Interventions that decrease the incidence of respiratory complications in high-risk patients undergoing thoracic surgery include cessation of smoking, physiotherapy, and thoracic epidural analgesia.
- Geriatric patients (see Chapter 80) are at high risk for cardiac complications, particularly cardiac arrhythmias (see Chapter 47), after large pulmonary resections. Preoperative exercise capacity is the best predictor of post thoracotomy outcome in the elderly.
- The ability to perform fiberoptic bronchoscopy and a detailed knowledge of bronchial anatomy are required for providing reliable lung isolation.
- The use of double-lumen endobronchial tubes (DLTs) is the standard method for providing lung isolation in adults. Bronchial blockers are a reasonable alternative for lung isolation in patients with abnormal upper or lower airways.
- With the use of intravenous anesthetic techniques or volatile anesthetics at less than or equal to 1-MAC doses, hypoxemia usually does not occur during one-lung ventilation (OLV). The use of continuous positive airway pressure (CPAP) or positive end-expiratory pressure (PEEP) as treatment for hypoxemia during OLV should be guided by the individual patient's lung mechanics.
- The use of large tidal volumes during OLV (e.g., 10 mL/kg) can contribute to acute lung injury, particularly in patients at increased respiratory risk, such as after pneumonectomy.
- The underlying principle of management of a patient with a bronchopleural fistula is to secure lung isolation before positive pressure ventilation or to reposition the patient for surgery.
- Anesthetic management of a patient with an anterior or superior mediastinal mass should be guided by the patient's symptoms, the preoperative computed tomography (CT) scan, and the echocardiography findings. The fundamental principle of anesthetic management for these patients is *noli ponti ignii consumere* ("don't burn your bridges").
- Continuous paravertebral local anesthetic blockade combined with multimodal analgesia is a reasonable alternative to epidural analgesia for thoracic surgery, with fewer side effects.

Thoracic anesthesia encompasses a wide variety of diagnostic and therapeutic procedures involving the lungs, airways, and other intrathoracic structures. As the patient population presenting for noncardiac thoracic surgery has evolved, so have the anesthetic techniques to manage these patients. At the beginning of the last century, thoracic surgery was primarily done to treat infectious indications (e.g., lung abscess, bronchiectasis, empyema). Although these cases still present for surgery in the post-antibiotic era, now the most common indications are related to malignancies (i.e., pulmonary, esophageal, and mediastinal). In addition, the past 2 decades have seen the beginning of surgical therapy for end-stage lung diseases with procedures such as lung transplantation and lung volume reduction. Fundamental to anesthetic management for the majority of thoracic procedures are two techniques: (1) lung isolation to facilitate surgical access within the thorax and (2) management of one-lung anesthesia. In this chapter, we initially discuss preanesthetic assessment for thoracic surgery, outline intraoperative management principles common to most thoracic surgical procedures, discuss specific anesthetic considerations in common and less common surgical operations, and we finally finish with a description of postoperative management issues in thoracic surgical patients.

PREOPERATIVE EVALUATION OF THE THORACIC SURGERY PATIENT
(See Chapter 38)

Preoperative anesthetic assessment before chest surgery is a continually evolving science and art. Recent advances in anesthetic management, surgical techniques, and perioperative care have expanded the realm of patients now considered to be "operable."[1] This discussion focuses primarily on preanesthetic assessment for pulmonary resection surgery in cancer patients. However, the basic principles described apply to all other types of nonmalignant pulmonary resections and to other chest surgeries.

Although 87% of patients with lung cancer will die of their disease, the 13% cure rate represents approximately 26,000 survivors per year in North America. Surgical resection is responsible for essentially all of these cures. A patient with "resectable" lung cancer has a disease that is still local or locoregional in scope and can be encompassed in a plausible surgical procedure. An operable patient is someone who can tolerate the proposed resection with acceptable risk.

The patient is commonly assessed initially as an outpatient, often not by anesthesia personnel. Yet it is necessary to organize and standardize the approach to preoperative evaluation for these patients into two temporally disjointed phases: the initial (clinic) assessment and the final (day of admission) assessment. Elements vital to each assessment are described.

Increasingly, thoracic surgeons are performing lung-sparing resections such as sleeve-lobectomies or segmentectomies, and resections with minimally invasive techniques such as video-assisted thoracoscopic surgery (VATS) or robotic surgery. The postoperative preservation of respiratory function is proportional to the amount of functioning lung parenchyma preserved. To assess patients with limited pulmonary function, these newer surgical options need to be understood in addition to the conventional open lobectomy or pneumonectomy.

Preoperative assessment should identify patients at increased risk and that risk assessment should stratify the perioperative management and focus resources on the high-risk patients to improve their outcome. This is the primary function of the preanesthetic assessment. There are occasions when the anesthesiologist should contribute his or her opinion about whether a specific high-risk patient will tolerate a specific surgical procedure. This may occur preoperatively but also occurs intraoperatively when the surgical findings suggest that a planned procedure, such as a lobectomy, may require a larger resection, such as a pneumonectomy. For these reasons, it is necessary that the anesthesiologist have a complete preoperative knowledge of the patient's medical status and the pathophysiology of lung resection surgery, which are needed for a proper anesthetic to be given. Prethoracotomy assessment naturally involves all of the factors of a complete anesthetic assessment: past history, allergies, medications, upper airway, and so on. This section concentrates on the additional information, beyond a standard anesthetic assessment, that the anesthesiologist needs to manage a patient undergoing a pulmonary resection.

PERIOPERATIVE COMPLICATIONS

The major cause of perioperative morbidity and mortality in the thoracic surgical population is respiratory complications. Major respiratory complications—atelectasis, pneumonia, and respiratory failure—occur in 15% to 20% of patients and account for the majority of the expected 3% to 4% mortality rate.[2] For other types of surgery, cardiac and vascular complications are the leading cause of early perioperative morbidity and mortality. Cardiac complications such as arrhythmia and ischemia occur in 10% to 15% of the thoracic population.

ASSESSMENT OF RESPIRATORY FUNCTION
(See Chapter 19)

The best assessment of respiratory function comes from a detailed history of the patient's quality of life. All patients undergoing a pulmonary resection should have baseline simple spirometry done preoperatively.[3] Objective measures of pulmonary function are required to guide anesthetic management and to have this information in a format that can be easily transmitted between members of the health care team. Respiratory function can be divided into three related but somewhat independent areas: respiratory mechanics, gas exchange, and cardiorespiratory interaction. The basic functional units of extracellular respiration are to move the oxygen: (1) into the alveoli, (2) into the blood, and (3) into the tissues (the process is reversed for carbon dioxide removal).

Respiratory Mechanics

Many tests of respiratory mechanics and volumes show correlation with postthoracotomy outcome: forced

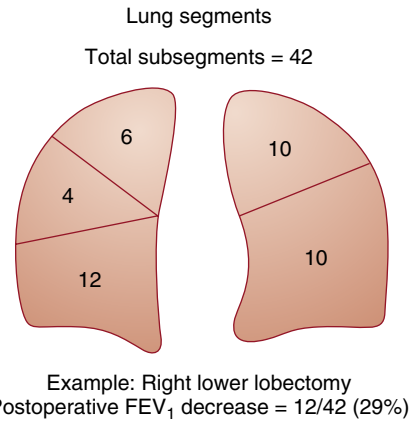

Figure 66-1. The number of subsegments of each lobe is used to calculate the predicted postoperative (ppo) pulmonary function (e.g., after a right lower lobectomy, a patient with a preoperative FEV_1 [or D_Lco] 70% of normal would be expected to have a $ppoFEV_1$ of 70% × (1 – 29/100) = 50%. *(Reproduced with permission from Slinger P:* Principles and practice of anesthesia for thoracic surgery. *New York, Springer, 2011.)*

expiratory volume in one second (FEV_1), forced vital capacity (FVC), maximal voluntary ventilation (MVV), residual volume/total lung capacity ratio (RV/TLC), and so on (see Chapter 19 on pulmonary function testing). It is useful to express these as a percent of predicted volumes corrected for age, sex, and height (e.g., FEV_1 %). Of these, the most valid single test for postthoracotomy respiratory complications is the predicted postoperative FEV_1 ($ppoFEV_1$ %),[4] which is calculated as:

$$ppoFEV_1\,\% = \text{preoperative } FEV_1\,\% \times (1 - \%\ \text{functional lung tissue removed}/100)$$

One method of estimating the percent of functional lung tissue is based on a calculation of the number of functioning subsegments of the lung removed (Fig. 66-1). Patients with a $ppoFEV_1$ greater than 40% are at low risk for postresection respiratory complications. The risk of major respiratory complications is increased in the subgroup with a $ppoFEV_1$ less than 40% (although not all patients in this subgroup develop respiratory complications), and patients with a $ppoFEV_1$ less than 30% are at high risk.

Lung Parenchymal Function

As important to the process of respiration as the mechanical delivery of air to the distal airways is the subsequent ability of the lung to exchange oxygen and carbon dioxide between the pulmonary vascular bed and the alveoli. Traditionally, arterial blood gas data such as partial pressure of oxygen in the blood (PaO_2) less than 60 mm Hg or partial pressure of carbon dioxide in the blood ($Paco_2$) greater than 45 mm Hg have been used as cutoff values for pulmonary resection. Cancer resections have now been successfully performed singly or even combined with volume reduction in patients who do not meet these criteria, although they remain useful as warning indicators of increased risk. The most useful test of the gas exchange capacity of the lung is the diffusing capacity for carbon monoxide (D_Lco). The D_Lco correlates with the total functioning surface area of alveolar-capillary interface. The corrected D_Lco can be used to calculate a postresection (ppo) value using the same calculation as for the FEV_1 (see Fig. 66-1). A $ppoD_Lco$ less than 40% predicted correlates with both increased respiratory and cardiac complications and is usually independent of the FEV_1.[5] The D_Lco, but not the FEV_1, is negatively affected by preoperative chemotherapy and may be the most important predictor of complications in this subgroup of patients. Some authors feel a higher cutoff risk-threshold for $ppoD_Lco$ of less than 50% may be more appropriate.[6] The National Emphysema Treatment Trial has shown that patients with a preoperative FEV_1 or D_Lco less than 20% had an unacceptably frequent perioperative mortality rate.[7] These can be considered as the absolute minimal values compatible with a successful outcome.

Cardiopulmonary Interaction

The final and perhaps most important assessment of respiratory function is an assessment of the cardiopulmonary interaction. Formal laboratory exercise testing is currently the gold standard for assessment of cardiopulmonary function,[8] and the maximal oxygen consumption (VO_{2max}) is the most useful predictor of postthoracotomy outcome. The risk of morbidity and mortality is increased if the preoperative VO_{2max} is less than 15 mL/kg/min and is considered very high if it is less than 10 mL/kg/min.[9] Few patients with a VO_{2max} greater than 20 mL/kg/min have respiratory complications (for comparison, the highest VO_{2max} recorded is 85 mL/kg/min by the American cyclist Lance Armstrong in 2005[10]). Complete laboratory exercise testing is expensive. Several alternatives have been demonstrated to be valid surrogate tests for prethoracotomy assessment.

The distance that a patient with chronic obstructive pulmonary disease (COPD) can walk during a 6-minute test shows an excellent correlation with VO_{2max} and requires little or no laboratory equipment.[11] VO_{2max} can be estimated from the 6-minute walk test distance in meters divided by 30 (i.e., 6-minute walk text of 450 m: estimated VO_{2max} = 450/30 = 15 mL/kg/min). Patients with a decrease of oxygen saturation (SpO_2) greater than 4% during exercise[12] are also at increased risk. The traditional exercise test in ambulatory patients is stair climbing. The ability to climb five flights of stairs correlates with a VO_{2max} more than 20 mL/kg/min, and climbing two flights corresponds to a VO_{2max} of 12 mL/kg/min.

After pulmonary resection, right ventricular dysfunction appears to be in proportion to the amount of functioning pulmonary vascular bed that has been removed. The exact etiology and duration of this dysfunction remains unknown. Clinical evidence of this hemodynamic problem is minimal when the patient is at rest but is dramatic when the patient exercises, leading to elevation of pulmonary vascular pressures, limitation of cardiac output, and absence of the normal decrease in pulmonary vascular resistance usually seen with exertion.[13]

Ventilation-Perfusion Scintigraphy

Prediction of postresection pulmonary function can be further refined by assessment of the preoperative contribution of the lung or lobe to be resected using ventilation-perfusion ($\dot{V}/\dot{Q}$) lung scanning. If the lung region to be

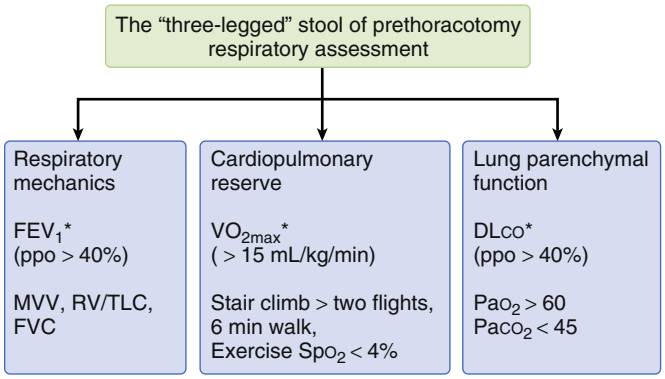

Figure 66-2. The "3-legged" stool of prethoracotomy respiratory assessment. *Most valid test (see text). *(Reproduced with permission from Slinger P:* Principles and practice of anesthesia for thoracic surgery, *New York, Springer, 2011.)*

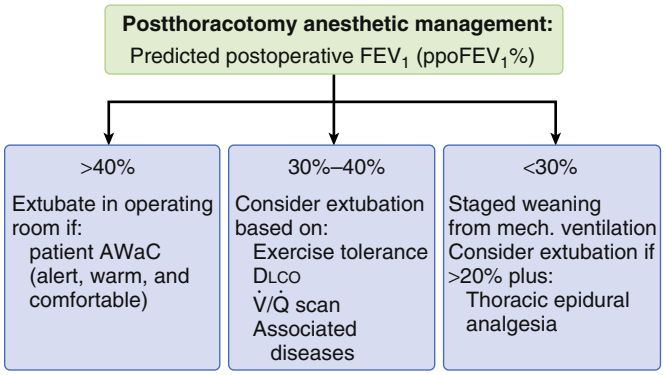

Figure 66-3. Anesthetic management guided by preoperative assessment and the amount of functioning lung tissue removed during surgery. *(Reproduced with permission from Slinger P:* Principles and practice of anesthesia for thoracic surgery, *New York, Springer, 2011.)*

resected is nonfunctioning or minimally functioning, the prediction of postoperative function can be modified accordingly. This is particularly useful in pneumonectomy patients[14] and $\dot{V}/\dot{Q}$ scanning should be considered for any pneumonectomy patient who has a preoperative FEV_1 and/or D_Lco less than 80%. However, $\dot{V}/\dot{Q}$ scanning is of limited usefulness to predict postlobectomy function.

Combination of Tests

No single test of respiratory function has shown adequate validity as a sole preoperative assessment. Before surgery, an estimate of respiratory function in all three areas—lung mechanics, parenchymal function, and cardiopulmonary interaction—should be made for each patient. These three aspects of pulmonary function form the "three-legged stool" that is the foundation of prethoracotomy respiratory assessment (Fig. 66-2) that can be used to plan intraoperative and postoperative management (Fig. 66-3). These plans and intraoperative surgical factors sometimes necessitate that a resection becomes more extensive than was foreseen. If a patient has a $ppoFEV_1$ greater than 40%, the trachea usually can be extubated in the operating room at the conclusion of surgery assuming the patient is alert, warm, and comfortable ("AWaC"). If the $ppoFEV_1$ is greater than 30% and exercise tolerance and lung parenchymal function exceed the increased-risk thresholds, then tracheal extubation can be done in the operating room depending on the status of associated medical conditions. Patients in this subgroup who do not meet the minimal criteria for cardiopulmonary and parenchymal function should be considered for staged weaning from mechanical ventilation postoperatively (see Chapter 103). Patients with a $ppoFEV_1$ of 20% to 30% and favorable predicted cardiorespiratory and parenchymal function can be considered for early tracheal extubation if thoracic epidural analgesia is used or if the resection is performed with VATS. In the increased-risk group, the presence of several associated factors and diseases should be documented during the preoperative assessment (see Chapter 3) and will enter into the consideration for postoperative management (discussed later).

CONCOMITANT MEDICAL CONDITIONS

CARDIAC DISEASE (See Chapter 39)

Cardiac complications are the second most common cause of perioperative morbidity and mortality in the thoracic surgical population.

Ischemia

Because the majority of pulmonary resection patients have a smoking history, they already have one risk factor for coronary artery disease. Elective pulmonary resection surgery is regarded as an intermediate-risk procedure in terms of perioperative cardiac ischemia.[15] The overall documented incidence of postthoracotomy ischemia is 5% and peaks on days 2 to 3 postoperatively. Beyond the standard history, physical, and electrocardiogram, routine screening testing for cardiac disease does not appear to be cost-effective for all prethoracotomy patients. Noninvasive testing is indicated in patients with major (i.e., unstable ischemia, recent infarction, severe valvular disease, significant arrhythmia) or intermediate (i.e., stable angina, remote infarction, previous congestive failure, diabetes) clinical predictors of myocardial risk. Therapeutic options to be considered in patients with significant coronary artery disease are optimization of medical therapy, coronary angioplasty, or coronary artery bypass, either before or at the time of lung resection. Timing of lung resection surgery after a myocardial infarction is always a difficult decision to make. Limiting the delay to 4 to 6 weeks in a medically stable and fully investigated and optimized patient seems acceptable after myocardial infarction. The appropriate delay after coronary stenting is conventionally 4 to 6 weeks after bare metal stents and 12 months after drug-eluting stents.[16] Surgery should be delayed until it is safe to temporarily discontinue major antiplatelet drugs (except aspirin). A recent study upholds the 6-week delay after bare metal stents but suggests that the risks after drug-eluting stents are minimal after 6 months (Fig. 66-4).[17]

Arrhythmia

Dysrhythmias (see Chapter 47) are a common complication of pulmonary resection surgery, and it occurs is 30% to 50% of patients within the first week postoperatively,

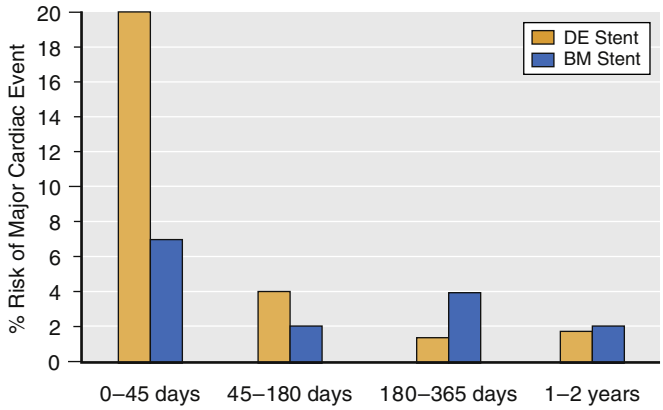

Figure 66-4. Risk of major 30-day postoperative cardiac event after elective noncardiac surgery in more than 2000 patients after coronary artery stents. *DE*, drug eluting; *BM*, bare metal. The risks after stent become minimal after 6 weeks for BM stents and after 6 months for DE stents. *(Based on data from Wijeysundera ND, Wijeysundera HC, Wasowicz M, et al: Risk of elective major non-cardiac surgery after coronary stent insertion,* Anesth Analg *113:s62, 2012).*

when Holter monitoring is used.[18] Of these arrhythmias, 60% to 70% are atrial fibrillation. Several factors correlate with an increased incidence of arrhythmias, including extent of lung resection (pneumonectomy 60% versus lobectomy 40% versus nonresection thoracotomy 30%), intrapericardial dissection, intraoperative blood loss, and age of the patient. Extrapleural pneumonectomy patients are a particularly high-risk group.[19]

Two factors in the early postthoracotomy period interact to produce atrial arrythmias: (1) increased flow resistance through the pulmonary vascular bed because of permanent (lung resection) or transient (atelectasis, hypoxemia) causes, with attendant strain on the right side of the heart; and (2) increased sympathetic stimuli and oxygen requirements, which are maximal on the second postoperative day as patients become more mobile.

In some patients undergoing a pneumonectomy, the right heart may not be able to increase its output adequately to meet the usual postoperative stress. Transthoracic echocardiographic studies have shown that pneumonectomy patients develop an increase in right ventricular systolic pressure as measured by the tricuspid regurgitation jet on postoperative day 2 but not on postoperative day 1. An increase in tricuspid regurgitation jet velocity is associated with postthoracotomy supraventricular tachyarrhythmias.[20] Preoperative exercise testing, which assesses the cardiopulmonary interaction, can predict postthoracotomy arrhythmias. Patients with COPD are more resistant to pharmacologic-induced heart rate control when they develop postthoracotomy atrial fibrillation and often require multiple drugs.[21]

Many antiarrhythmics are used to decrease the incidence of atrial arrhythmias after lung surgery, of which digoxin preparations are the most common. Digoxin does not prevent arrhythmias after pneumonectomy or other intrathoracic procedures. Other antiarrhythmics that have been used to prevent postthoracotomy arrhythmias include β-adrenergic blockers, verapamil, and amiodarone. Although all of these drugs decrease arrhythmias in thoracic patients, their side effects preclude their widespread application in this surgical population. At present, diltiazem is the most useful drug for postthoracotomy arrhythmia prophylaxis.[19] It seems that atrial arrhythmias are a sign of a dysfunctional right heart, for which prevention does not solve the underlying problem.

AGE-RELATED FACTORS (See Chapter 80)

There is no maximum age that is a cutoff for pulmonary resection.[4] The operative mortality in a group of patients 80 to 92 years of age was 3%, a very respectable figure, in one series.[22] However, the rate of respiratory complications (40%) was double that expected in a younger population, and the rate of cardiac complications (40%), particularly arrhythmias, was nearly triple that which would be seen in younger patients. In older patients, thoracotomy should be considered a high-risk procedure for cardiac complications, and cardiopulmonary function is the most important part of the preoperative assessment. An algorithm for the cardiac assessment of the older patient for thoracic surgery is presented in Figure 66-5. Although the mortality resulting from lobectomy among the older patients is acceptable, the mortality from pneumonectomy, particularly right pneumonectomy, is excessive.[23] Quality of life after pneumonectomy is significantly worse than it is after lesser pulmonary resections.[24] For these reasons, lung-sparing pulmonary resections are performed whenever possible. As a proportion of all lung cancer resections, pneumonectomy has decreased to approximately one third of its share of 15 years ago.[25] Exercise tolerance seems to be the primary determinant of outcome in older patients (see Chapter 80). Older patients should have, as a minimum cardiac investigation, a transthoracic echocardiogram to rule out pulmonary hypertension.

RENAL DYSFUNCTION

Renal dysfunction after pulmonary resection surgery was previously associated with a high mortality rate. Gollege and Goldstraw[26] reported a perioperative mortality of 19% (6/31) in patients in whom a significant elevation of serum creatinine developed in the postthoracotomy period, compared with 0% (0/99) in those who did not show any renal dysfunction. More recently, postthoracotomy renal dysfunction, as assessed by significant increases in serum creatinine levels, has been found to be associated with prolonged length of stay but not increased mortality.[27] Predictive factors for renal dysfunction include preoperative hypertension, angiotensin II receptor blockers, use of hydroxyethel starch, and open thoracotomies.

CHRONIC OBSTRUCTIVE PULMONARY DISEASE

The most common concurrent illness in the thoracic surgical population is COPD, which incorporates three disorders: emphysema, peripheral airways disease, and chronic bronchitis (see Chapter 39). Any individual patient may have one or all of these conditions, but the dominant clinical feature is impairment of expiratory airflow.[28] Assessment of the severity of COPD is made on the basis of the FEV_1% of predicted values. The American Thoracic

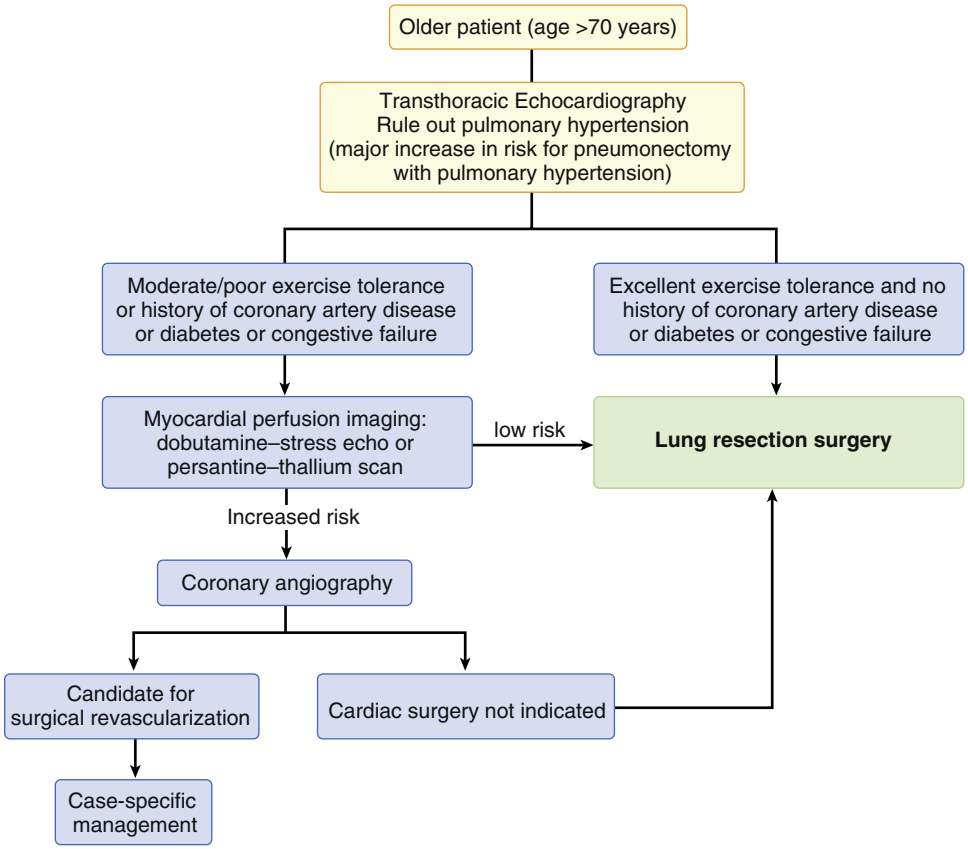

Figure 66-5. Algorithm for the preoperative cardiac assessment of older patients for thoracic (noncardiac) surgery.

Society categorizes stage I as greater than 50% predicted, stage II as 35% to 50%, and stage III as less than 35%. Stage I patients should not have significant dyspnea, hypoxemia, or hypercarbia, and other causes should be considered if these are present.

Respiratory Drive

Many patients with stage II or III COPD have an elevated $Paco_2$ at rest. It is not possible to differentiate these "CO_2 retainers" from nonretainers on the basis of history, physical examination, or spirometric pulmonary function testing.[29] CO_2 retention is related more to an inability to maintain the increased work of respiration required to keep the $Paco_2$ normal in patients with mechanically inefficient pulmonary function and not primarily resulting from an alteration of respiratory control mechanisms. It was previously thought that chronically hypoxemic/hypercapnic patients relied on a hypoxic stimulus for ventilatory drive and became insensitive to $Paco_2$. This explained the clinical observation that COPD patients in incipient respiratory failure could be put into a hypercapnic coma by the administration of a high concentration of oxygen (FiO_2). In actuality, only a minor fraction of the increase in $Paco_2$ in such patients is caused by a diminished respiratory drive, because minute ventilation is basically unchanged.[30] The $Paco_2$ rises because a high FiO_2 causes a relative decrease in alveolar ventilation and an increase in alveolar dead space and shunt by the redistribution of perfusion away from lung areas of relatively normal $\dot{V}/\dot{Q}$ matching to areas of very low $\dot{V}/\dot{Q}$ ratio because regional hypoxic pulmonary vasoconstriction (HPV) is decreased[31] and also as a result of the Haldane effect.[32] However, supplemental oxygen must be administered to these patients postoperatively to prevent hypoxemia associated with the unavoidable fall in functional residual capacity (FRC). The attendant rise in $Paco_2$ should be anticipated and monitored. To identify these patients preoperatively, all stage II and III COPD patients need an arterial blood gas analysis.

Nocturnal Hypoxemia

COPD patients have decreases in blood oxygen saturation more frequently and severely than normal patients during sleep.[33] This is because of the rapid/shallow breathing pattern that occurs in all patients during rapid-eye-movement sleep. In COPD patients breathing air, this causes a significant increase in the respiratory dead space/tidal volume (V_D/V_T) ratio and a fall in alveolar oxygen tension (PAO_2) and PaO_2. This is not the sleep apnea–hypoventilation syndrome (SAHS). There is no increased incidence of SAHS in COPD.

Right Ventricular Dysfunction

Right ventricular (RV) dysfunction occurs in as many as 50% of COPD patients. The dysfunctional right ventricle is poorly tolerant of sudden increases in afterload,[34] such as the change from spontaneous to controlled ventilation.[35] RV function becomes critical in maintaining cardiac output as the pulmonary artery pressure rises. The RV ejection fraction does not increase with exercise in COPD patients as it does in normal patients. Chronic recurrent hypoxemia is the cause of the RV dysfunction and the subsequent progression to cor pulmonale. Patients who have

episodic hypoxemia in spite of normal lungs (e.g., central alveolar hypoventilation, SAHS)[36] develop the same secondary cardiac problems as COPD patients. The only therapy that improves long-term survival and decreases right-sided heart strain in COPD is administration of increasing concentrations of oxygen. COPD patients who have a resting PaO_2 less than 55 mm Hg, as well as those who have decreases to less than 44 mm Hg with exercise, should receive supplemental oxygen at home. The goal of supplemental oxygen is to maintain a PaO_2 of 60 to 65 mm Hg. Compared with patients with chronic bronchitis, emphysematous COPD patients tend to have a decreased cardiac output and mixed venous oxygen tension while maintaining lower pulmonary artery pressures.

Bullae

Many patients with moderate or severe COPD develop cystic air spaces in the lung parenchyma known as *bullae*. These bullae are often asymptomatic unless they occupy more than 50% of the hemithorax, in which case the patient presents with findings of restrictive respiratory disease in addition to their obstructive disease. A bulla is a localized area of loss of structural support tissue in the lung with elastic recoil of surrounding parenchyma (Fig. 66-6). The pressure in a bulla is actually the mean pressure in the surrounding alveoli averaged over the respiratory cycle. This means that during normal spontaneous ventilation, the intrabulla pressure is actually slightly negative in comparison with the surrounding parenchyma.[37] However, whenever positive-pressure ventilation is used, the pressure in a bulla becomes positive in relation to the adjacent lung tissue, and the bulla expands with the attendant risk of rupture, tension pneumothorax, and bronchopleural fistula. Positive-pressure ventilation can be used safely in patients with bullae provided the airway pressures are kept low and there is adequate expertise and equipment immediately available to insert a chest drain and obtain lung isolation if necessary. Management of patients for bullectomy is discussed later.

Flow Limitation

Patients with severe COPD are often "flow-limited" even during tidal volume expiration at rest.[38] Flow limitation is present in normal patients only during a forced expiratory maneuver. Flow limitation occurs when an equal pressure point develops in the intrathoracic airways during expiration. During quiet expiration in the normal patient, the pressure in the lumen of the airways always exceeds the intrapleural pressure because of the upstream elastic recoil pressure that is transmitted from the alveoli. The effect of this elastic recoil pressure diminishes as air flows downstream in the airway. With a forced expiration, the intrapleural pressure may equal the intraluminal pressure at a certain point, the equal pressure point, which then limits the expiratory flow. Then, any increase in expiratory effort will not produce an increase in flow at that given lung volume.[39]

Flow limitation occurs particularly in emphysematous patients who primarily have a problem with loss of lung elastic recoil and have marked dyspnea on exertion. Flow limitation causes dyspnea because of stimulation of mechanoreceptors in the muscles of respiration, the thoracic cage, and the airway distal to the equal pressure point. Any increase in the work of respiration leads to increased dyspnea. This variable mechanical compression of airways by overinflated alveoli is the primary cause of the airflow obstruction in emphysema.

Severely flow-limited patients are at risk for hemodynamic collapse with the application of positive-pressure ventilation because of dynamic hyperinflation of the lungs. Even the modest positive airway pressures associated with manual ventilation with a bag/mask at induction can lead to hypotension because these patients have no increased resistance to inspiration but a marked obstruction of expiration. In some of these patients, this has contributed to the "Lazarus" syndrome, in which patients have recovered from a cardiac arrest only after resuscitation and positive-pressure ventilation were discontinued.[40]

Auto-PEEP

Patients with severe COPD often breathe in a pattern that interrupts expiration before the alveolar pressure has fallen to atmospheric pressure. This incomplete expiration is caused by a combination of factors that include flow limitation, increased work of respiration, and increased airway resistance. This interruption leads to an elevation of the end-expiratory lung volume above

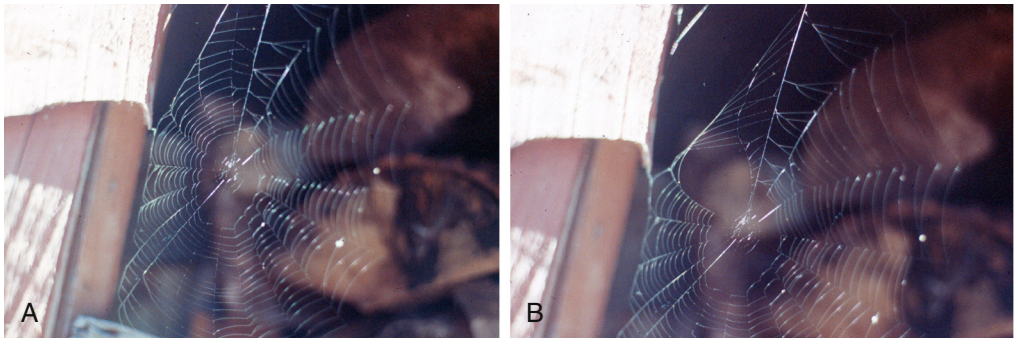

Figure 66-6. A, A spider's web as a lung model to demonstrate the pathophysiology of bullae. **B,** Breaking one septum of the spider's web causes a bulla to appear as elastic recoil pulls the web away from the area where structural support has been lost. Although the cells surrounding the bulla appear compressed, this is only because of redistribution of elastic forces. It is not positive pressure inside the bulla that causes this appearance of surrounding compression. *(Reproduced with permission from Slinger P:* Principles and practice of anesthesia for thoracic surgery, *New York, Springer, 2011.)*

the FRC. This positive end-expiratory pressure (PEEP) in the alveoli at rest has been termed auto-PEEP or intrinsic PEEP. During spontaneous respiration, the intrapleural pressure has to be decreased to a level that counteracts auto-PEEP before inspiratory flow can begin. Thus COPD patients can have an increased inspiratory load added to their already increased expiratory load.

Auto-PEEP becomes even more important during mechanical ventilation. It is directly proportional to tidal volume and inversely proportional to expiratory time. The presence of auto-PEEP is not detected by the manometer of standard anesthesia ventilators. It can be measured by end-expiratory flow interruption, a feature available on most intensive care ventilators. Auto-PEEP has been found to develop in most COPD patients during one-lung anesthesia.[41]

PREOPERATIVE THERAPY OF COPD

There are four treatable complications of COPD that must be actively sought and therapy begun at the time of the initial prethoracotomy assessment: atelectasis, bronchospasm, respiratory tract infections, and pulmonary edema (Table 66-1). Atelectasis impairs local lung lymphocyte and macrophage function, predisposing to infection. Pulmonary edema can be very difficult to diagnose by auscultation in the presence of COPD and may present very abnormal radiologic distributions (e.g., unilateral, upper lobes). Bronchial hyperreactivity may be a symptom of congestive failure or may represent an exacerbation of reversible airways obstruction. All COPD patients should receive maximal bronchodilator therapy as guided by their symptoms. Only 20% to 25% of COPD patients respond to corticosteroids. In a patient who is poorly controlled on sympathomimetic and anticholinergic bronchodilators, a trial of corticosteroids may be beneficial.

PHYSIOTHERAPY

Patients with COPD have fewer postoperative pulmonary complications when a perioperative program of intensive chest physiotherapy is initiated preoperatively.[42] Among the different modalities available (cough and deep breathing, incentive spirometry, PEEP, continuous positive airway pressure [CPAP]), there is no clearly proven superior method. Family members or nonphysiotherapy hospital staff can easily be trained to perform effective preoperative chest physiotherapy, and this should be arranged at the time of the initial preoperative assessment. Even in patients with the most severe COPD, exercise tolerance with a physiotherapy program will improve. Little improvement is seen before 1 month. Among COPD patients, those with excessive sputum benefit the most from chest physiotherapy.

A comprehensive program of pulmonary rehabilitation involving physiotherapy, exercise, nutrition, and education can improve functional capacity for patients with severe COPD.[43] These programs are usually of several months duration and are generally not an option in resections for malignancy, although for nonmalignant resections in severe COPD patients, rehabilitation should be considered. The benefits of short-duration rehabilitation programs before malignancy resection have not been fully assessed.

TABLE 66-1 **CONCURRENT PROBLEMS THAT SHOULD BE TREATED PRIOR TO ANESTHESIA IN COPD PATIENTS**

Problem	Method of Diagnosis
Bronchospasm	Auscultation
Atelectasis	Chest radiograph
Infection	History, sputum analysis
Pulmonary edema	Auscultation, chest radiograph

SMOKING

Pulmonary complications are decreased in thoracic surgical patients who cease smoking for more than 4 weeks before surgery.[44] Carboxyhemoglobin concentrations decrease if smoking is stopped more than 12 hours.[45] It is extremely important for patients to avoid smoking postoperatively. Smoking leads to a prolonged period of tissue hypoxemia. Wound tissue oxygen tension correlates with wound healing and resistance to infection. There is no rebound increase in pulmonary complications if patients stop for shorter (<8 weeks) periods before surgery.[46] Intensive smoking-cessation interventions are the most successful.[47]

PRIMARY THORACIC TUMORS

The majority of patients presenting for major pulmonary surgery will have some type of malignancy. Because the different types of thoracic malignancies have varying implications for both surgery and anesthesia, it is important for the anesthesiologist to have some knowledge of the presentation and biology of these cancers. By far the most common tumor is lung cancer. There are more than 200,000 new cases of lung cancer diagnosed per year in North America and more than 1.2 million diagnosed in the world. Lung cancer is currently the leading cause of cancer deaths in both genders in North America subsequent to the peak incidence of smoking in the period 1940 to 1970.[48] Worldwide, lung cancer incidence is more than double in men than in women (rate ratio 2.5:1.0).[49]

Lung cancer is broadly divided into small-cell lung cancer (SCLC) and non–small-cell lung cancer (NSCLC), with approximately 75% to 80% of these tumors diagnosed as NSCLC. Other less common and less aggressive tumors of the lung include the carcinoid tumors (typical and atypical) and adenoid cystic carcinoma. Compared with lung cancer, primary pleural tumors are rare. They include the localized fibrous tumors of pleura (previously referred to as *benign mesotheliomas*) and malignant pleural mesothelioma. Asbestos exposure is implicated in as many as 80% of malignant pleural mesotheliomas. A dose-response relationship is not always apparent, and even brief exposures can lead to the disease. An exposure history is often difficult to obtain because the latent period before clinical manifestation of the tumor may be as long as 40 to 50 years.

Tobacco smoke is responsible for approximately 90% of all lung cancers, and the epidemiology of lung cancer follows the epidemiology of cigarette smoking with approximately a 3-decade lag time.[50] Other environmental causes include asbestos and radon gas (a decay product of naturally occurring uranium), which act as co-carcinogens with tobacco smoke. For a pack-a-day cigarette smoker, the lifetime risk of lung cancer is approximately 1 in 14. Assuming that current mortality patterns continue, cancer will pass heart disease as the leading cause of death in North America in this decade.

Non–Small-Cell Lung Cancer

This pathologically heterogeneous group of tumors includes squamous cell, adenocarcinoma, and large-cell carcinoma. Overall 5-year survival with surgery approaches 40%. This seemingly low figure must be viewed in the light of an estimated 5-year survival without surgery of less than 10%. Although it is not always possible to be certain of the pathology of a given lung tumor preoperatively, many patients will have a known tissue diagnosis at the time of preanesthetic assessment based on prior cytology, bronchoscopy, mediastinoscopy, or transthoracic needle aspiration. This is useful information for the anesthesiologist to obtain preoperatively. Specific anesthetic implications of the different types of lung cancer are listed in Table 66-2.

Squamous Cell Carcinoma

This subgroup of NSCLC is strongly linked to cigarette smoking. The tumors tend to grow to a large size and metastasize later than others. They tend to cause symptoms related to local effects of a large tumor mass with a dominant endobronchial component, such as cavitation, hemoptysis, obstructive pneumonia, superior vena cava syndrome, and involvement of mainstem bronchus, trachea, carina, and main pulmonary arteries. Hypocalcemia may be associated with this cell type because of elaboration of a parathyroid-like factor and not as a result of bone metastases.

TABLE 66-2 ANESTHETIC CONSIDERATIONS FOR DIFFERENT TYPES OF LUNG CANCER

Type	Considerations
Squamous cell	Central lesions (predominantly) Often with endobronchial tumor Mass effects: obstruction, cavitation Hypercalcemia
Adenocarcinoma	Peripheral lesions Extrapulmonary invasion common Most Pancoast tumors Growth hormone, corticotropin Hypertrophic osteoarthropathy
Large cell	Large, cavitating peripheral tumors Similar to adenocarcinoma
Small cell	Central lesions (predominantly) Surgery usually not indicated Paraneoplastic syndromes Lambert-Eaton syndrome Fast growth rate Early metastases
Carcinoid	Proximal, endobronchial Bronchial obstruction with distal pneumonia Highly vascular Benign (predominantly) No association with smoking Carcinoid syndrome (rarely)

Adenocarcinoma

Adenocarinoma is currently the most common NSCLC in both sexes. These tumors tend to be peripheral and often metastasize early in their course, particularly to brain, bones, liver, and adrenals. They often invade extrapulmonary structures, including the chest wall, diaphragm, and pericardium. Almost all Pancoast tumors are adenocarcinomas. A variety of paraneoplastic metabolic factors can be secreted by adenocarcinomas, such as growth hormone and corticotropin. Hypertrophic pulmonary osteoarthropathy is particularly associated with adenocarcinoma.

Bronchioloalveolar carcinoma is a subtype of adenocarcinoma that is not related to cigarette smoking. In its early stages, it lines the alveolar membrane with a thin layer of tumor cells without destroying the alveolar architecture. Because of its low potential to spread outside of the lungs, multifocal bronchioloalveolar carcinoma can be treated by lung transplantation.[51]

Large-Cell Undifferentiated Carcinoma

This is the least common of the NSCLCs. It tends to present as a large, often cavitating peripheral tumor. The rapid growth rate may lead to widespread metastases, similar to adenocarcinoma.

Small-Cell Lung Cancer

This tumor of neuroendocrine origin is considered metastatic on presentation and is usually regarded as a medical, not a surgical, disease. Surgery is only very rarely indicated. The staging system differs from NSCLC and is divided simply into a limited stage and an extensive stage. Treatment of limited-stage SCLC with combination chemotherapy (etoposide/cisplatin or cyclophosphamide/doxorubicin/vincristine) gives objective response rates in more than 80% of patients. In addition, these patients typically receive aggressive radiotherapy to the primary lung tumor and prophylactic cranial irradiation. Despite this initial response, the tumor invariably recurs and is quite resistant to further treatment. The overall survival rate is no more than 10%. Extensive-stage disease is treated with chemotherapy and palliative radiation as needed.

SCLC causes a variety of paraneoplastic syndromes owing to the production of peptide hormones and antibodies. The most common of these is hyponatremia, usually as a result of an inappropriate production of antidiuretic hormone. Cushing syndrome and hypercortisolism through ectopic production of adrenocorticotropic hormone are also commonly seen.

A rare neurologic paraneoplastic syndrome associated with small-cell lung tumors is the Lambert-Eaton (also called Eaton-Lambert) myasthenic syndrome caused by impaired release of acetylcholine from nerve terminals. This typically presents as proximal lower limb weakness and fatigability that may temporarily improve with exercise.

The diagnosis is confirmed by electromyography showing increasing amplitude of unusual action potentials with high-frequency stimulation. Similar to those with true myasthenia gravis, paitents with myasthenic syndrome are extremely sensitive to nondepolarizing muscle relaxants (see Chapter 18). However, they respond poorly to acetylcholinesterase inhibitors such as neostigmine.[52] Of clinical importance, subclinical involvement of the diaphragm and muscles of respiration may exist. Thoracic epidural analgesia has been used after thoracotomy in these patients without complication. Neuromuscular function may improve after resection of the lung cancer.

Carcinoid Tumors

These are part of a continuum of neuroendocrine tumors that form a spectrum of diseases from SCLC as the most malignant to typical carcinoid as the most benign. Five-year survival after resection for typical carcinoid exceeds 90%. Systemic metastasis is rare, as is the carcinoid syndrome, which is caused by the ectopic synthesis of vasoactive mediators, and is usually seen with carcinoid tumors of gut origin that have metastasized to the liver. Atypical carcinoid tumors are more aggressive and may metastasize. Carcinoid tumors can precipitate an intraoperative hemodynamic crisis or coronary artery spasm, even during bronchoscopic resection.[53] The anesthesiologist should be prepared to deal with severe hypotension that may not respond to the usual vasoconstrictors and will require the use of the specific antagonists octreotide or somatostatin.[54]

Pleural Tumors

Localized fibrous tumors of the pleura are usually large, space-occupying masses that are attached to visceral or parietal pleura. They can be either benign or malignant.

Malignant pleural mesotheliomas are strongly associated with exposure to asbestos fibers. Their incidence in Canada has almost doubled in the past 15 years. With the phasing out of asbestos-containing products and the long latent period between exposure and diagnosis, the peak incidence is not predicted for another 10 years. The tumor initially proliferates within the visceral and parietal pleura, typically forming a bloody effusion. Most patients present with shortness of breath or dyspnea on exertion from this pleural effusion. Thoracentesis often relieves the symptoms but rarely provides a diagnosis. Pleural biopsy by VATS is the most efficient method to secure a diagnosis, and talc pleurodesis is performed during the same anesthetic period to treat the effusion.

Malignant pleural mesotheliomas respond poorly to therapy, and the median survival is less than 1 year. In patients with early disease, extrapleural pneumonectomy may be considered but it is difficult to know whether survival is improved. Recently, several groups have reported improved results with combinations of radiation, chemotherapy, and surgery. Extrapleural pneumonectomy is an extensive procedure that is rife with potential complications, both intraoperative and postoperative.[55] Blood loss from the denuded chest wall or major vascular structures is always a risk. Complications related to resection of the diaphragm and pericardium are additional risks to those of pneumonectomy.

ASSESSMENT OF THE PATIENT WITH LUNG CANCER (See Chapter 38)

At the time of initial assessment, cancer patients should be assessed for the "4 Ms" associated with malignancy (Box 66-1): **m**ass effects, **m**etabolic abnormalities, **m**etastases, and **m**edications. The prior use of medications that can exacerbate oxygen-induced pulmonary toxicity, such as bleomycin, should be considered.[56] Bleomycin is not used to treat primary lung cancers, but patients presenting for excision of lung metastases from germ-cell tumors often have received prior bleomycin therapy. Although the association between previous bleomycin therapy and pulmonary toxicity from high inspired oxygen concentrations is well documented, none of the details of the association are understood (i.e., safe doses of oxygen or safe period after bleomycin exposure). The safest anesthetic management is to use the lowest FiO_2 consistent with patient safety and to closely monitor oximetry in any patient who has received bleomycin. We have seen lung cancer patients who received preoperative chemotherapy with cisplatin and then developed an elevation of serum creatinine when they received nonsteroidal antiinflammatory drugs (NSAIDs) postoperatively. For this reason, we do not routinely administer NSAIDs to patients who have been treated recently with cisplatin.

PLANNING POSTOPERATIVE ANALGESIA

The strategy for postoperative analgesia (see Chapter 98) should be developed and discussed with the patient during the initial preoperative assessment. A discussion of postoperative analgesia is presented at the end of this chapter. Many techniques are superior to the use of on-demand parenteral (intramuscular or intravenous) opioids alone in terms of pain control. These include the addition of neuraxial blockade, paravertebral blocks, and antiinflammatories to narcotic-based analgesia. However, only epidural techniques can decrease postthoracotomy respiratory complications in high-risk patients.[2] As well, continuous paravertebral blockade may offer comparable analgesia with a less frequent rate of block failure and fewer side effects.[57]

At the time of initial preanesthetic assessment, the risks and benefits of the various forms of postthoracotomy analgesia should be explained to the patient. Potential contraindications to specific methods of analgesia should

BOX 66-1 *Anesthetic Considerations in Lung Cancer Patients (the "4 Ms")*

1. **M**ass effects: Obstructive pneumonia, lung abscess, SVC syndrome, tracheobronchial distortion, Pancoast syndrome, recurrent laryngeal nerve or phrenic nerve paresis, chest wall or mediastinal extension
2. **M**etabolic effects: Lambert-Eaton syndrome, hypercalcemia, hyponatremia, Cushing syndrome
3. **M**etastases: Particularly to brain, bone, liver, adrenal
4. **M**edications: Chemotherapy agents, pulmonary toxicity (bleomycin, mitomycin), cardiac toxicity (doxorubicin), renal toxicity (cisplatin)

be determined, such as coagulation problems, sepsis, or neurologic disorders. If the patient is to receive prophylactic anticoagulants and it has been elected to use epidural analgesia, appropriate timing of anticoagulant administration and neuraxial catheter placement need to be arranged. American Society of Regional Anesthesia guidelines suggest an interval of 2 to 4 hours before or 1 hour after catheter placement for prophylactic heparin administration.[58] Low-molecular-weight heparin (LMWH) recommendations and precautions are: (1) a minimal interval of 12 hours after low-dose LMWH and (2) 24 hours after higher-dose LMWH before catheter placement.

PREMEDICATION

We do not routinely order preoperative sedation or analgesia for pulmonary resection patients. Mild sedation such as an intravenous short-acting benzodiazepine is often given immediately before placement of invasive monitoring lines and catheters. In patients with copious secretions, an antisialogogue (e.g., glycopyrrolate) is useful to facilitate fiberoptic bronchoscopy for positioning of a double-lumen endobronchial tube (DLT) or bronchial blocker. To avoid an intramuscular injection, this can be given orally or intravenously immediately after placement of the intravenous catheter. It is a common practice to use short-term intravenous antibacterial prophylaxis such as a cephalosporin in thoracic surgical patients. If it is the local practice to administer these drugs before admission to the operating room, they will have to be ordered preoperatively. Consideration for patients allergic to cephalosporins or penicillin should be made at the time of the initial preoperative visit.

SUMMARY OF THE INITIAL PREOPERATIVE ASSESSMENT

The anesthetic considerations that should be addressed at the time of the initial preoperative assessment are summarized in Box 66-2. Patients need to be specifically assessed for risk factors associated with respiratory complications, which are the major cause of morbidity and mortality afte thoracic surgery.

FINAL PREOPERATIVE ASSESSMENT

The final preoperative anesthetic assessment for the majority of thoracic surgical patients is carried out immediately before admission of the patient to the operating room. At this time, it is important to review the data from the initial prethoracotomy assessment and the results of tests ordered at that time. In addition, two other specific areas affecting thoracic anesthesia need to be assessed: (1) the potential for difficult lung isolation and (2) the risk of desaturation during one-lung ventilation (OLV) (Box 66-3).

BOX 66-2 *Initial Preanesthetic Assessment for Thoracic Surgery*

1. All patients: Assess exercise tolerance, estimate ppoFEV_1%, discuss postoperative analgesia, discontinue smoking
2. Patients with ppoFEV_1 < 40%: $D_L$co, $\dot{V}/\dot{Q}$ scan, VO_{2max}
3. Cancer patients: consider the four *M*s: mass effects, metabolic effects, metastases, medications
4. COPD patients: arterial blood gas, physiotherapy, bronchodilators
5. Increased renal risk: measure creatinine and blood urea nitrogen levels

DIFFICULT ENDOBRONCHIAL INTUBATION

The most useful predictor of difficult endobronchial intubation is the plain chest radiograph (Fig. 66-7).

The anesthesiologist should view the chest imaging before induction of anesthesia because neither the radiologist's nor the surgeon's report of the imaging is made with the specific consideration of lung isolation in mind. Distal airway problems not detectable on the plain chest film can sometimes be visualized on the computed tomography (CT) scan: a side-to-side compression of the distal trachea, the so-called saber-sheath trachea

BOX 66-3 *Final Preanesthetic Assessment for Thoracic Surgery*

1. Review initial assessment and test results
2. Assess difficulty of lung isolation: examine chest radiograph and computed tomographic scan
3. Assess risk of hypoxemia during one-lung ventilation

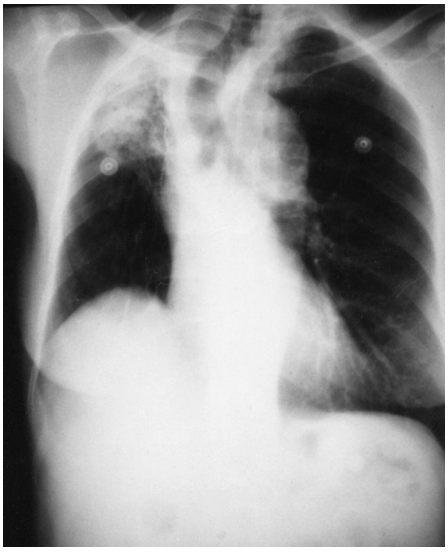

Figure 66-7. Preoperative chest radiograph of a 50-year-old woman with a history of previous tuberculosis, right upper lobectomy, and recent hemoptysis presenting for right thoracotomy and possible completion pneumonectomy. The potential problems positioning a left-sided double-lumen tube (DLT) in this patient are easily appreciated by viewing the radiograph but are not mentioned in the radiologist's report. The anesthesiologist must solely examine the chest imaging preoperatively to anticipate problems in lung isolation. *(Reproduced with permission from Slinger P:* Principles and practice of anesthesia for thoracic surgery, *New York, Springer, 2011.)*

can cause obstruction of the tracheal lumen of a left-sided DLT during ventilation of the dependent lung for a left thoracotomy.[59] Similarly, extrinsic compression or intraluminal obstruction of a mainstem bronchus that can interfere with endobronchial tube placement may only be evident on the CT scan. The major factors in successful lower airway management are anticipation and preparation based on the preoperative assessment. Management of lung isolation in patients with difficult upper and lower airways is discussed later in this chapter.

PREDICTION OF DESATURATION DURING ONE-LUNG VENTILATION

In the vast majority of cases, it is possible to determine the patients who are most at risk of desaturation during OLV for thoracic surgery. The factors that correlate with desaturation during OLV are listed in Box 66-4. In patients at high-risk of desaturation, prophylactic measures can be used during OLV to decrease this risk. The most useful prophylactic measures are the use of CPAP (2 to 5 cm H_2O of oxygen) to the nonventilated lung or PEEP to the dependent lung (see Treatment of Hypoxemia During OLV) (also see Chapter 19 regarding more detailed physiology.).

The most important predictor of PaO_2 during OLV is the PaO_2 during two-lung ventilation (TLV), specifically the intraoperative PaO_2 during TLV in the lateral position before OLV.[60] The proportion of perfusion or ventilation to the nonoperated lung on preoperative $\dot{V}/\dot{Q}$ scans also correlates with the PaO_2 during OLV.[61] If the operative lung has little perfusion preoperatively because of unilateral disease, the patient is unlikely to desaturate during OLV. The side of the thoracotomy has an effect on PaO_2 during OLV. Because the left lung is 10% smaller than the right lung, there is less shunt when the left lung is collapsed. In a series of patients, the mean PaO_2 during left thoracotomy was approximately 70 mm Hg higher than during right thoracotomy.[62] Finally, the degree of obstructive lung disease correlates in an inverse fashion with PaO_2 during OLV. Other factors being equal, patients with more severe airflow limitation on preoperative spirometry tend to have a better PaO_2 during OLV than patients with normal spirometry (this is discussed later in Anesthetic Management).[63]

BOX 66-4 ***Factors That Correlate with an Increased Risk of Desaturation During One-Lung Ventilation***

1. High percentage of ventilation or perfusion to the operative lung on preoperative $\dot{V}/\dot{Q}$ scan
2. Poor PaO_2 during two-lung ventilation, particularly in the lateral position intraoperatively
3. Right-sided thoracotomy
4. Normal preoperative spirometry (FEV_1 or FVC) or restrictive lung disease
5. Supine position during one-lung ventilation

ASSESSMENT FOR REPEAT THORACIC SURGERY

Patients who survive lung cancer surgery form a high-risk cohort to have a recurrence of the original tumor or to develop a second primary tumor. The incidence of developing second primary lung tumors is estimated at 2% per year. The use of routine screening low-dose spiral CT scans probably increases the rate of early detection.[64] Patients who present for repeat thoracotomy should be assessed using the same framework as those who present for surgery the first time. Predicted values for postoperative respiratory function based on the preoperative lung mechanics, parenchymal function, exercise tolerance, and the amount of functioning lung tissue resected should be calculated and used to identify patients at increased risk.

INTRAOPERATIVE MONITORING
(See Chapters 44 and 51)

A few points specific to intraoperative monitoring of the thoracic surgical patient should be emphasized. The majority of these operations are major procedures of moderate duration (2 to 4 hours) and are performed with the patient in the lateral position and the hemithorax open. Thus consideration for monitoring and maintenance of body temperature and fluid volume should be given to all of these cases. Because surgery is usually performed with the patient in the lateral position, monitors are initially placed with the patient in the supine position and have to be rechecked and repositioned after the patient is turned. It is difficult to add additional monitoring, particularly invasive vascular monitoring, after the case is started if complications arise. Thus, the risk-benefit ratio often tends to favor being overly invasive at the outset. Choice of monitoring should be guided by a knowledge of which complications are likely to occur (Table 66-3).

OXYGENATION

Significant desaturation (SpO_2 <90%) during OLV occurs in 1% to 10% of the surgical population despite a high

TABLE 66-3 **INTRAOPERATIVE COMPLICATIONS THAT OCCUR WITH INCREASED FREQUENCY DURING THORACOTOMY**

Complication	Etiology
Hypoxemia	Intrapulmonary shunt during one-lung ventilation
Sudden severe hypotension	Surgical compression of the heart or great vessels
Sudden changes in ventilating pressure or volume	Movement of endobronchial tube/blocker, air leak
Arrhythmias	Direct mechanical irritation of the heart
Bronchospasm	Direct airway stimulation, increased frequency of reactive airways disease
Massive hemorrhage	Surgical blood loss from great vessels or inflamed pleura
Hypothermia	Heat loss from the open hemithorax

FiO_2 (1.0) (see Management of OLV later in the chapter). Pulse oximetry (SpO_2) has not negated the need for direct measurement of arterial PaO_2 via intermittent blood gases in the majority of thoracotomy patients. The PaO_2 value offers a more useful estimate of the margin of safety above desaturation than the SpO_2. A patient with a TLV PaO_2 greater than 400 mm Hg with an FiO_2 of 1.0 (or an equivalent PaO_2/FiO_2 ratio) is unlikely to desaturate during OLV, whereas a patient with a PaO_2 of 200 mm Hg is prone to desaturate during OLV, although both may have SpO_2 values of 99% to 100%.

CAPNOMETRY

The end-tidal CO_2 ($PetCO_2$) is a less reliable indicator of the $Paco_2$ during OLV than during TLV, and the $Paco_2$-$PetCO_2$ gradient tends to increase during OLV. Although the $PetCO_2$ is less directly correlated with alveolar minute ventilation during OLV, because the $PetCO_2$ also reflects lung perfusion and cardiac output, it gives an indication of the relative changes in perfusion of the two lungs independently during position changes and during OLV.[65] As the patient is turned to the lateral position, the $PetCO_2$ of the nondependent lung will fall relative to the dependent lung, reflecting increased perfusion of the dependent lung and increased dead space of the nondependent lung. However, the fractional excretion of CO_2 will be higher from the nondependent lung in most patients because of the increased fractional ventilation of this lung. At the onset of OLV, the $PetCO_2$ of the dependent lung will usually fall transiently as all of the minute ventilation is transferred to this lung. The $PetCO_2$ will then rise as the fractional perfusion is increased to this dependent lung by collapse and pulmonary vasoconstriction of the nonventilated lung. If there is no correction of minute ventilation, the net result will be both an increased baseline $Paco_2$ and $PetCO_2$ with an increased gradient. Severe (>5 mm Hg) or prolonged decreases in $PetCO_2$ can indicate a maldistribution of perfusion between ventilated and nonventilated lungs and may be an early warning sign of a patient who will subsequently desaturate during OLV.

INVASIVE HEMODYNAMIC MONITORING
(See Chapter 45)

ARTERIAL LINE

Transient severe hypotension from surgical compression of the heart or great vessels can occur during intrathoracic procedures. For this reason, in addition to the utility of intermittent arterial blood gas sampling, it is useful to have beat-to-beat assessment of systemic blood pressure during the majority of thoracic surgery cases. Naturally, exceptions occur during limited procedures, such as thoracoscopic resections in younger and healthier patients. For most thoracotomies, placement of a radial artery catheter can be in either the dependent or nondependent arm.

CENTRAL VENOUS PRESSURES

It is a common impression that central venous pressure (CVP) readings in the lateral position with the chest open are not reliable as a monitor of volume status. The CVP may be a useful monitor postoperatively, particularly for cases in which fluid management is critical (e.g., pneumonectomies). A CVP may be required in some cases for vascular access or for vasopressor/inotrope infusions. It is our practice to routinely place CVP lines in pneumonectomy cases, complex procedures, or redo thoracotomies, but not for lesser resections unless there is significant other concurrent illness. Our choice is to use the right internal jugular vein to minimize the risk of pneumothorax for CVP access unless there is a contraindication. Internal jugular CVP data are not reliable in patients with superior vena cava obstruction.

PULMONARY ARTERY CATHETERS

Similar to CVP data, intraoperative pulmonary artery pressure may be a less accurate indicator of true left-heart preload in the lateral position with the chest open than in other clinical situations. This is partly because it is often initially not known whether the catheter tip lies in the dependent or nondependent lung. In addition, it is possible that thermodilution cardiac output data may be unreliable if there are significant transient unilateral differences in perfusion between the lungs, as can occur during OLV. There is no consensus on the reliability of thermodilution cardiac output data during OLV.[66]

FIBEROPTIC BRONCHOSCOPY

Placement of DLTs and bronchial blockers is discussed later in the section "Lung Isolation." Significant malpositions of DLTs and blockers that can lead to desaturation during OLV are often not detected by auscultation or other traditional methods of confirming placement.[67] Placement of DLTs or blockers should be performed with fiberoptic bronchoscopic guidance and should be reconfirmed after placing the patient in the surgical position, because a large number of these tubes/blockers migrate during repositioning of the patient.[68]

CONTINUOUS SPIROMETRY

The development of side-stream spirometry has made it possible to continuously monitor inspiratory and expiratory volumes, pressures, and flow interactions during one-lung anesthesia. This monitoring is particularly useful during pulmonary resection surgery. The breath-by-breath monitoring of inspired and expired tidal volumes gives early warning of accidental changes in the intraoperative position of a DLT, with loss of lung isolation if the expired volume suddenly decreases (there is normally a 20- to 30-mL/breath difference caused in part by the uptake of inspired oxygen). The development of a persistent end-expiratory flow during OLV, which correlates with the development of auto-PEEP, can be seen on the flow-volume loop.[69] Also the ability to accurately measure differences in inspiratory and expiratory tidal volumes is extremely useful in assessing and managing air leaks during and after pulmonary resections.

TRANSESOPHAGEAL ECHOCARDIOGRAPHY

Transesophageal echocardiography (TEE) allows the anesthesiologist to view a continuous real-time monitor of myocardial function and cardiac preload (see Chapter 46). This information is difficult to estimate intraoperatively in the lateral position from other hemodynamic monitors.[70] Potential indications for intraoperative TEE that apply to thoracic surgery include hemodynamic instability (Fig. 66-8), pericardial effusions, cardiac involvement by tumor, air emboli, pulmonary thromboendarterectomy, thoracic trauma, lung transplantation, and pleuropulmonary disease. A rare cause of hypoxemia associated with thoracic surgery is reversal of shunt flow through an undiagnosed patient foramen ovale. When PEEP (to 15 cm H_2O) was applied during controlled ventilation for nonthoracic surgery, 9% of the patients developed a right-to-left intracardiac shunt.[71] TEE should be capable of detecting situations in patients who might intraoperatively develop a right-to-left interatrial shunt during or after thoracic surgery.

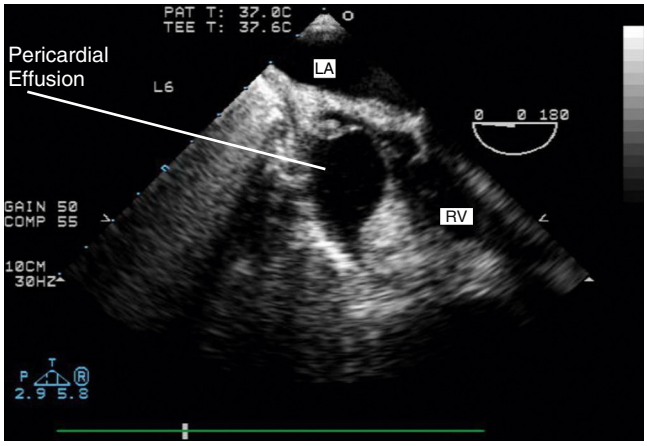

Figure 66-8. Midesophageal TEE view of a patient with metastatic breast cancer who had a hemodynamic collapse after induction of general anesthesia for video-assisted thoracoscopic drainage of a left pleural effusion. TEE was performed for diagnosis of hemodynamic instability and revealed a previously undiagnosed large pericardial effusion. The "Pericardial Effusion" label shows complete collapse of the right atrium during systole as a result of the effusion, consistent with tamponade. The procedure was modified to include creation of a pericardial window. *LA*, Left atrium; *RV*, right ventricle.

OTHER NEW MONITORING TECHNOLOGY

Cerebral oximetry ($SctO_2$) has been reported for intraoperative monitoring during OLV.[72] Older, debilitated patients are more likely to have falls in $SctO_2$ during OLV, and these are associated with decreases in SpO_2 and postoperative cognitive dysfunction. However, it has not been shown whether any treatment for decreases in $SctO_2$ affects outcomes. Goal-directed fluid therapy using indirect monitors of cardiac output or venous oxygen saturation seems to improve fluid management in abdominal surgery.[73] This is currently a much needed area of research in thoracic anesthesia.

LUNG ISOLATION

Lung isolation techniques are primarily designed to facilitate OLV in patients undergoing cardiac, thoracic, mediastinal, vascular, esophageal, or orthopedic procedures involving the chest cavity.[74] Lung isolation is also used to protect the lung from soiling by the contralateral lung in such cases as bronchopleural fistula, pulmonary hemorrhage, and whole-lung lavage. In addition, lung isolation can be used to provide differential patterns of ventilation in cases of unilateral reperfusion injury (after lung transplantation or pulmonary thromboendarterectomy) or in unilateral lung trauma.

Lung isolation can be achieved by three different methods: DLTs, bronchial blockers, or single-lumen tubes (SLTs) (Table 66-4). The most common technique is with a DLT. The DLT is a bifurcated tube with both an endotracheal and an endobronchial lumen and can be used to achieve isolation of either the right or the left lung. The second method involves blockade of a mainstem bronchus to allow lung collapse distal to the occlusion. These bronchial blockers can be used with a standard endotracheal tube or contained within a separate channel inside a modified SLT such as the Univent tube (LMA North America, San Diego, Calif). The final option for lung isolation is to use either an SLT or an endobronchial tube that is advanced into the contralateral mainstem bronchus, protecting this lung while allowing collapse of the lung on the side of surgery (Fig. 66-9). This technique is rarely used today in adult practice (except in some cases of difficult airways, carinal resection, or after a pneumonectomy), owing to the limited access to the nonventilated lung and the difficulty in positioning a standard SLT in the bronchus. This technique is still used when needed in infants and small children: an uncuffed uncut pediatric-size endotracheal tube is advanced into the mainstem bronchus under direct guidance with an infant bronchoscope.

DOUBLE-LUMEN ENDOTRACHEAL TUBES

The design of the Carlens DLT for lung surgery in 1950 was a landmark in the development of thoracic anesthesia because it allowed anesthesiologists to obtain reliable lung isolation in a majority of patients using only laryngoscopy and auscultation. However, the Carlens tube had a high flow resistance owing to the narrow lumina and the carinal hook was difficult to pass through the glottis in some patients. In the 1960s, Robertshaw introduced design modifications for separate left- and right-sided DLTs, removing the carinal hook and using larger lumina. In the 1980s, manufacturers introduced disposable DLTs made of polyvinyl chloride based on the design of the Robertshaw DLT. Among other subsequent improvements is the inclusion of radiographic markers near the endotracheal and endobronchial cuffs and a radiographic marker surrounding the ventilation slot for the right upper lobe bronchus for the right-sided DLT version. Bright blue, low-volume, low-pressure endobronchial cuffs are incorporated for easier visualization during fiberoptic bronchoscopy. Table 66-5 lists the sizes of DLTs, the

TABLE 66-4 **OPTIONS FOR LUNG ISOLATION**

Options	Advantages	Disadvantages
Double-lumen tube	Easy to place successfully	Size selection more difficult
1. Direct laryngoscopy	Repositioning rarely required	Difficult to place in patients with difficult airways or abnormal tracheas
2. Via tube exchanger	Bronchoscopy to isolated lung	
3. Fiberoptically	Suction to isolated lung	Not optimal for postoperative ventilation
	CPAP easily added	Potential laryngeal trauma
	Can alternate one-lung ventilation to either lung easily	Potential bronchial trauma
	Placement still possible if bronchoscopy not available	
	Best device for absolute lung isolation	
Bronchial blockers (BB)	Size selection rarely an issue	More time needed for positioning
1. Arndt	Easily added to regular ETT	Repositioning needed more often
2. Cohen	Allows ventilation during placement	Bronchoscope essential for positioning
3. Fuji	Easier placement in patients with difficult airways	Limited right lung isolation due to RUL anatomy
4. EZ Blocker	and in children	Bronchoscopy to isolated lung impossible
	Postoperative two-lung ventilation by withdrawing blocker	Minimal suction to isolated lung
		Difficult to alternate one-lung ventilation to either lung
	Selective lobar lung isolation possible	
	CPAP to isolated lung possible	
Univent tube	Same as BBs	Same as for BBs
	Less repositioning compared with BBs	ETT portion has higher air flow resistance than regular ETT
	Rarely used	ETT portion has larger diameter than regular ETT
Endobronchial tube	Like regular ETTs, easier placement in patients with difficult airways	Bronchoscopy necessary for placement
		Does not allow for bronchoscopy, suctioning, or CPAP to isolated lung
	Longer than regular ETT	
	Short cuff designed for lung isolation	Difficult one-lung ventilation (right lung)
Endotracheal tube advanced into bronchus	Easier placement in patients with difficult airways	Does not allow for bronchoscopy, suctioning, or CPAP to isolated lung
		Cuff not designed for lung isolation
		Extremely difficult right one-lung ventilation

CPAP, continuous positive airway pressure; *ETT*, endotracheal tube; *RUL*, right upper lobe.

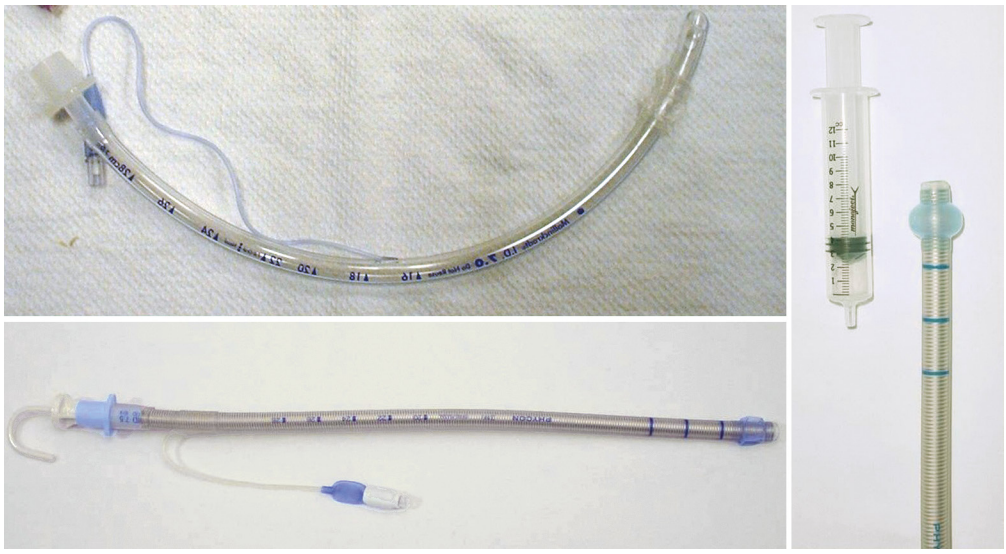

Figure 66-9. Photographs of a standard single-lumen endotracheal tube (SLT) *(upper left)* and a specifically designed SLT *(lower left and right)*. The endobronchial tube is longer and has a shorter cuff. It can be used as an endotracheal tube and advanced into a mainstem bronchus with fiberoptic guidance when needed for lung isolation. *(Courtesy Phycon, Fuji Systems, Tokyo, Japan.)*

appropriate fiberoptic bronchoscope sizes to be used, and the comparable diameters of SLTs.

Size Selection

A properly sized, left-sided DLT should have a bronchial tip 1 to 2 mm smaller than the patient's left bronchus diameter to allow for the space occupied by the deflated bronchial cuff. A study by Eberle and associates[75] used a three-dimensional image reconstruction of tracheobronchial anatomy from the spiral CT scans combined with superimposed transparencies of DLTs to predict proper size for a right- or left-sided DLT. Chest radiographs and CT scans are valuable tools for selection of proper DLT size in addition to their proven value in assessment of abnormal tracheobronchial anatomy and should be reviewed before the placement of the DLT (Fig. 66-10).

TABLE 66-5 COMPARATIVE DIAMETERS OF SINGLE- AND DOUBLE-LUMEN TUBES

Single-Lumen Tubes		Double-Lumen Tubes			
ID (mm)	ED (mm)	French Size (Fr)	Double-Lumen ED (mm)	Bronchial Lumen ID (mm)	FOB size (mm)
6.5	8.9	26	8.7	3.2	2.4
7.0	9.5	28	9.3	3.4	2.4
8.0	10.8	32	10.7	3.5	2.4
8.5	11.4	35	11.7	4.3	≥3.5
9.0	12.1	37	12.3	4.5	≥3.5
9.5	12.8	39	13.0	4.9	≥3.5

ED, external diameter; *FOB,* fiberoptic bronchoscope; *ID,* internal diameter.
Double-lumen ED is equal to the approximate external diameter of the double-lumen portion of the tube. FOB size is equal to the maximal diameter of fiberoptic bronchoscope that will pass through both lumina of a given size of double-lumen tube.

TABLE 66-6 SELECTION OF DOUBLE-LUMEN TUBE SIZE BASED ON ADULT PATIENT'S SEX AND HEIGHT

Sex	Height (cm)	Size of Double-Lumen Tube (Fr)
Female	<160 (63 in)*	35
Female	>160	37
Male	<170 (67 in)†	39
Male	>170	41

*For females of short stature (<152 cm or 60 in), examine the bronchial diameter on computed tomographic scan, consider 32-Fr double-lumen tube.
†For males of short stature (<160 cm) consider 37-Fr double-lumen tube.

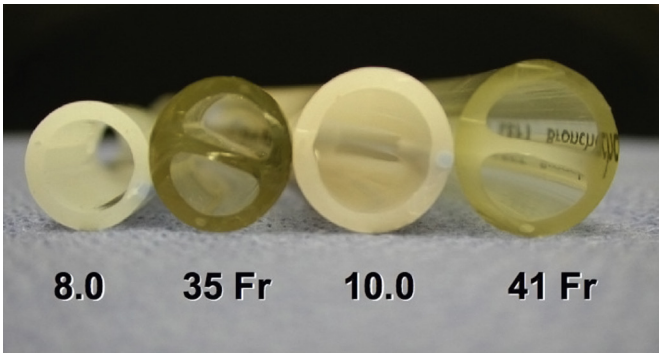

Figure 66-11. Photograph of the cut cross sections of several SLTs and DLTs. The external diameter of a 35-Fr DLT is larger than that of an 8.0-mm (internal diameter) SLT, and a 41-Fr DLT is larger than a 10-mm SLT. *(Courtesy Dr. J. Klafta.)*

A multidetector CT scan (MDCT) of the chest allows appreciation of any abnormal tracheobronchial anatomy before placement of a DLT. A simplified method of selection of DLT size is given in Table 66-6. It is important to appreciate that compared with SLTs, DLTs have a large external diameter (Fig. 66-11) and they should not be advanced against significant resistance.

Methods of Insertion

Two techniques are commonly used when inserting and placing a DLT. One is the blind technique: the DLT is passed by direct laryngoscopy and then turned 90 degrees counterclockwise (for a left-sided DLT placement) after the endobronchial cuff has passed beyond the vocal cords. The DLT should pass the glottis without any resistance. Seymour[76] showed that the mean diameter of the cricoid ring is approximately the same as that of the left mainstem bronchus. The optimal depth of insertion for a left-sided DLT is correlated with the patient's height in average-sized adults. In adults, depth, measured at the teeth for a properly positioned DLT, will be approximately 12 + (patient height/10) cm.[77] In patients of Asian

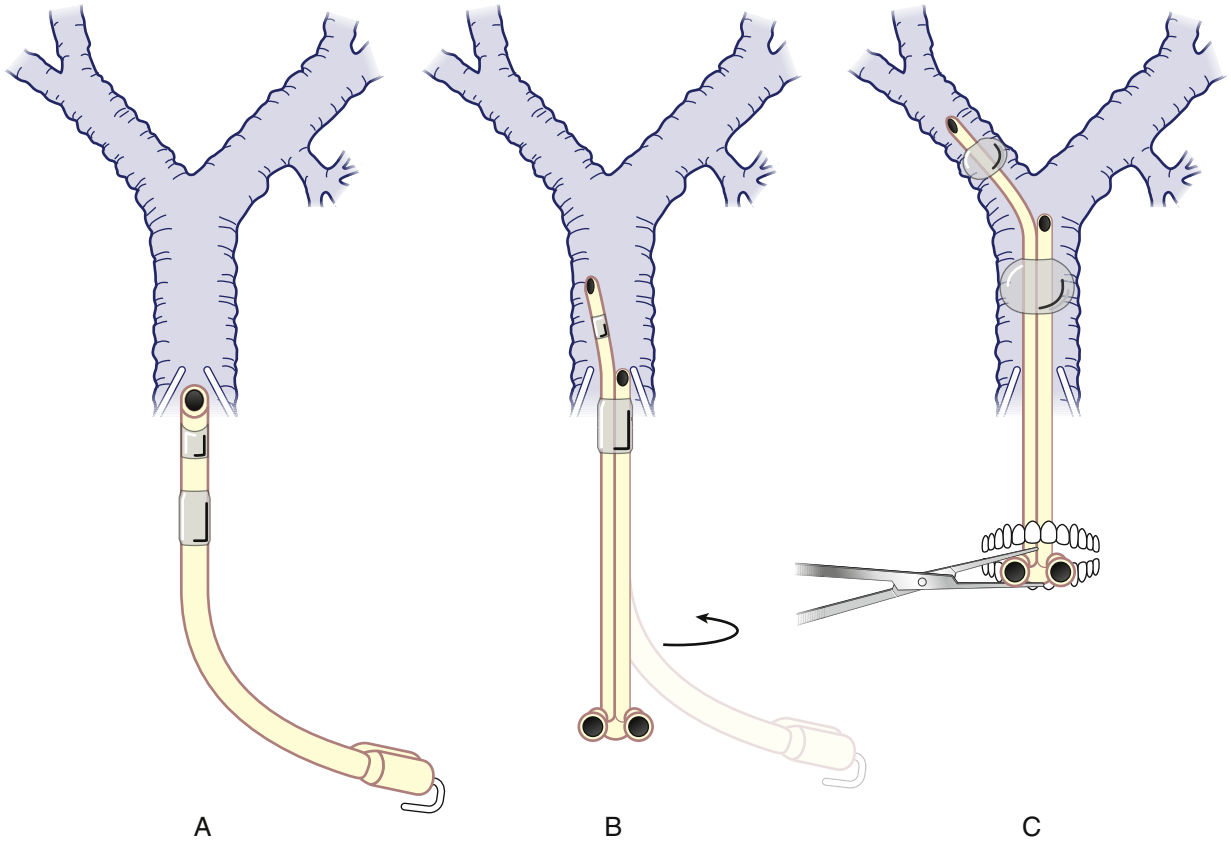

Figure 66-12. Blind method for placement of a left-sided DLT. **A,** The DLT is passed with direct laryngoscopy beyond the vocal cords. **B,** The DLT is rotated 90 degrees to the left (counter-clockwise). **C,** The DLT is advanced to an appropriate depth (in general 27-29 cm marking at the level of the teeth). *(Reproduced with permission from Slinger P:* Principles and practice of anesthesia for thoracic surgery, *New York, Springer, 2011.)*

descent, many of whom are of shorter stature (<155 cm), patient height is not a good predictor of depth of insertion of a DLT.[78] An inadvertently deep insertion of a DLT can lead to serious complications, including rupture of the left mainstem bronchus. Figure 66-12 depicts the blind method technique for insertion of a left-sided DLT.

The direct vision technique uses bronchoscopic guidance, in which the tip of the endobronchial lumen is guided into the correct bronchus after the DLT passes the vocal cords using direct vision with a flexible fiberoptic bronchoscope. A study by Boucek and associates[79] comparing the blind technique versus fiberoptic bronchoscopy-guided technique showed that of the 32 patients who underwent the blind technique approach, primary success occurred in 27 patients and eventual success occurred in 30 patients. In contrast, in the 27 patients using the bronchoscopy-guided technique, primary success was achieved only in 21 patients and eventual success in 25 patients. Although both methods resulted in successful left mainstem bronchus placement in all patients, more time was required when the fiberoptic bronchoscopy guidance technique was used (181 versus 88 seconds).

RIGHT-SIDED DOUBLE-LUMEN ENDOBRONCHIAL TUBES

Although a left-sided DLT is used more commonly for most elective thoracic procedures,[80] there are specific clinical situations in which the use of a right-sided DLT is indicated (Box 66-5). The anatomic differences between the right and the left mainstem bronchus are reflected in the fundamentally different designs of the right-sided and left-sided DLTs. Because the right mainstem bronchus is shorter than the left bronchus, and because the right upper lobe bronchus originates at a distance of 1.5 to 2 cm from the carina, techniques using right endobronchial intubation must take into account the location and potential for obstruction of the orifice of the right upper

BOX 66-5 ***Indications for a Right-Sided Double-Lumen Tube****

- Distorted anatomy of the entrance of left mainstem bronchus
  - External or intraluminal tumor compression
  - Descending thoracic aortic aneurysm
- Site of surgery involving the left mainstem bronchus
  - Left lung transplantation
  - Left-sided tracheobronchial disruption
  - Left-sided pneumonectomy†
  - Left-sided sleeve resection

*This is a common clinical practice pattern for using right-sided double-lumen tubes (DLTs) and assumes normal tracheobronchial anatomy, specifically a normal position of the orifice of the right upper lobe; however, some clinicians prefer to use right DLTs for all left-sided surgeries.

†It is possible to manage a left pneumonectomy with a left-sided DLT or bronchial blocker; however, the DLT or blocker will have to be withdrawn before stapling the left mainstem bronchus.

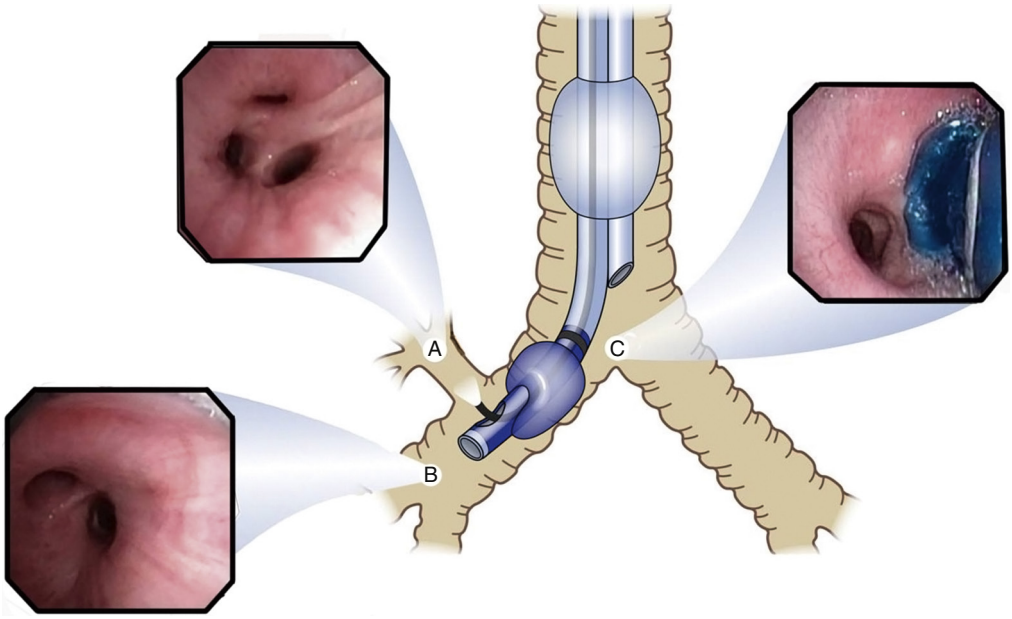

Figure 66-13. Fiberoptic bronchoscopic examination of a Rusch right-sided DLT. **A,** Slot of the bronchial lumen properly aligned within the entrance of the right upper lobe bronchus. **B,** Part of the bronchus intermedius when the bronchoscope is advanced through the distal portion of the bronchial lumen. **C,** The edge of the bronchial cuff at the entrance of the right mainstem bronchus when the bronchoscope is passed through the tracheal lumen. *(Reproduced with permission from Slinger P:* Principles and practice of anesthesia for thoracic surgery, *New York, Springer, 2011.)*

lobe bronchus. The right-sided DLT incorporates a modified cuff and slot on the endobronchial lumen that allows ventilation for the right upper lobe (Fig. 66-13).[81]

Positioning of Double-Lumen Tubes

Auscultation alone is unreliable for confirmation of proper DLT placement. Auscultation (Fig. 66-14) and bronchoscopy should both be used each time a DLT is placed and again when the patient is repositioned. Fiberoptic bronchoscopy is performed first through the tracheal lumen to ensure that the endobronchial portion of the DLT is in the left bronchus and that there is no bronchial cuff herniation over the carina after inflation. Through the tracheal view, the blue endobronchial cuff ideally should be seen approximately 5 mm below the tracheal carina in the left bronchus. It is crucial to identify the takeoff of the right upper lobe bronchus through the tracheal view. Going inside this right upper lobe with the bronchoscope should reveal three orifices (apical, anterior, posterior). This is the only structure in the tracheobronchial tree that has three orifices. In the supine patient, the takeoff of the right upper lobe is normally on the lateral wall of the right mainstem bronchus at the 3- to 4-o'clock position in relation to the main carina. Broncho-Cath tubes from Mallinckrodt (St. Louis, Mo) have a radiopaque line encircling the tube. This line is proximal to the bronchial cuff and can be useful while positioning a left-sided DLT. The radiopaque marker is 4 cm from the distal tip of the endobronchial lumen. This marker reflects white during fiberoptic visualization and, when positioned slightly above the tracheal carina, should provide the necessary margin of safety for positioning into the left mainstem bronchus.[82] The next observation with the fiberoptic bronchoscope is made through the endobronchial lumen to check for patency of the tube and determination of the margin of safety. The orifices of both the left upper and lower lobes must be identified to avoid distal impaction in the left lower lobe and occlusion of the left upper lobe (Fig. 66-15). Figure 66-16 displays the tracheobronchial anatomy along with fiberoptic bronchoscopy findings from the endotracheal or endobronchial lumen for a left-sided DLT.

Problems Related to Double-Lumen Tubes

The most common problems and complications associated with the use of a DLT are malpositioning and airway trauma. A malpositioned DLT will fail to allow collapse of the lung, causing gas trapping during positive-pressure ventilation, or it may partially collapse the ventilated or dependent lung, producing hypoxemia. A common cause of malpositioning is dislodgment of the endobronchial cuff because of overinflation, surgical manipulation of the bronchus, or extension of the head and neck during or after patient positioning. Fiberoptic bronchoscopy is the recommended method to diagnose and correct intraoperative malpositioning of DLTs, along with proper recognition of tracheobronchial anatomy. If a DLT is malpositioned with the patient in the supine or lateral decubitus position, there is a greater likelihood of hypoxemia during OLV. If a DLT is in the optimal position, but lung deflation is not completely achieved, a suction catheter should be passed to the side where lung collapse is supposed to occur. This suction will expedite lung deflation. The suction catheter must then be removed to avoid including it in a suture line.

Airway trauma and rupture of the membranous part of the trachea or the bronchus is a potential complication with the use of DLTs.[83] Airway trauma can occur from an oversized DLT or when an undersized DLT migrates distally into the lobar bronchus and the main (i.e., tracheal) body of the DLT comes into the bronchus, producing lacerations or rupture of the airway. Airway damage during the use of DLTs can present an unexpected air leak,

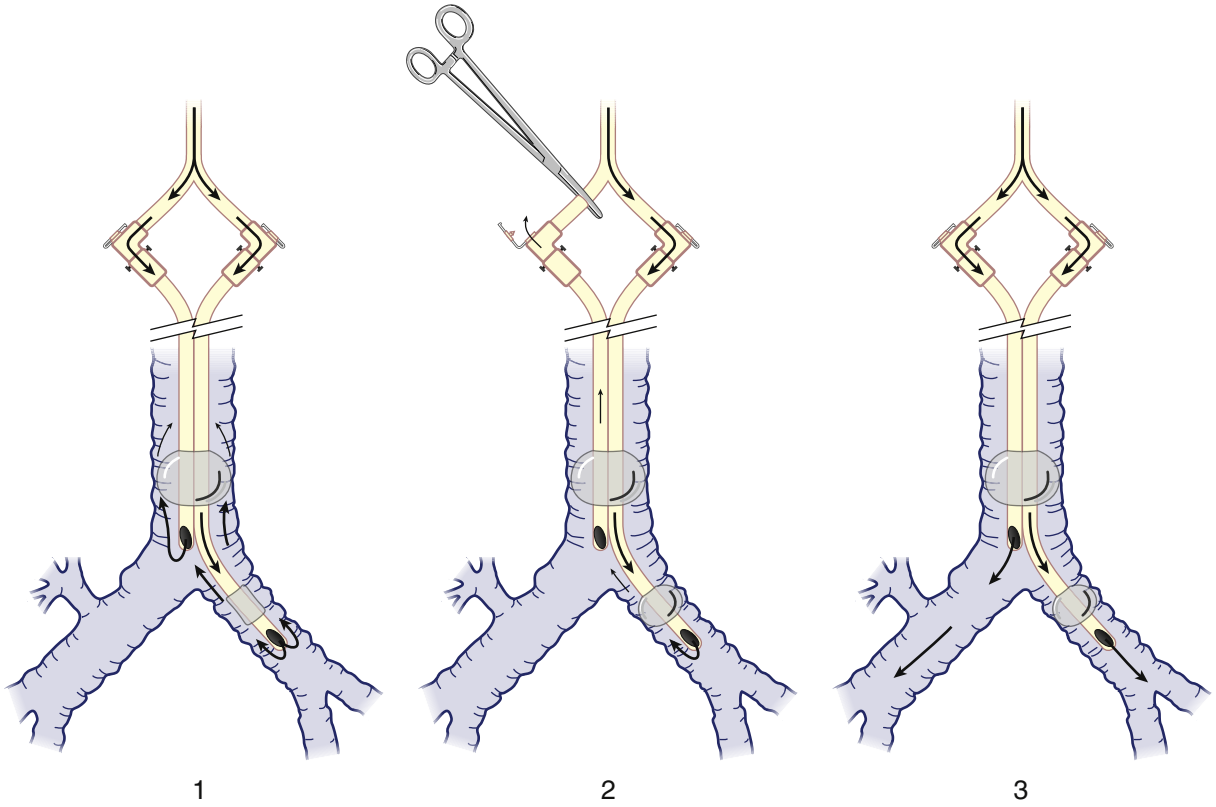

Figure 66-14. A "3-step" method to confirm position of a left DLT by auscultation. *Step 1,* During bilateral ventilation, the tracheal cuff is inflated to the minimal volume that seals the air leak at the glottis. Auscultate to confirm bilateral ventilation. *Step 2,* The tracheal lumen of the DLT is clamped proximally ("clamp the short side short") and the port distal to the clamp is opened. During ventilation via the bronchial lumen, the bronchial cuff is inflated to the minimal volume that seals the air leak from the open tracheal lumen port. Auscultate to confirm correct unilateral ventilation. *Step 3,* The tracheal lumen clamp is released and the port is closed. Auscultate to confirm resumption of bilateral breath sounds. *(From Youngberg, JA:* Cardiac, vascular, and thoracic anesthesia. *Philadelphia, Churchill Livingstone, 2000.)*

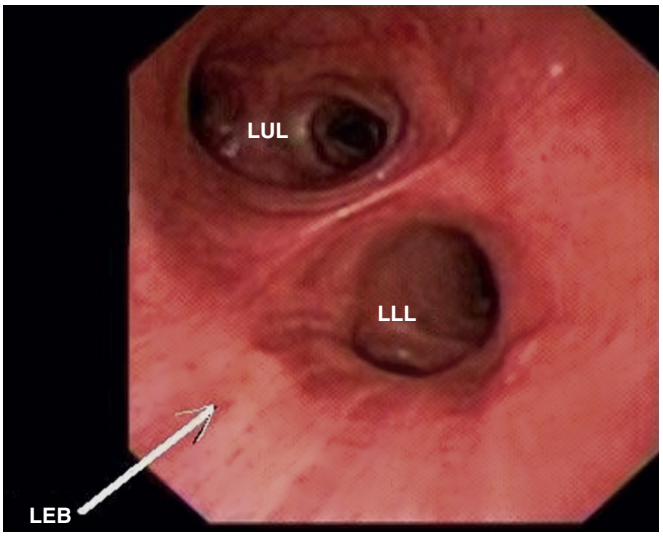

Figure 66-15. The view from the distal bronchial lumen of a well-positioned left-sided DLT. Both the orifices of the left upper lobe (LUL) and left lower lobe (LLL) can be identified. Note the longitudinal elastic bundles (LEB, *arrow*). These extend down the posterior membranous walls of the trachea and mainstem bronchi. They are useful landmarks to orient the bronchoscopist to anterior-posterior directions. In the left mainstem bronchus, they extend into the left lower lobe and are a useful landmark to distinguish the lower from the upper lobe.

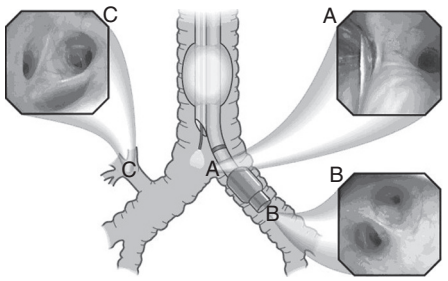

Figure 66-16. Fiberoptic bronchoscopic examination of a Mallinckrodt left-sided DLT. **A,** The edge of the endobronchial cuff around the entrance of the left mainstem bronchus when the bronchoscope is passed through the tracheal lumen. A white line marker is seen above the tracheal carina. **B,** A clear view of the bronchial bifurcation (left upper and left lower bronchi) when the left-sided DLT is in the optimal position and the fiberoptic bronchoscope is being advanced through the endobronchial lumen. **C,** Clear view of the right upper lobe bronchus and its three orifices: apical, anterior, and posterior segments. *(Reproduced with permission from Slinger P:* Principles and practice of anesthesia for thoracic surgery, *New York, Springer, 2011.)*

subcutaneous emphysema, massive airway bleeding into the lumen of the DLT, or protrusion of the endotracheal or endobronchial cuffs into the surgical field, with visualization of this by the surgeon. If any of the aforementioned problems occur, a bronchoscopic examination and surgical repair should be performed. Another potential problem is the development of a tension pneumothorax in the dependent, ventilated lung during OLV.[84]

BRONCHIAL BLOCKERS

An alternative method to achieve lung separation involves blockade of a mainstem bronchus to allow lung collapse distal to the occlusion (Fig. 66-17). Bronchial blockers also can be used selectively to achieve lobar collapse if necessary. Currently, there are several different bronchial blockers available to facilitate lung separation. These devices are either within a modified SLT as an enclosed bronchial blocker (Torque Control Blocker Univent; Vitaid, Lewinston, N.Y.) or are used independently with a conventional SLT, the Arndt wire-guided endobronchial blocker (Cook Critical Care, Bloomington, Ind), the Cohen tip-deflecting endobronchial blocker (Cook Critical Care), the Fuji Uniblocker (Vitaid), or the EZ Blocker (Teleflex, Dresden, Germany).

There are specific conditions in which a bronchial blocker may be preferred to a DLT, such as patients with previous oral or neck surgery who present with a challenging airway and require lung separation for intrathoracic surgery. In these cases, the use of an SLT during an awake nasotracheal or orotracheal intubation or via tracheostomy secures the airway, and thereafter an independent bronchial blocker can be placed to achieve lung separation. Another group of patients who may benefit from the use of bronchial blockers are cancer patients who have undergone a previous contralateral pulmonary resection. In such cases, selective lobar blockade with a bronchial blocker in the ipsilateral side improves oxygenation and facilitates surgical exposure. Blockers can be advanced over a guidewire placed with a fiberoptic bronchoscope into the required lobar bronchus. Bronchial blockers are most commonly used intraluminally (coaxially) with the SLT. The Cohen and Fuji Uniblockers can also be placed separately through the glottis or tracheostomy exterior to the SLT. This allows the use of a smaller SLT and is often an option in pediatrics. Another advantage of the bronchial blockers is when postoperative mechanical ventilation is being considered after prolonged thoracic or esophageal surgery. In many instances, these patients have an edematous upper airway at the end of the procedure. If a bronchial blocker is used, there is no need to change the SLT and there is no compromise of the airway if mechanical ventilation is needed in the postoperative period. Table 66-7 describes the characteristics of current

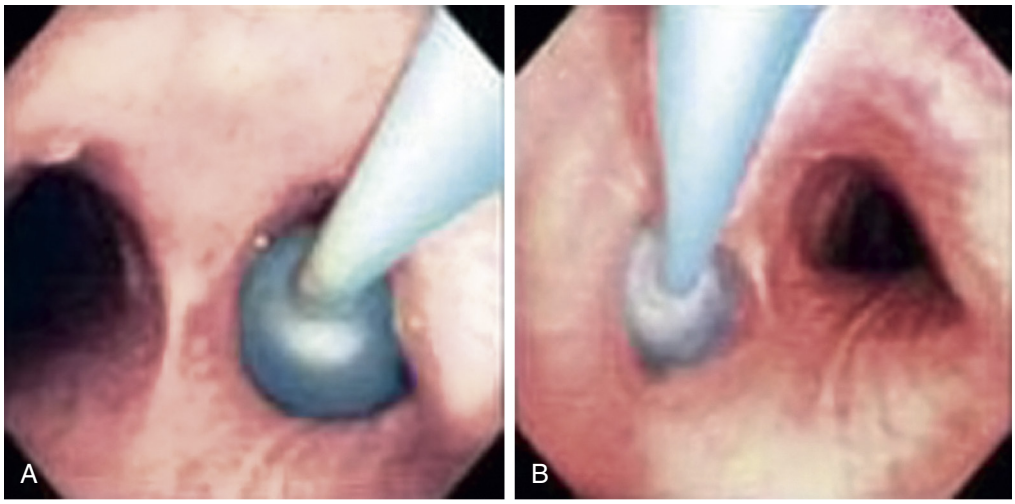

Figure 66-17. Placement of a bronchial blocker. Correct positioning of a blocker in the right **(A)** and left **(B)** mainstem bronchi as seen through a fiberoptic bronchoscope just above the carina in the trachea. *(Reproduced with permission from Slinger P: Principles and practice of anesthesia for thoracic surgery, New York, Springer, 2011.)*

TABLE 66-7 **CHARACTERISTICS OF THE COHEN, ARNDT, FUJI, AND EZ BRONCHIAL BLOCKERS**

	Cohen Blocker	Arndt Blocker	Fuji Uniblocker	EZ Blocker
Size	9 Fr	5 Fr, 7 Fr, 9 Fr	5 Fr, 9 Fr	7 Fr
Balloon shape	Spherical	Spherical or elliptical	Spherical	Spherical × 2
Guidance mechanism	Wheel device to deflect the tip	Nylon wire loop that is coupled with the fiberoptic bronchoscope	None, preshaped tip	None
Smallest recommended ETT for coaxial use	9 Fr (8.0 ETT)	5 Fr (4.5 ETT), 7 Fr (7.0 ETT), 9 Fr (8.0 ETT)	9 Fr (8.0 ETT)	7.5
Murphy eye	Present	Present in 9 Fr	Not present	No
Center channel	1.6 mm ID	1.4 mm ID	2.0 mm ID	1.4 mm ID

ETT, endotracheal tube; ID, internal diameter.
Modified with permission from Campos JH: Which device should be considered the best for lung isolation: double-lumen endotracheal tube versus bronchial blockers, Curr Opin Anaesthesiol *20:30,2007.*

bronchial blockers. The smallest internal diameter (ID) of an endotracheal tube that will allow passage of both a bronchial blocker and a fiberoptic bronchoscope depends on the diameters of the bronchoscope and blocker. For standard adult 9-Fr blockers, an endotracheal tube greater than or equal to 7.0 mm ID can be used with a bronchoscope less than 4.0 mm in diameter. Larger bronchoscopes will require an endotracheal tube greater than 7.5 mm ID. All blockers need to be well lubricated before placement.

Wire-Guided Endobronchial Blocker (Arndt Blocker)

Figure 66-18, *A*, displays the Arndt blockers. The Arndt blocker has a retractable loop that is placed over the fiberoptic bronchoscope, which is then used to guide the blocker into place. The Arndt blockers usually advance easily into the right mainstem bronchus without the loop. The original Arndt design was an elliptical blocker, but a spherical blocker is now available that may function better in the short, right mainstem bronchus.

Cohen Endobronchial Blocker

The Cohen blocker (see Fig. 66-18, *B*, *left*) uses a wheel located in the most proximal part of the unit that deflects the tip of the distal part of the blocker into the desired bronchus. This blocker has been preangled at the distal tip to facilitate insertion into a target bronchus. On the distal shaft above the balloon, there is an arrow that, when seen with the fiberoptic bronchoscope, indicates in which direction the tip deflects. To position the Cohen blocker, the arrow is aligned with the bronchus to be intubated, the proximal wheel is turned to deflect the tip toward the desired side, and then the blocker is advanced with fiberoptic guidance.

Fuji Uniblocker

The Fuji Uniblocker (see Fig. 66-18, *B*, *right*) is an independent blocker that is made of silicone material and has a simple, fixed distal hockey-stick (ice hockey) angulation to facilitate insertion. The blocker is simply rotated to the left or right as needed under fiberoptic bronchoscope guidance for placement in the required bronchus.

EZ Blocker

The EZ blocker is a recently introduced 7-Fr, 4-lumen catheter with a Y-shaped bifurcation. Each distal end has a balloon that can be guided into the right and left main bronchus. This device comes with its own multiport adapter and is used through an 8.0 SLT. The end of the Y sits in the tracheal carina. Each distal end is positioned into the right and left bronchus, and the bronchial balloon is inflated in the operative side for lung isolation.

Complications Related to the Bronchial Blockers

Failure to achieve lung separation because of abnormal anatomy or lack of a seal within the bronchus has been reported.[85] Inclusion of the bronchial blocker or the distal wire loop of an Arndt blocker into the stapling line has been reported during a lobectomy[86] and required surgical reexploration after unsuccessful removal of the bronchial blocker after extubation. To avoid these mishaps, communication with the surgical team regarding the presence of a bronchial blocker in the surgical side is crucial. Clearly, the bronchial blocker needs to be withdrawn a few centimeters before stapling.

Another potentially dangerous complication with all bronchial blockers is that the inflated balloon can move and lodge above the carina or be accidentally inflated in the trachea. This leads to an inability to ventilate and possibly the development of hypoxia and potentially cardiorespiratory arrest unless quickly recognized and the blocker deflated.[87] There is a report of more malpositions with the use of bronchial blockers when compared with DLTs.[88]

DIFFICULT AIRWAYS AND ONE-LUNG VENTILATION

Some patients requiring OLV are identified during preoperative evaluation to have a potentially difficult airway. Others present with unexpected difficulty to intubate after induction of anesthesia. Between 5% and 8% of patients with primary lung carcinoma also have a carcinoma of the pharynx, usually in the epiglottic area.[89]

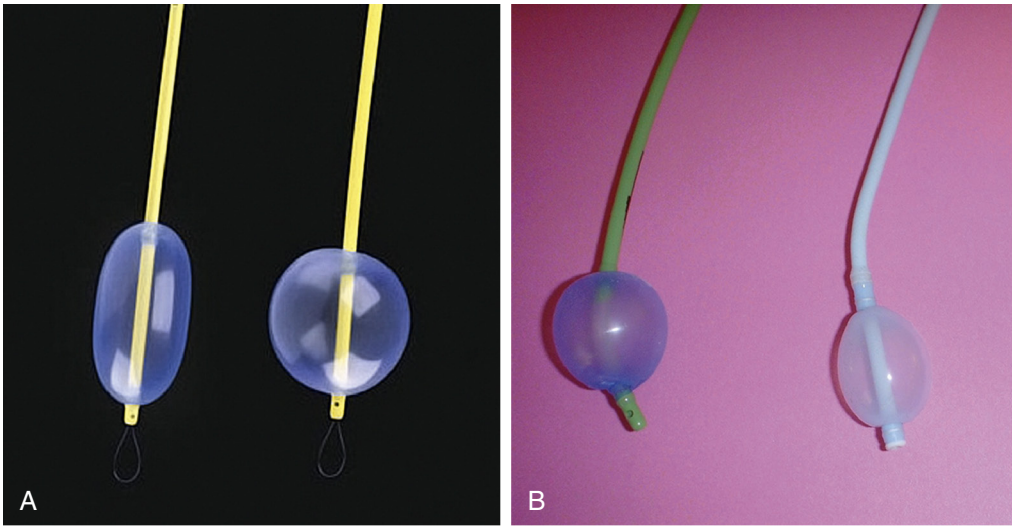

Figure 66-18. A, The original elliptical *(left)* and the newer spherical *(right)* Arndt designs of bronchial blocker (Cook Critical Care, Bloomington, Ind) (see text for details). **B,** The Cohen *(left)* (Cook Critical Care) and Fuji Uniblocker *(right)* (Vitaid, Lewinston, NY) bronchial blockers.

Many of these patients have had previous radiation therapy on the neck or previous airway surgery, such as hemimandibulectomy or hemiglossectomy, making intubation and achievement of OLV difficult because of distorted upper airway anatomy. In addition, a patient who requires OLV may have distorted anatomy at or beyond the tracheal carina, such as a descending thoracic aortic aneurysm compressing the entrance of the left mainstem bronchus or an intraluminal or extraluminal tumor near the tracheobronchial bifurcation that makes the insertion of a left-sided DLT relatively difficult or impossible. Such anomalies can be detected by reviewing the chest radiographs and CT scans of the chest. A flexible fiberoptic bronchoscopic examination is necessary to assess a distorted area of the airway before selection of a specific tube or blocker to achieve OLV.

In patients who require OLV and present with a difficult airway, the primary goal is to establish an airway with an SLT placed orally with the aid of a flexible fiberoptic bronchoscope, after appropriate airway anesthesia is achieved. In selected patients who seem easy to ventilate, this may be performed after induction of anesthesia with a bronchoscope or with a videolaryngoscope.[90] Once the SLT is in place, an independent bronchial blocker can be passed. If the patient requires OLV and cannot be intubated orally, an awake nasotracheal intubation can be performed with an SLT and, once the airway is established, then a bronchial blocker can be used.

An alternative to achieve OLV in a patient with a difficult airway is to intubate the patient's trachea with an SLT; then a DLT-SLT tube-exchange catheter can be used to replace the existing SLT with a DLT after general anesthesia is induced. For a DLT, the exchange catheter should be at least 83 cm. A 14-Fr exchange catheter can be used for 41-Fr and 39-Fr DLTs; for 37-Fr or 35-Fr DLTs, an 11-Fr exchange catheter is used. Specially designed exchange catheters for DLTs are available with a softer distal tip to try to decrease the risk of distal airway trauma (e.g., Cook Exchange Catheter, Cook Critical Care).

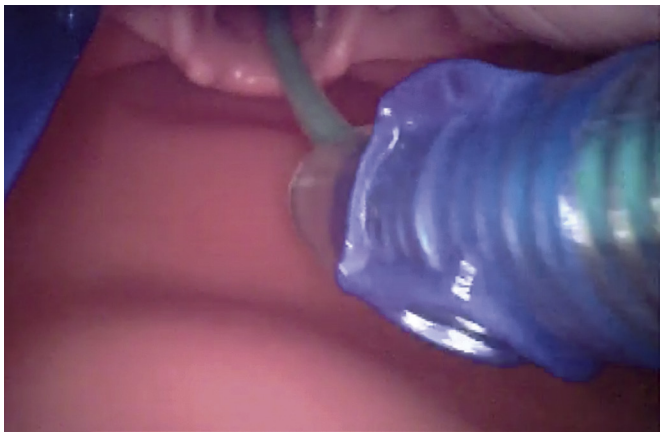

Figure 66-19. A DLT is placed over a tube-exchange catheter using a video laryngoscope for guidance. The green SLT-DLT tube-exchange catheter (Cook Critical Care, Bloomington, Ind) was passed initially through the SLT, which has been withdrawn (before the photo was taken) and the catheter then passed retrograde through the bronchial lumen of a DLT, which is advanced under direct vision through the glottis. The DLT in this picture (Fuji, Phycon, Vitaid, Lewinston, NY) has a bevel on the distal bronchial orifice and a flexible bronchial lumen that facilitates this procedure.

The exchange catheter, SLT, and the DLT combination should be tested in vitro before the exchange. A sniffing position facilitates tube exchange. After the exchange catheter is lubricated, it is advanced through the SLT. The catheter should not be inserted deeper than 24 cm at the lips to avoid accidental rupture or laceration of the trachea or bronchi. After cuff deflation, the SLT is withdrawn. Then the endobronchial lumen of the DLT is advanced over the exchange catheter. It is optimal to use a videolaryngoscope during the tube exchange to guide the DLT through the glottis under direct vision (Fig. 66-19). If a videolaryngoscope is not available, having an assistant perform standard laryngoscopy during tube exchange partially straightens out the alignment of the oropharynx and glottis and facilitates the exchange. Proper final position of the DLT is then achieved with auscultation and bronchoscopy.

LUNG ISOLATION TECHNIQUES IN PATIENTS WITH A TRACHEOSTOMY IN PLACE

Placement of a DLT through a tracheostomy stoma may be prone to malpositioning because the upper airway has been shortened and the conventional DLT may be too long. Before placing any lung isolation devices through a tracheostomy stoma, it is important to consider whether it is a fresh stoma (i.e., a few days old, when the airway can be lost immediately on decannulation) versus a chronic tracheostomy. The alternatives to achieve OLV in a tracheostomized patient include (1) insertion of an SLT followed by an independent bronchial blocker passed coaxially or external to the SLT[91]; (2) the use of a disposable cuffed tracheostomy cannula with an independent bronchial blocker; (3) replacement of the tracheostomy cannula with a specially designed short DLT such as the Naruke DLT, which is made for use in tracheostomized patients[92]; (4) placement of a small DLT through the tracheostomy stoma; or (5) if possible, oral access to the airway for standard placement of a DLT or blocker (this is occasionally an option in patients on prolonged mechanical ventilation for respiratory failure or postoperative complications).

In summary, the optimal method of lung isolation depends on a number of factors, including the patient's airway anatomy, the indication for lung isolation, the available equipment, and the training of the anesthesiologist. Suggested methods for lung isolation in specific clinical situations are listed in Table 66-8. Whichever method of lung isolation is used, the "ABCs" of lung isolation are:

Anatomy: Know the tracheobronchial anatomy. One of the major problems that many anesthesiologists have in achieving satisfactory lung isolation is a lack of familiarity with distal airway anatomy (Fig. 66-20).

Bronchoscopy: Whenever possible, use a fiberoptic bronchoscope to position endobronchial tubes and blockers. The ability to perform fiberoptic bronchoscopy is now a fundamental skill needed by all anesthesiologists

TABLE 66-8 SUGGESTED METHODS OF LUNG ISOLATION FOR SPECIFIC INDICATIONS

Indication for Lung Isolation	Preferred Methods	Possible Alternatives
Pulmonary resection right side	Left DLT	BB/Left EBT
Pulmonary resection left side		
Pneumonectomy unlikely	Left DLT	BB/Right DLT
Pneumonectomy	Right DLT	Left DLT/BB
Thoracoscopy (either side)	Left DLT	BB/Right DLT
Pulmonary hemorrhage	Left DLT	BB/contralateral EBT
Bronchopleural fistula		
Left mainstem bronchus	Right DLT	EBT
All other sites	Left DLT	Right DLT/BB/EBT
Purulent secretions (e.g., abscess, cyst)	Left DLT	Right DLT/BB/EBT
Bullae, blebs	Left DLT	Right DLT/BB
Nonpulmonary surgery (e.g., thoracic aorta, esophagus)	Left DLT/ BB	Right DLT/EBT
Bronchial surgery (e.g., tumor, trauma)		
Left side	Right DLT	EBT
Right side	Left DLT	EBT
Upper airway abnormalities	BB	Left DLT/EBT
Lung transplantation		
Bilateral	Left DLT	BB/EBT
Single right lung	Left DLT	BB/EBT
Single left lung	Right DLT	BB/Left DLT/EBT
Whole lung lavage	Left DLT	—
Independent lung ventilation	Left DLT	Right DLT

providing anesthesia for thoracic surgery. An online bronchoscopy simulator has been developed to help train anesthesiologists in positioning DLTs and blockers. This simulator, which uses real-time video, is available without cost at www.thoracicanesthesia.com.

Chest imaging: The anesthesiologist should always consult the chest imaging before placement of a DLT or blocker. Abnormalities of the lower airway can often be identified in advance, and this will affect the selection of the optimal method of lung isolation for a specific case (see Figs. 66-7 and 66-10).

POSITIONING

The majority of thoracic procedures are performed in the lateral position, most often the lateral decubitus position, but depending on the surgical technique, a supine, semisupine, or semiprone lateral position may be used. These lateral positions have specific implications for the anesthesiologist.

Position Change (See Chapter 41)

It is awkward to induce anesthesia with the patient in the lateral position. Thus monitors will be placed and anesthesia will usually be induced in the supine position and the anesthetized patient will then be repositioned for surgery. It is possible to induce anesthesia in the lateral position, and this may rarely be indicated with unilateral lung diseases such as bronchiectasis or hemoptysis until lung isolation can be achieved. However, even these patients will then have to be repositioned and the diseased lung turned to the nondependent side.

Because of the loss of venous vascular tone in the anesthetized patient, it is not uncommon to observe hypotension in the patient when turning them to or from the

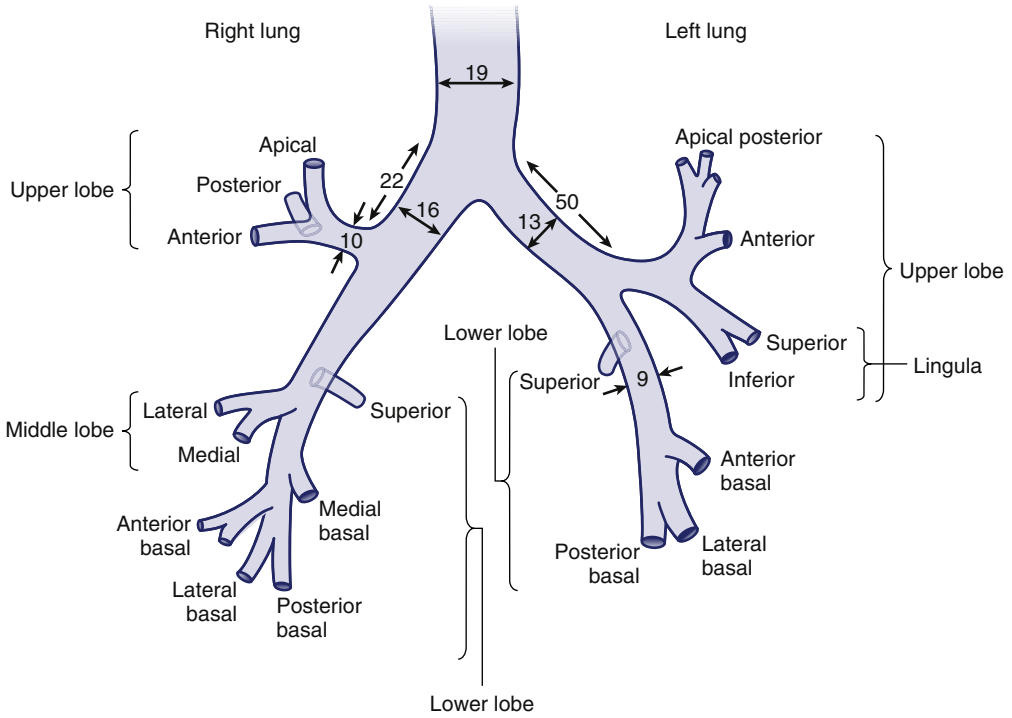

Figure 66-20. Diagram of the tracheobronchial tree. Mean lengths and diameters are shown in millimeters. Note that the right middle lobe bronchus exits directly anteriorly and the superior segments (some authors refer to these as the "apical" segments) of the lower lobes exit directly posteriorly. Using the apical designation, on the right side the segmental bronchi in a rostral to caudal sequence give the mnemonic "A PALM A MAPL." *(From Youngberg, JA:* Cardiac, vascular, and thoracic anesthesia. *Philadelphia, Churchill Livingstone, 2000.)*

lateral position. All lines and monitors will have to be secured during positioning changes and their function reassessed after repositioning. The anesthesiologist should take responsibility for the head, neck, and airway during position changes and must be in charge of the operating team to direct repositioning. It is useful to make an initial "head-to-toe" survey of the patient after induction and intubation to check oxygenation, ventilation, hemodynamics, lines, monitors, and potential nerve injuries. This survey then must be repeated after repositioning. It is nearly impossible to avoid some movement of a DLT or bronchial blocker during repositioning. Certainly the patient's head, neck, and endobronchial tube should be turned "en-bloc" with the patient's thoracolumbar spine. However, the margin of error in positioning endobronchial tubes or blockers is often so narrow that even very small movements can have significant clinical implications. The carina and mediastinum may shift independently with repositioning and this can lead to proximal misplacement of a previously well-positioned tube. Endobronchial tube/blocker position and the adequacy of ventilation must be rechecked by auscultation and fiberoptic bronchoscopy after patient repositioning.

Neurovascular Complications

There are a specific set of nerve and vascular injuries related to the lateral position that must be appreciated. The brachial plexus is the site of the majority of intraoperative nerve injuries related to the lateral position.[93] These are basically of two varieties: the majority are compression injuries of the brachial plexus of the dependent arm, but there is also a significant risk of stretch injuries to the brachial plexus of the nondependent arm. The brachial plexus is fixed at two points: proximally by the transverse process of the cervical vertebrae and distally by the axillary fascia. This two-point fixation, plus the extreme mobility of neighboring skeletal and muscular structures, makes the brachial plexus extremely liable to injury (Box 66-6). The patient should be positioned with padding under the dependent thorax (Fig. 66-21) to keep the weight of the upper body off the dependent arm brachial plexus. However, this padding will exacerbate the pressure on the brachial plexus if it migrates superiorly into the axilla.

BOX 66-6 ***Factors That Contribute to Brachial Plexus Injury in the Lateral Position***

- Dependent arm (compression injuries)
  - Arm directly under thorax
  - Pressure on clavicle into retroclavicular space
  - Cervical rib
  - Cranial migration of thorax padding into the axilla*
- Nondependent arm (stretch injuries)
  - Lateral flexion of cervical spine
  - Excessive abduction of arm (>90 degrees)
  - Semiprone or semisupine repositioning after arm fixed to a support

*Unfortunately, this padding under the thorax is misnamed an "axillary roll" in some institutions. This padding absolutely should *not* be placed in the axilla.

The arms should not be abducted beyond 90 degrees and should not be extended posteriorly beyond the neutral position nor flexed anteriorly more than 90 degrees. Fortunately, the majority of these nerve injuries resolve spontaneously over a period of months. Anterior flexion of the arm at the shoulder (circumduction) across the chest or lateral flexion of the neck toward the opposite side can cause a traction injury of the suprascapular nerve.[94] This causes a deep, poorly circumscribed pain of posterior and lateral aspects of the shoulder and may be responsible for some cases of postthoracotomy shoulder pain.

It is very easy, after repositioning the patient in the lateral decubitus position, to cause excessive lateral flexion of the cervical spine because of improper positioning of the patient's head. This malpositioning, which exacerbates brachial plexus traction, can cause a "whiplash" syndrome and can be difficult to appreciate from the head of the operating table, particularly after the surgical drapes have been placed. It is useful for the anesthesiologist to survey the patient from the side of the table immediately after turning to ensure that the entire vertebral column is aligned properly.

The dependent leg should be slightly flexed with padding under the knee to protect the peroneal nerve lateral to the proximal head of the fibula. The nondependent leg is placed in a neutral extended position and padding placed between it and the dependent leg. The dependent leg must be observed for vascular compression. Excessively tight strapping at the hip level can compress the sciatic nerve of the nondependent leg. Other sites particularly liable for neurovascular injury in the lateral position are the dependent ear pinna and eye. A head-to-toe protocol to monitor for possible neurovascular injuries related to the lateral decubitus position is presented in Box 66-7.

Figure 66-21. Typical positioning of a patient in the lateral decubitus position for thoracotomy seen from the side. It is useful for the anesthesiologist to survey the anesthetized patient from this perspective before draping to ensure that there is no lateral flexion of the cervical spine, which can be very difficult to appreciate from the head of the operating table. Note also the padding of the dependent thorax and the nondependent leg. *(From Youngberg, JA:* Cardiac, vascular, and thoracic anesthesia. *Philadelphia, Churchill Livingstone, 2000.)*

Physiologic Changes in the Lateral Position (See Chapter 41)

Ventilation. Significant changes in ventilation develop between the lungs when the patient is placed in the lateral position.[95] The compliance curves of the two lungs are different because of their difference in sizes. The lateral position, anesthesia, paralysis, and opening of the thorax all combine to magnify these differences between the lungs (Fig. 66-22). The compliance curve (change in volume versus change in pressure) of a lung depends on the balance of two "springs": the chest wall (normally distending the lung) and the elastic recoil of the lung itself. Any factor that changes the mechanics of either of these springs places the lung on a different compliance curve.[96]

In a healthy, conscious, spontaneously breathing patient, the ventilation of the dependent lung increases approximately 10% when the patient is turned to the lateral position. Once the patient is anesthetized and paralyzed, the ventilation of the dependent lung then decreases by 15%. Although the ventilation does not change significantly once the nondependent hemithorax is open, the FRC of this nondependent lung tends to increase by approximately 10%. These changes depend on the method used for ventilation in the individual patient. When the chest is open, because of disruption of the chest wall, both lungs tend to collapse to a minimal lung volume if expiration is prolonged. Thus the end-expiratory volume of each lung is directly a function of the time allowed for expiration. The compliance of the entire respiratory system increases significantly once the nondependent hemithorax is open.

Because of the fall in FRC and compliance of the nondependent lung in the lateral position, application of PEEP selectively to this lung only (using a DLT and two anesthetic circuits) will improve gas exchange.[97] This is different from the effect of nonselectively applying PEEP to both lungs in the lateral position, where PEEP tends to preferentially distribute to the most compliant lung regions and will tend to hyperinflate the nondependent lung without causing any improvement in gas exchange.[98]

Atelectasis will develop in an average of 6% of the lung parenchyma after induction of anesthesia in the supine position. This atelectasis will be evenly distributed in the dependent portions of both lungs.[99] By turning the patient to the lateral position, there will be a slight decrease of total atelectasis to 5% of lung volume, but this will now be concentrated totally in the dependent lung.

Perfusion. Gravity has some effect on distribution of pulmonary blood flow. In the lateral position, the blood flow to the dependent lung is generally thought to be increased by 10% compared with the same lung in the supine position.[100] However, the distribution of pulmonary blood flow in various positions may be related more to inherent pulmonary vascular anatomy than to gravity (Fig. 66-23).[101] The matching of ventilation and perfusion will usually be decreased in the lateral position compared with the supine position during anesthesia. Pulmonary arteriovenous shunt during general anesthesia will usually increase from approximately 5% in the supine position to 10% to 15% in the lateral position.[102]

BOX 66-7 ***Neurovascular Injuries Specific to the Lateral Position: Routine "Head-to-Toe" Survey***

- Dependent eye
- Dependent ear pinna
- Cervical spine in line with thoracic spine
- Dependent arm: (a) brachial plexus, (b) circulation
- Nondependent arm: (a) brachial plexus, (b) circulation*
- Dependent and nondependent suprascapular nerves
- Nondependent leg sciatic nerve
- Dependent leg: (a) peroneal nerve, (b) circulation

*Neurovascular injuries of the nondependent arm are more likely to occur if the arm is suspended or held in an independently positioned arm rest.

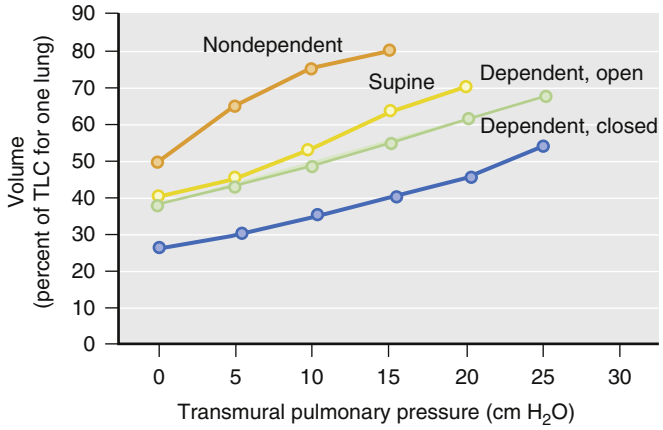

Figure 66-22. Changes in the compliance of a single lung during position changes in an anesthetized, paralyzed patient during controlled mechanical ventilation. These compliance changes are responsible for the resulting differences in ventilation between the lungs that occur in the lateral position. The compliance of the dependent lung is increased when the nondependent hemithorax is open versus closed.

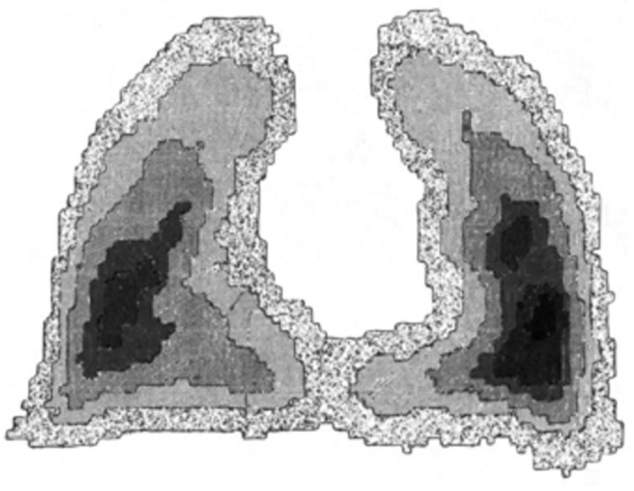

Figure 66-23. In vivo perfusion lung scanning in the upright position demonstrates a predominant central to peripheral distribution of pulmonary blood flow in addition to a gravitational effect that also increases the blood flow in dependent lung regions. *(From Youngberg, JA:* Cardiac, vascular, and thoracic anesthesia. *Philadelphia, Churchill Livingstone, 2000.)*

ANESTHETIC MANAGEMENT

The development of thoracic anesthesia and thoracic surgery was delayed more than 50 years after the introduction of ether because anesthesiologists could not manage patients during mask anesthesia with spontaneous ventilation and an open chest. These patients developed what was originally called the "pneumothorax syndrome."[103] The respiratory systems of mammals do not function adequately with an open hemithorax because of two physiologic problems. The first is paradoxical ventilation (also called *pendelluft*), in which gas moves into the open-chest lung from the intact lung during expiration and then reverses flow during inspiration. This leads to hypercapnia and hypoxemia. The second is caused by the swinging motion of the mediastinum between the hemithoraces during the respiratory cycle, which interferes with cardiac preload and causes hemodynamic instability. In the early 1900s, several pioneers, such as the New Orleans surgeon Matas, advocated positive-pressure ventilation and a primitive form of endotracheal ventilation, which had been demonstrated to be safe in animal experiments, for thoracic anesthesia. Modern methods incorporating OLV have evolved from this. Essentially, any anesthetic technique that provides safe and stable general anesthesia for major surgery can and has been used for lung resection.

FLUID MANAGEMENT

Because of hydrostatic effects, excessive administration of intravenous fluids can cause increased shunting and subsequently lead to pulmonary edema of the dependent lung, particularly during prolonged surgery.[104] Because the dependent lung is the lung that must carry on gas exchange during OLV, it is best to be as judicious as possible with fluid administration. Intravenous fluids are administered to replace volume deficits and for maintenance only during lung resection anesthesia. No volume is given for "third space" losses (Box 66-8). It is possible that there is no "third space."[105]

TEMPERATURE (See Chapter 54)

Maintenance of body temperature can be a problem during thoracic surgery because of heat loss from the open hemithorax. This is particularly a problem at the extremes of the age spectrum. Most of the body's physiologic functions, including HPV, are inhibited during hypothermia. Increasing the ambient room temperature, fluid warmers and the use of lower and/or upper body forced-air patient warmers are the best methods to prevent inadvertent intraoperative hypothermia.

BOX 66-8 ***Fluid Management for Pulmonary Resection Surgery***

- Total positive fluid balance in the first 24-hour perioperative period should not exceed 20 mL/kg.
- For an average adult patient, crystalloid administration should be limited to less than 3 L in the first 24 hours.
- No fluid administration for third-space fluid losses during pulmonary resection
- Urine output greater than 0.5 mL/kg/h is unnecessary.
- If increased tissue perfusion is needed postoperatively, it is preferable to use invasive monitoring and inotropes rather than to cause fluid overload.

PREVENTION OF BRONCHOSPASM

Because of the frequent incidence of coexisting reactive airways disease in the thoracic surgical population, an anesthetic technique that decreases bronchial irritability should be chosen. This is particularly important because the added airway manipulation caused by placement of a DLT or bronchial blocker is a potent trigger for bronchoconstriction. The principles of anesthetic management are the same as they are for any asthmatic patient: avoid manipulation of the airway in a lightly anesthetized patient, use bronchodilating anesthetics, and avoid drugs that release histamine. For intravenous induction of anesthesia, either propofol or ketamine can be expected to diminish bronchospasm. This benefit will not be seen with barbiturate, opioid, benzodiazepine, or etomidate intravenous induction of anesthesia. For maintenance of anesthesia, propofol and/or any of the volatile anesthetics will diminish bronchial reactivity. Sevoflurane may be the most potent bronchodilator of the volatile anesthetics.[106]

CORONARY ARTERY DISEASE (See Chapter 47)

Because the lung resection population is largely elderly and/or smokers, there is a high coincidence of coronary artery disease. This consideration will be a major factor in the choice of the anesthetic technique for most thoracic patients. The anesthetic technique should optimize the myocardial oxygen supply/demand ratio by maintaining arterial oxygenation and diastolic blood pressure while avoiding unnecessary increases in cardiac output and heart rate. Thoracic epidural anesthesia/analgesia may aid in this (see Postoperative Analgesia later in this chapter).

The ability to provide effective regional anesthesia with thoracic epidural blockade has opened the possibility of performing some thoracic surgical procedures in awake patients. A wide variety of thoracic operations have been reported using this technique, including thoracoscopy, thoracotomy, and sternotomy.[107] Epidural block is often combined with ipsilateral stellate ganglion block to decrease the cough reflex from stimulation of the hilum. The specific indications to use these techniques do not arise commonly but may occur in severely compromised patients with airway management issues.[108] Obviously the original concerns with the pneumothorax syndrome apply to prolonged surgery with these techniques. However, during VATS, the operative hemithorax is effectively closed and gas exchange is usually adequate during spontaneous ventilation with supplemental oxygen.

MANAGEMENT OF ONE-LUNG VENTILATION

During OLV, the anesthesiologist has the unique and often conflicting goals of trying to maximize atelectasis in the nonventilated lung to improve surgical access while

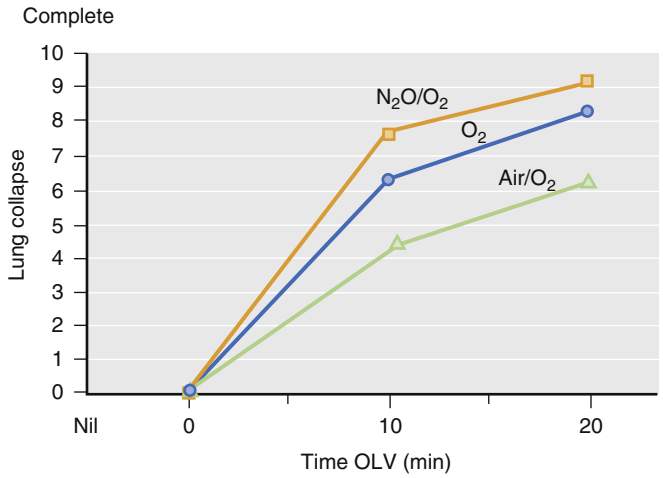

Figure 66-24. The effects of the gas mixture used during two-lung ventilation (TLV), immediately before one-lung ventilation (OLV), on the speed of collapse of the nonventilated lung during OLV. O_2 = FiO_2 1.0; N_2O/O_2 = nitrous oxide/oxygen 60/40; air/O_2 = air/oxygen FiO_2 0.4. All patients were ventilated with an FiO_2 of 1.0 during OLV. The poorly soluble nitrogen in the air/oxygen mixture delays collapse of the nonventilated lung. *(Based on data from Unzueta C, Tusman G, Suarez-Sipman F, et al: Alveolar recruitment improves ventilation during thoracic surgery: a randomized controlled trial,* Br J Anaesth *108: 517, 2012.)*

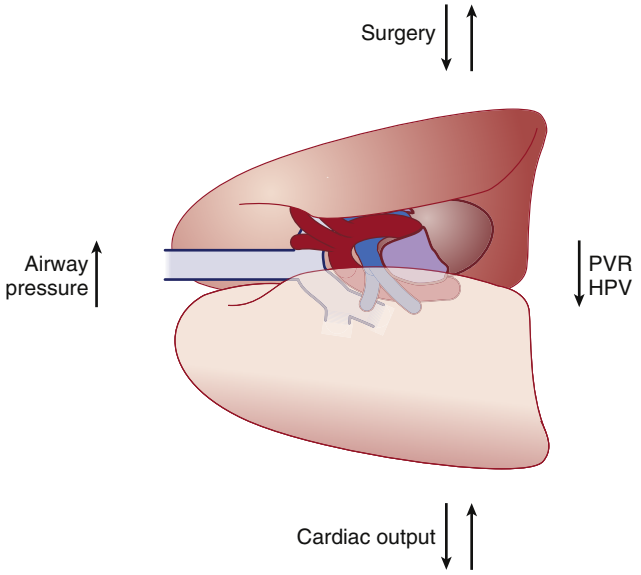

Figure 66-25. Factors affecting the distribution of pulmonary blood flow during OLV. Hypoxic pulmonary vasoconstriction (HPV) and the collapse of the nonventilated lung, which increases pulmonary vascular resistance (PVR), tend to distribute blood flow toward the ventilated lung. The airway pressure gradient between the ventilated and nonventilated thoraces tends to encourage blood flow to the nonventilated lung. Surgery and cardiac output can have variable effects, either increasing or decreasing the proportional flow to the ventilated lung.

trying to avoid atelectasis in the ventilated lung (usually the dependent lung) to optimize gas exchange. The gas mixture in the nonventilated lung immediately before OLV has a significant effect on the speed of collapse of this lung. Because of its low blood-gas solubility, nitrogen (or an air-oxygen mixture) will delay collapse of this lung (Fig. 66-24).[109] This is particularly a problem at the start of VATS surgery when surgical visualization in the operative hemithorax is limited, and in patients with emphysema who have delayed collapse of the nonventilated lung because of decreased lung elastic recoil. It is important to thoroughly de-nitrogenate the operative lung, by ventilating with oxygen, immediately before it is allowed to collapse. Although nitrous oxide is even more effective than oxygen in speeding lung collapse, for the reasons just cited it is not commonly used in thoracic anesthesia because many patients may have blebs or bullae.

Also, during the period of two-lung anesthesia before the start of OLV, atelectasis will develop in the dependent lung. It is useful to perform a recruitment maneuver to the dependent lung (similar to a Valsalva maneuver, holding the lung at an end-inspiratory pressure of 20 cm H_2O for 15 to 20 seconds) immediately after the start of OLV to decrease this atelectasis. Recruitment is important to maintain PaO_2 levels during subsequent OLV.[110]

HYPOXEMIA

A major concern that influences anesthetic management for thoracic surgery is the occurrence of hypoxemia during OLV. There is no universally acceptable figure for the safest lower limit of oxygen saturation during OLV. A saturation greater than or equal to 90% (PaO_2 >60 mm Hg) is commonly accepted, and for brief periods a saturation in the high 80s may be acceptable in patients without significant comorbidity. However, the lowest acceptable saturation will be higher in patients with organs at risk of hypoxia because of limited regional blood flow (e.g., coronary or cerebrovascular disease) and in patients with limited oxygen transport (e.g., anemia or decreased cardiopulmonary reserve). It has been shown that during OLV, patients with COPD desaturate more quickly during isovolemic hemodilution than normal patients.[111]

Previously, hypoxemia occurred frequently during OLV. Reports for the period between 1950 and 1980 describe an incidence of hypoxemia (arterial saturation <90%) of 20% to 25%.[112] Current reports describe an incidence of less than 5%.[113] This improvement is most likely a result of several factors: improved lung isolation techniques such as routine fiberoscopy to prevent lobar obstruction from DLTs, improved anesthetic agents that cause less inhibition of HPV, and better understanding of the pathophysiology of OLV. The pathophysiology of OLV involves the body's ability to redistribute pulmonary blood flow to the ventilated lung. Several factors aid and impede this redistribution and these are under the control of the anesthesiologist to a variable degree. These factors are illustrated in Figure 66-25. The anesthesiologist's goal during OLV is to maximize pulmonary vascular resistance (PVR) in the nonventilated lung while minimizing PVR in the ventilated lung. The key to understanding this physiology is the appreciation that PVR is correlated with lung volume in a hyperbolic fashion (Fig. 66-26). PVR is lowest at FRC and increases as lung volume rises or falls above or below FRC.[114] The anesthesiologist's aim, to optimize pulmonary blood flow redistribution during OLV, is to maintain the ventilated lung as close as possible to its FRC while facilitating collapse of the nonventilated lung to increase its PVR.

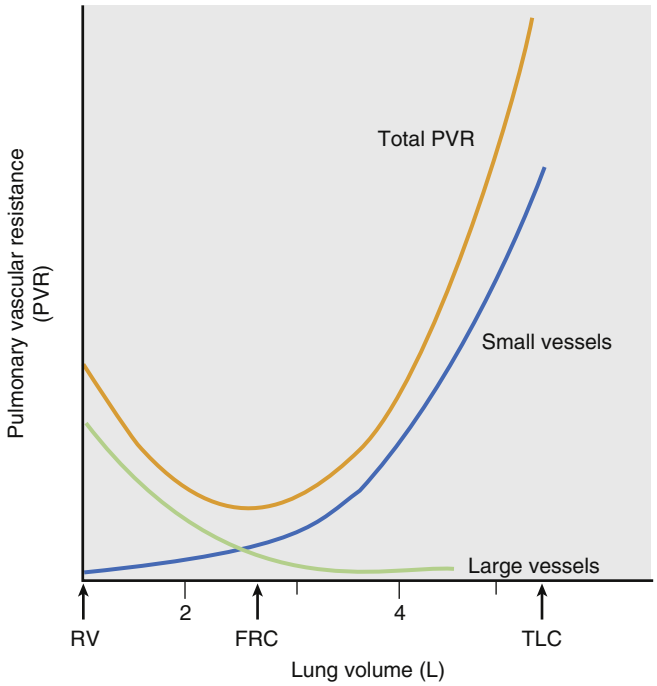

Figure 66-26. The relationship between PVR and lung volume. PVR is lowest at functional residual capacity (FRC) and increases as the lung volume decreases toward residual volume (RV), caused primarily by an increase in the resistance of large pulmonary vessels. PVR also increases as lung volume increases above FRC toward total lung capacity (TLC) as a result of an increase in the resistance of small interalveolar lung vessels.

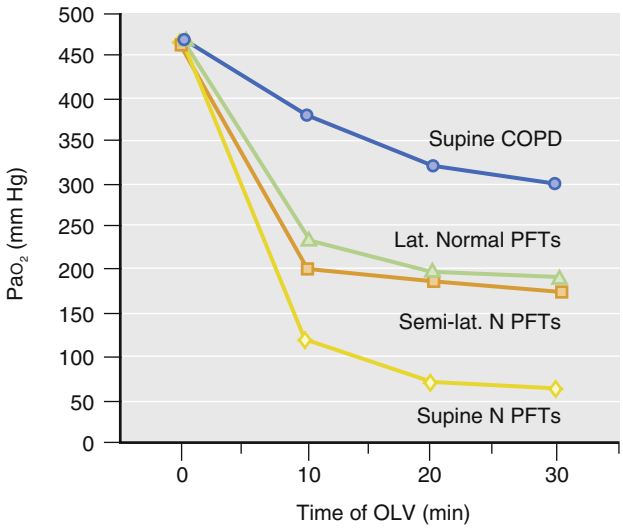

Figure 66-27. Mean PaO_2 in groups of patients versus time of OLV. Supine COPD = patients with COPD having OLV in the supine position. Lat. Normal PFTs = patients with normal pulmonary function having OLV in the lateral position. Semi-lat. N PFTs = patients with normal pulmonary function having OLV in the semilateral position. Supine N PFTs = patients with normal pulmonary function having OLV in the supine position. Patients with normal pulmonary function having OLV in the supine position are the most likely to desaturate. *(Based on data from Bardoczky GI, Szegedi LL, d'Hollander AA, et al: Two-lung and one-lung ventilation in patients with chronic lung disease: the effects of position and FiO2,* Anesth Analg *90:35, 2000; Eisenkraft JB: Effects of anaesthetics on the pulmonary circulation,* Brit J Anaesth *65:63, 1990.)*

INTRAOPERATIVE POSITION
(See Chapter 41)

Most thoracic surgery is performed with patients in the lateral position. Patients having OLV in the lateral position have significantly better PaO_2 levels than patients during OLV in the supine position.[115] This applies both to patients with normal lung function and to those with COPD (Fig. 66-27).[116]

HYPOXIC PULMONARY VASOCONSTRICTION

HPV is thought to be able to decrease the blood flow to the nonventilated lung by 50%.[117] The stimulus for HPV is primarily the alveolar oxygen tension (PAO_2), which stimulates precapillary vasoconstriction, redistributing pulmonary blood flow away from hypoxemic lung regions via a pathway involving nitric oxide and/or cyclooxygenase synthesis inhibition.[118] The mixed venous PO_2 (PVo_2) is also a stimulus, although considerably weaker than PAO_2. HPV has a biphasic temporal response to alveolar hypoxia. The rapid-onset phase begins immediately and reaches a plateau by 20 to 30 minutes. The second (delayed) phase begins after 40 minutes and plateaus after 2 hours (Fig. 66-28).[119] The offset of HPV is also biphasic, and pulmonary vascular resistance may not return to baseline for several hours after a prolonged period of OLV. This may contribute to increased desaturation during the collapse of the second lung during bilateral

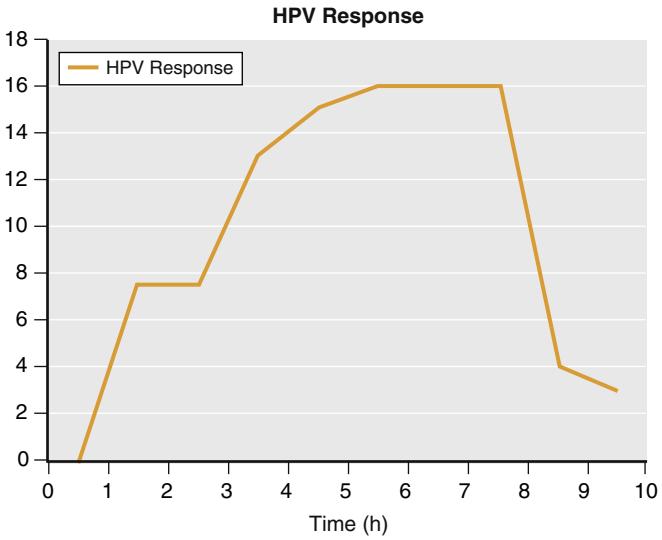

Figure 66-28. The relationship between hypoxic pulmonary vasoconstriction (HPV) (vertical axis) and time in hours (h) (horizontal axis) in humans exposed to isocapnic hypoxia (approximate inspired PO_2 60 mm Hg) beginning at baseline with a return to normoxia at 8 hours. HPV response was measured as the increase in echocardiographic right ventricular systolic pressure. Note the two-phase, rapid and slow, onset of HPV. Also note that after prolonged HPV, the pulmonary pressures do not return to baseline for several hours. *(Based on data from Van Der Spek AFL, Spargo PM, Norton ML: The physics of lasers and implications for their use during airway surgery,* Br J Anaesth *60: 709, 1988.)*

thoracic procedures. HPV is also a reflex that has a preconditioning effect, and the response to a second hypoxic challenge will be greater than to the first challenge.[120]

The surgical trauma to the lung can affect pulmonary blood flow redistribution. Surgery may oppose HPV by release of vasoactive metabolites locally in the lung. Conversely, surgery can dramatically decrease blood flow to the nonventilated lung by deliberately or accidentally mechanically interfering with either the unilateral pulmonary arterial or venous blood flow.[121] Ventilation increases blood flow through a hypoxic lung more than in a normoxic lung, which is generally not of clinical relevance but does complicate studies of HPV. HPV is decreased by vasodilators such as nitroglycerin and nitroprusside. In general, vasodilators can be expected to cause deterioration in PaO_2 during OLV. Thoracic epidural sympathetic blockade probably has little or no direct effect on HPV, which is a localized chemical response in the lung.[122] However, thoracic epidural anesthesia can have an indirect effect on oxygenation during OLV if it is allowed to cause hypotension and a fall in cardiac output (see Cardiac Output later in this chapter).

CHOICE OF ANESTHETIC

All of the volatile anesthetics inhibit HPV in a dose-dependent fashion with halothane > enflurane > isoflurane.[123] The older anesthetics were potent inhibitors of HPV and this may have contributed to the high incidence of hypoxemia reported during OLV in the 1960s and 1970s (see earlier); many of these studies used 2- to 3-MAC doses of halothane.

In doses of less than or equal to 1 MAC, the modern volatile anesthetics (isoflurane, sevoflurane,[124] and desflurane[125]) are weak, and equipotent, inhibitors of HPV. The inhibition of the HPV response by 1 MAC of a volatile anesthetic such as isoflurane is approximately 20% of the total HPV response, and this could account for only a net 4% increase in total arteriovenous shunt during OLV, which is a difference too small to be detected in most clinical studies.[126] In addition, volatile anesthetics cause less inhibition of HPV when delivered to the active site of vasoconstriction via the pulmonary arterial blood than via the alveolus. This pattern is similar to the HPV stimulus characteristics of oxygen. During established OLV, the volatile agent only reaches the hypoxic lung pulmonary capillaries via the mixed venous blood. No clinical benefit in oxygenation during OLV has been shown for total intravenous anesthesia above that seen with 1 MAC of the modern volatile anesthetics.[127]

The use of nitrous oxide/oxygen (N_2O/O_2) mixtures is associated with a higher incidence of postthoracotomy radiographic atelectasis (51%) in the dependent lung than when air/oxygen mixtures are used (24%). Nitrous oxide also tends to increase pulmonary artery pressures in patients who have pulmonary hypertension, and N_2O inhibits HPV. For these reasons, N_2O is usually avoided during thoracic anesthesia.

CARDIAC OUTPUT

The effects of alterations of cardiac output during OLV are complex (Fig. 66-29). Increasing cardiac output tends to cause increased pulmonary artery pressures and passive dilation of the pulmonary vascular bed, which in turn opposes HPV and has been shown to be associated with increased arteriovenous shunt ($\dot{Q}s/\dot{Q}t$) during OLV.[128] However, in patients with a relatively fixed oxygen consumption, as is seen during stable anesthesia, the effect of an increase in cardiac output is to increase the mixed venous oxygen saturation (SvO_2). Thus increasing cardiac output during OLV tends to increase both shunt and SvO_2, which have opposing effects on PaO_2. There is a ceiling effect to the amount that SvO_2 can be increased. Increasing the cardiac output to supranormal levels by administering inotropes such as dopamine tends to have an overall negative effect on PaO_2.[129] Conversely, allowing the cardiac output to fall will lead to decreases in both shunt and SvO_2, with a net effect of decreasing PaO_2. Because even with optimal anesthetic management there is usually a shunt of 20% to 30% during OLV, it is very important to maintain cardiac output.

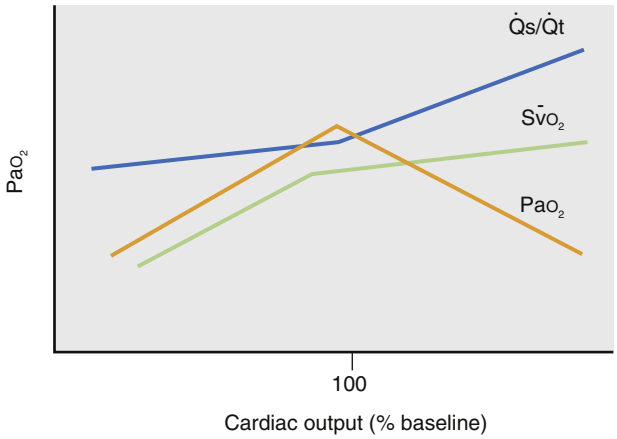

Figure 66-29. The relationship between PaO_2 and cardiac output during OLV. As cardiac output falls below baseline, arteriovenous shunt ($\dot{Q}s/\dot{Q}t$) falls, but the mixed venous oxygen saturation (SvO_2) also decreases, resulting in a net fall in PaO_2. Conversely, raising cardiac output above baseline tends to increase SvO_2 but also increase $\dot{Q}s/\dot{Q}t$ and the net result again is a decrease in PaO_2. *(Based on data from Russell WJ, James MF: The effects on arterial haemoglobin oxygen saturation and on shunt of increasing cardiac output with dopamine or dobutamine during one-lung ventilation,* Anaesth Intensive Care *32:644, 2004; Kim SH, Jung KT, AN TH: Effects of tidal volume and PEEP on arterial blood gases and pulmonary mechanics during one-lung ventilation,* J Anesth *26:568, 2012.)*

VENTILATION STRATEGIES DURING ONE-LUNG VENTILATION

The strategy used to manage the ventilated lung during OLV plays an important part in the distribution of pulmonary blood flow between the lungs. It has been the practice of many anesthesiologists to use the same large tidal volume (e.g., 10 mL/kg ideal body weight) during OLV as during TLV. This strategy probably decreases hypoxemia by recurrently recruiting atelectatic regions in the dependent lung and may result in higher PaO_2 values during OLV compared with smaller

tidal volumes.[130] However, there is a trend to use smaller tidal volumes with PEEP during OLV for several reasons. First, the incidence of hypoxemia during OLV is much lower than it was 20 to 30 years ago. Second, there is a risk of causing acute injury to the ventilated lung with prolonged use of large tidal volumes. And finally, third, a ventilation pattern that allows recurrent atelectasis and recruitment of lung parenchyma seems to be injurious.[131] The ventilation technique needs to be individualized depending on the patient's underlying lung mechanics.

RESPIRATORY ACID-BASE STATUS
(See Chapter 60)

The efficacy of HPV in a hypoxic lung region is increased in the presence of respiratory acidosis and is inhibited by respiratory alkalosis. However, there is no net benefit to gas exchange during OLV from hypoventilation because the respiratory acidosis preferentially increases the pulmonary vascular tone of the well-oxygenated lung, and this opposes any clinically useful pulmonary blood flow redistribution.[132] Overall, the effects of hyperventilation will usually tend to decrease pulmonary vascular pressures.

POSITIVE END-EXPIRATORY PRESSURE

Resistance to blood flow through the lung is related to lung volume in a biphasic pattern and is lowest when the lung is at its FRC (see Fig. 66-26). Keeping the ventilated lung as close as possible to its normal FRC favorably encourages pulmonary blood flow to this lung. Several intraoperative factors known to alter FRC tend to cause the FRC of the ventilated lung to fall below its normal level; these include lateral position, paralysis, and opening the nondependent hemithorax, which allows the weight of the mediastinum to compress the dependent lung. Attempts to measure FRC in human patients during OLV have been complicated by the presence of a persistent end-expiratory airflow in patients with COPD.[133] Many patients do not actually reach their end-expiratory equilibrium FRC lung volume as they try to exhale a relatively large tidal volume through one lumen of a DLT. These patients develop dynamic hyperinflation and an occult positive end-expiratory pressure (auto-PEEP).[41]

AUTO-PEEP

Auto-PEEP occurs in patients with decreased lung elastic recoil, such as in older patients or those with emphysema.[134] Auto-PEEP increases as the inspiratory/expiratory (I:E) ratio increases (i.e., as the time of expiration decreases). This auto-PEEP, which averages 4 to 6 cm H_2O in most series of lung cancer patients studied, opposes the previously mentioned factors which tend to diminish dependent-lung FRC during OLV. The effects of applying external PEEP through the ventilator circuit to the lung in the presence of auto-PEEP are complex (Fig. 66-30). Patients with a very low auto-PEEP (<2 cm H_2O) will have a greater increase in total PEEP from a moderate (5 cm H_2O) external PEEP than those with a high level of auto PEEP (>10 cm H_2O). Whether the application of PEEP during OLV will improve a patient's gas exchange depends on the individual's lung mechanics. If the application of PEEP tends to shift the expiratory equilibration position on the compliance curve toward the lower inflection point of the curve (i.e., toward the FRC), then external PEEP is of benefit (Fig. 66-31). However, if the application of PEEP raises the equilibration point such that it is further from the lower inflection point, then gas exchange deteriorates.

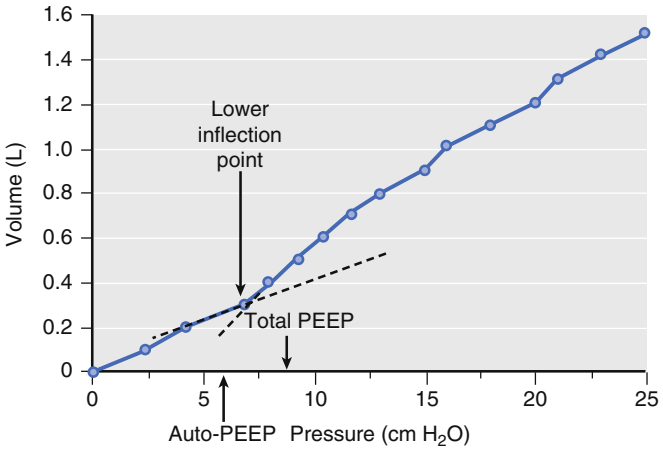

Figure 66-30. The static compliance curve of the ventilated (dependent) lung in a typical lung cancer patient with mild COPD. The Lower Inflection Point is thought to represent FRC. This patient had 6 cm H_2O of auto-PEEP during OLV. Adding 5 cm H_2O PEEP to the ventilator resulted in a total PEEP in the circuit of 9 cm H_2O. This patient had a decrease in PaO_2 with the addition of PEEP. *(Based on data from Slinger P, Kruger M, McRae K, et al: Relation of the static compliance curve and positive end-expiratory pressure to oxygenation during one-lung ventilation,* Anesthesiology *95:1096, 2001.)*

Auto-PEEP is difficult to detect and measure using currently available anesthetic ventilators. To detect auto-PEEP, the respiratory circuit must be held closed at the end of a normal expiration until an equilibrium appears in the airway pressure.[135] Most current intensive care ventilators can be used to measure auto-PEEP.

TIDAL VOLUME

There will be an optimal combination of tidal volume, respiratory rate, I:E ratio, or pressure- or volume-control ventilation for each individual patient during OLV. However, to try to assess each of these parameters while still providing anesthesia with the available anesthetic ventilators is not practical, and the clinician must initially rely on a simplified strategy (Table 66-9). The results of alterations in tidal volume are unpredictable. This may be caused partly by the interaction of tidal volume with auto-PEEP. The use of 5 to 6 mL/kg ideal body weight tidal volumes plus 5 cm H_2O PEEP initially for most patients (except those with COPD) seems a logical starting point during OLV. Tidal volume should be managed so that peak airway pressures do not exceed 35 cm H_2O. This will correspond to a plateau airway pressure of approximately 25 cm H_2O.[136] Peak airway pressures exceeding 40 cm

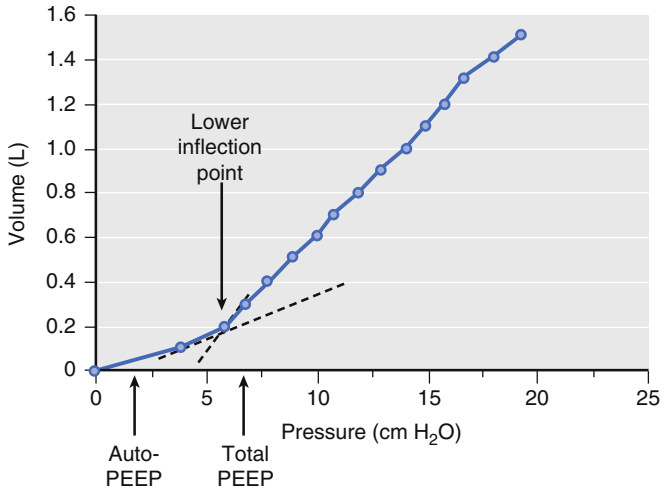

Figure 66-31. Static compliance curve of a young patient with normal pulmonary function during OLV (in this case for removal of a mediastinal tumor). The lower inflection point of the curve (FRC) was at 6 cm H_2O. The patient had 2 cm H_2O auto-PEEP during OLV. Adding 5 cm H_2O PEEP to the ventilator raised the total PEEP to 7 cm H_2O and improved PaO_2. Young patients and patients with increased lung elastic recoil (such as caused by restrictive lung diseases) have an increase in PaO_2 from PEEP during OLV. *(Based on data from Slinger P, Kruger M, McRae K, et al: Relation of the static compliance curve and positive end-expiratory pressure to oxygenation during one-lung ventilation,* Anesthesiology *95:1096, 2001.)*

TABLE 66-9 SUGGESTED VENTILATION PARAMETERS FOR ONE-LUNG VENTILATION

Parameter	Suggested	Guidelines/Exceptions
Tidal volume	5-6 mL/kg	Maintain: Peak airway pressure <35 cm H_2O Plateau airway pressure <25 cm H_2O
Positive end-expiratory pressure	5 cm H_2O	Patients with COPD, no added PEEP
Respiratory rate	12 breaths/min	Maintain normal $Paco_2$, Pa-etCO_2 will usually increase 1-3 mm Hg during one-lung ventilation
Mode	Volume or pressure controlled	Pressure control for patients at risk of lung injury (e.g., bullae, pneumonectomy, post lung transplantation)

H_2O may contribute to hyperinflation injury of the ventilated lung during OLV.[137]

Turning the patient to the lateral position will increase respiratory dead space and the arterial to end-tidal CO_2 tension gradient (Pa-etCO_2). This will usually require a 20% increase in minute ventilation to maintain the same $PaCO_2$. Individual variations in Pa-$ETCO_2$ gradient can become much larger, and $PetCO_2$ is less reliable as a monitor of $Paco_2$ during OLV. This effect is possibly because there are individual differences in the excretion of CO_2 between the dependent and nondependent lungs.

VOLUME-CONTROLLED VERSUS PRESSURE-CONTROLLED VENTILATION

Traditionally, volume-controlled ventilation has been used in the operating room for all types of surgery. The recent availability of anesthesia ventilators with pressure-control modes has made it possible to study and use this form of ventilation during thoracic surgery. Pressure-control ventilation has not been shown to improve oxygenation versus volume-controlled ventilation for most patients, although the peak airway pressures are lower.[138] The decrease in peak pressure with pressure control ventilation may be largely in the anesthetic circuit and not at the distal airway.[139] Pressure-control ventilation will avoid sudden increases in peak airway pressures that may result from surgical manipulation in the chest. This will be of benefit in patients at increased risk for lung injury from high volumes or pressures such as after lung transplantation or during a pneumonectomy.[140] Because of the rapid changes of lung compliance that occur during pulmonary surgery, when pressure-control ventilation is used, the delivered tidal volume needs to be closely monitored because it may change suddenly.

PREDICTION OF HYPOXEMIA DURING ONE-LUNG VENTILATION

The problem of hypoxemia during OLV has prompted much research in thoracic anesthesia. Hypoxemia during OLV is predictable (see Box 66-4), preventable, and treatable in the vast majority of cases.[141]

PREOPERATIVE VENTILATION-PERFUSION SCAN

The shunt and PaO_2 during intraoperative OLV are highly correlated with the fractional perfusion of the ventilated lung as determined by a preoperative ventilation perfusion scan.[142] Patients with long-standing unilateral disease on the operative side develop a unilateral decrease of ventilation and perfusion and tolerate OLV very well. Similarly, patients who intraoperatively have a higher proportion of gas exchange in the dependent lung during OLV tend to have better oxygenation during OLV.

SIDE OF OPERATION

Patients having right-sided thoracotomies tend to have a larger shunt and lower PaO_2 during OLV because the right lung is larger and normally 10% better perfused than the left. The overall mean PaO_2 difference between left and right thoracotomies during stable OLV is approximately 100 mm Hg.[143]

TWO-LUNG OXYGENATION

Patients who have better PaO_2 levels during TLV in the lateral position tend to have better oxygenation during OLV. These patients may have better abilities to match ventilation and perfusion (individual variability of HPV response) and/or they may have less atelectasis in the

dependent lung. This is a particularly relevant consideration in trauma patients who may require a thoracotomy but have a contusion of the dependent lung.

PREOPERATIVE SPIROMETRY

Studies consistently show that when the previous factors are controlled, patients with better spirometric lung function preoperatively are more likely to desaturate and have lower PaO_2 values during OLV. Clinically this is evident because emphysematous lung volume reduction patients generally tolerate OLV very well. The explanation is not clear but may be related to maintenance of a more favorable FRC in patients with obstructive airways disease during OLV with an open hemithorax because of the development of auto-PEEP.[54]

TREATMENT OF HYPOXEMIA DURING ONE-LUNG VENTILATION

During OLV there will be a fall in arterial oxygenation that usually reaches its nadir 20 to 30 minutes after the initiation of OLV, and then the saturation will stabilize or may rise slightly as HPV increases over the next 2 hours. The majority of patients who desaturate do so quickly and within the first 10 minutes of OLV. Hypoxemia during OLV responds readily to treatment in the vast majority of cases. Potential therapies are outlined in Box 66-9.

1. *Resume two-lung ventilation.* Reinflate the nonventilated lung and deflate the bronchial cuff of the DLT or the bronchial blocker. This will necessitate interruption of surgery but is necessary in case of severe or precipitate desaturation. After an adequate level of oxygenation is obtained, the diagnosis of the cause of desaturation can be made and prophylactic measures instituted (see later) before another trial of OLV is attempted.
2. *Increase FiO_2.* Ensure that the delivered FiO_2 is 1.0. This is an option in essentially all patients except those who have received bleomycin or similar therapies that potentiate pulmonary oxygen toxicity.
3. *Recheck the position of the DLT or bronchial blocker.* Ensure that there is no lobar obstruction in the ventilated lung.
4. *Check to be sure there has been no decrease in cardiac output.* The surgeon can accidentally compress the inferior vena cava during pulmonary resections, which decreases arterial blood pressure and cardiac output that leads to a rapid desaturation during OLV. Treat the decrease in cardiac output as indicated (e.g., inotropes/vasopressors if caused by thoracic epidural sympathetic blockade). Stop administration of vasodilators, decrease the MAC of volatile anesthetics to less than or equal to 1 MAC.
5. *Perform a recruitment maneuver of the ventilated lung.* To eliminate any atelectasis, inflate the lung to 20 cm H_2O or more for 15 to 20 seconds. This may cause transient hypotension and will also cause a transient further fall in the PaO_2 as the blood flow is temporarily redistributed to the nonventilated lung.
6. *Apply PEEP to the ventilated lung.* It is necessary to perform a recruitment maneuver before applying PEEP to get the maximal benefit. PEEP will raise the end-expiratory volume of the ventilated lung toward the FRC in patients with normal lung mechanics and in those with increased elastic recoil caused by restrictive disease. It is not possible to predict the optimal PEEP for individual patients; a level of 5 cm H_2O is a useful starting point. PEEP will increase the end-expiratory lung volume of patients with significant levels of auto-PEEP (e.g., emphysema patients). Unlike CPAP, application of PEEP does not require reinflation of the nonventilated lung and interruption of surgery. PEEP has been shown to be as effective for increasing PaO_2 levels during OLV in patients with normal lung function as CPAP (Fig. 66-32).[144] For patients with normal pulmonary function, it is logical to routinely apply a recruitment maneuver and PEEP from the start of OLV.
7. *Continuous positive airway pressure (CPAP) with oxygen to the nonventilated lung is the next line of therapy after application of PEEP.*[145] There is an important caveat to be observed when CPAP is applied to the nonventilated lung, and that is that CPAP must be applied to an inflated (recruited) lung to be completely effective. The opening pressure of atelectatic lung regions is greater than 20 cm H_2O[146] and these units will not be recruited by simple application of CPAP levels of 5 to 10 cm H_2O. Even a period as short as 5 minutes of collapse before CPAP application can have deleterious effects on oxygenation during OLV.[147] When CPAP is applied to a fully inflated lung, levels of CPAP as low as 1 to 2 cm H_2O can be used.[148] Because the normal transpulmonary pressure of the lung at FRC is approximately 5 cm H_2O, levels of 5 to 10 cm H_2O CPAP applied to a fully recruited lung result in a large-volume lung that impedes surgery, particularly during minimally invasive procedures.

BOX 66-9 ***Therapies for Desaturation during One-Lung Ventilation***

- Severe or precipitous desaturation: resume two-lung ventilation (if possible).
- Gradual desaturation
  - Ensure that delivered FiO_2 is 1.0.
  - Check position of double-lumen tube or blocker with fiberoptic bronchoscopy.
  - Ensure that cardiac output is optimal; decrease volatile anesthetics to <1 MAC.
  - Apply a recruitment maneuver to the ventilated lung (this will transiently make the hypoxemia worse).
  - Apply PEEP 5 cm H_2O to the ventilated lung (except in patients with emphysematous pathology).
  - Apply CPAP 1-2 cm H_2O to the nonventilated lung (apply a recruitment maneuver to this lung immediately before CPAP).
  - Use intermittent reinflation of the nonventilated lung.
  - Partial ventilation techniques of the nonventilated lung:
    - Lung oxygen insufflation
    - Lobar insufflation
  - Lobar collapse (using a bronchial blocker)
  - Use mechanical restriction of the blood flow to the nonventilated lung

PEEP, positive end-expiratory pressure; *CPAP,* continuous positive airway pressure.

CPAP levels less than 10 cm H_2O do not interfere with hemodynamics. The beneficial effects of low levels of CPAP are primarily caused by oxygen uptake from the nonventilated lung and not because of blood flow diversion to the ventilated lung. CPAP is most effective when oxygen (FiO_2 1.0) is applied to the nonventilated lung. Lower FiO_2 levels of CPAP are of clinical benefit and can be used along with decreased FiO_2 to the ventilated lung in patients at risk of oxygen toxicity.

Numerous anesthetic systems to apply CPAP to the nonventilated lung have been described. Essentially all that is required is a CPAP (or PEEP) valve and an oxygen source. Ideally the circuit should permit variation of the CPAP level and include a reservoir bag to allow easy reinflation of the nonventilated lung and a manometer to measure the actual CPAP supplied. Such circuits are commercially available (Fig. 66-33) or can be readily constructed from standard anesthetic equipment. CPAP can be applied with either a DLT or through the suction channel of a bronchial blocker.

CPAP, even when properly administered, is not completely reliable to improve oxygenation during OLV. When the bronchus of the operative lung is obstructed, or open to atmosphere (as in a bronchopleural fistula or during endobronchial surgery), CPAP will not improve oxygenation. Also in certain situations, particularly during thoracoscopic surgery where access to the operative hemithorax is limited, CPAP can significantly interfere with surgery.[149]

PHARMACOLOGIC MANIPULATIONS

Eliminating known potent vasodilators such as nitroglycerin and halothane and large doses of other volatile anesthetics will improve oxygenation during OLV.[150] The selective administration of the vasodilator prostaglandin E_1 to the ventilated lung[151] or a NO synthase inhibitor (L-NAME)[152] to a hypoxic lobe results in improved redistribution of pulmonary blood flow in animal models. This is not currently applicable in humans. Selective administration of NO alone to the ventilated lung was not shown to be of benefit in humans.[153] The combination of NO (20 ppm) to the nonventilated lung and an intravenous infusion of almitrene, which enhances HPV, has been shown to restore PaO_2 values during OLV in humans to essentially the same levels as during TLV. However, this may have been primarily a result of the augmentation of HPV by almitrene.[154] It is unlikely that almitrene, which was previously available in North America as a respiratory stimulant, will be reintroduced to this market because of side effects such as hepatic enzyme changes and lactic acidosis. However, the combination of NO and other pulmonary vasoconstrictors such as phenylephrine has been shown to improve oxygenation in ventilated intensive care unit patients with adult respiratory distress syndrome,[155] and this may have applications in OLV.

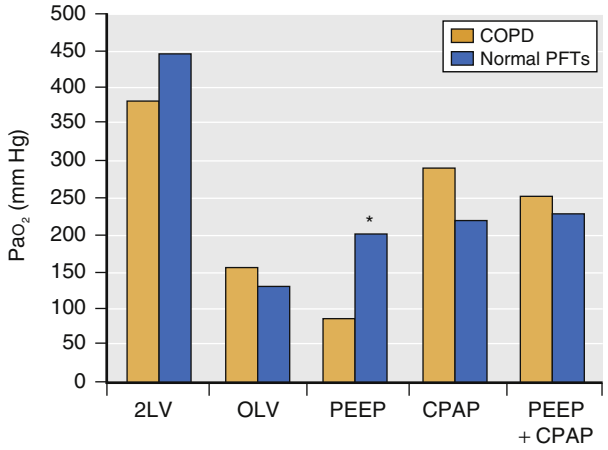

Figure 66-32. A comparison of the effects of positive end-expiratory pressure (PEEP) to the ventilated lung and continuous positive airway pressure (CPAP) to the nonventilated lung on mean PaO_2 levels during OLV. *2LV*, two-lung ventilation; *COPD*, a group of lung cancer surgery patients; *Normal PFTs*, a group of esophageal surgery patients with normal preoperative pulmonary function tests. *Significance of $P < .05$ versus OLV. *(Based on data from Capan LM, Turndorf H, Patel C, et al: Optimization of arterial oxygenation during one-lung anesthesia,* Anesth Analg *59:847, 1980; Rothen HU, Sporrc B, Engberg G et al: Re-expansion of atelectasis during general anesthesia: a computed tomographic study,* Br J Anaesth *71:788, 1993.)*

INTERMITTENT REINFLATION OF THE NONVENTILATED LUNG

HPV becomes more effective during repeated hypoxic exposure. Often after reinflation, the oxygen saturation will be more acceptable during a second period of lung collapse. Reexpansion can be performed by regular reexpansion of the operative lung via an attached CPAP circuit.

PARTIAL VENTILATION METHODS

Several alternative methods of OLV, all involving partial ventilation of the nonventilated lung, have been described and improve oxygenation during OLV. These techniques are useful in patients who are particularly at risk of desaturation, such as those who have had previous

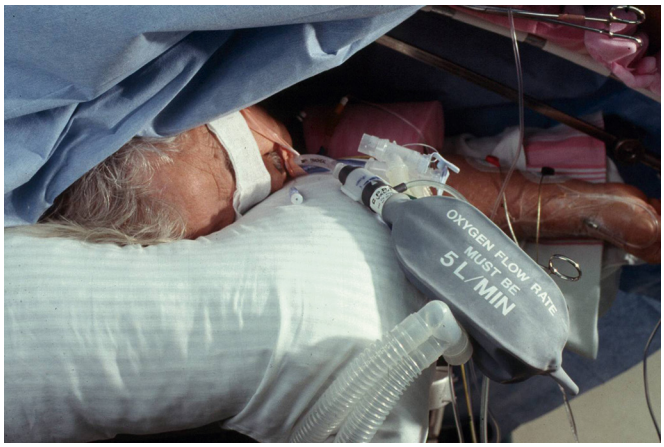

Figure 66-33. Photograph of a commercial (Mallinckrodt, St. Louis, Mo) disposable CPAP circuit applied to the nonventilated lung during a left thoracotomy (in this case applied to the tracheal lumen of a right-sided DLT). This circuit has an adjustable exhaust valve that allows titration of CPAP between 1 and 10 cm H_2O. *CPAP,* continuous positive airway pressure; *DLT,* double-lumen endobronchial tube.

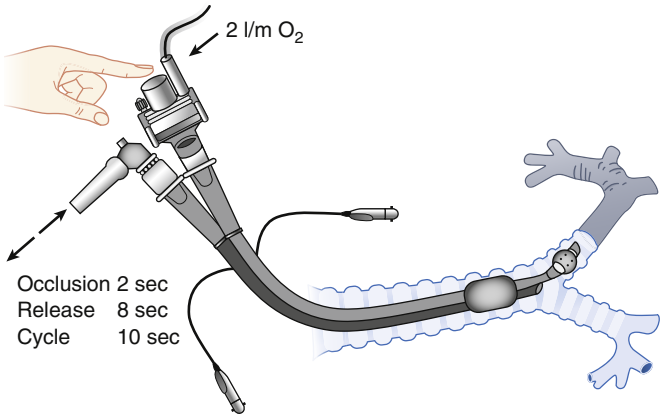

Figure 66-34. A simple device to provide intermittent positive airway pressure to the nonventilated lung. A standard bacteriostatic filter is attached to the lumen of the DLT to the nonventilated lung and an oxygen source is connected to the CO_2 sampling port of the filter. Intermittent manual occlusion of the open filter end improves oxygenation with minimal impact on surgical exposure (see text for details). *(Reproduced with permission from Slinger P:* Principles and practice of anesthesia for thoracic surgery, *New York, Springer, 2011.)*

pulmonary resections of the contralateral lung. These alternatives include:

1. *Intermittent positive airway pressure to the nonventilated lung.* This can be performed by a variety of methods. Russell described attaching a standard bacteriostatic filter to the nonventilated lumen of the DLT with a 2-L oxygen inflow attached to the CO_2 port of the filter (Fig. 66-34).[156] Manual occlusion of the filter for 2 seconds gives an insufflation of approximately 66 mL of oxygen to the nonventilated lung. This could be repeated at 10-second intervals with minimal interference with surgical exposure.
2. *Selective insufflation of oxygen to recruit lung segments on the side of surgery but remote from the site of surgery* (Fig. 66-35).[157] A useful technique in minimally invasive surgery is intermittent insufflation of oxygen using a fiberoptic bronchoscope. A 5-L oxygen flow is attached to the suction port of a fiberoptic bronchoscope that is passed under direct vision into a segment of the lung remote from the site of surgery, which is then reinflated by triggering the suction on the fiberoptic bronchoscope. The surgeon aids this technique by

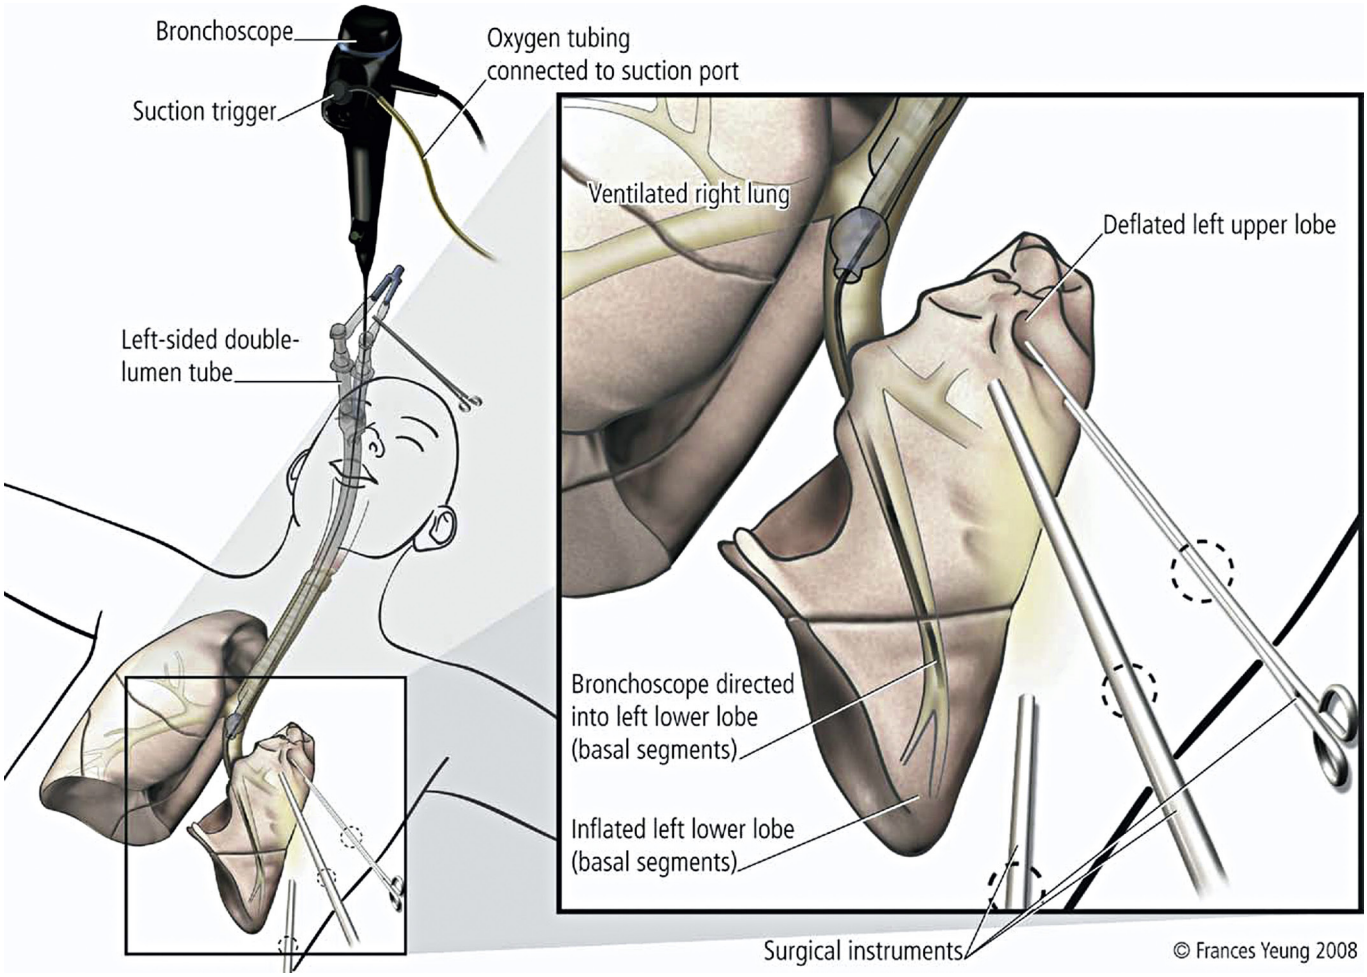

Figure 66-35. Intermittent oxygen insufflation during thoracoscopic surgery to segments of the nonventilated lung on the side of surgery using a fiberoptic bronchoscope (see text for details). *(Reproduced with permission from Slinger P:* Principles and practice of anesthesia for thoracic surgery, *New York, Springer, 2011.)*

observing the lung inflation with the videoscope to avoid overdistention of the recruited segment(s).

3. *Selective lobar collapse of only the operative lobe in the open hemithorax.*[158] This is accomplished by placement of a blocker in the appropriate lobar bronchus of the ipsilateral operative lung.

MECHANICAL RESTRICTION OF PULMONARY BLOOD FLOW

It is possible for the surgeon to directly compress or clamp the blood flow to the nonventilated lung.[159] This can be done temporarily in emergency desaturation situations or definitively in cases of pneumonectomy or lung transplantation. Another technique of mechanical limitation of blood flow to the nonventilated lung is the inflation of a pulmonary artery catheter balloon in the main pulmonary artery of the operative lung. The pulmonary artery catheter can be positioned at induction with fluoroscopic guidance and inflated as needed intraoperatively. This has been shown to be a useful technique for resection of large pulmonary arteriovenous fistulas.[160]

HYPOXEMIA PROPHYLAXIS

Most treatments outlined as therapies for hypoxemia can be used prophylactically to prevent hypoxemia in patients who are at high risk of desaturation during OLV. The advantage of prophylactic therapy of hypoxemia, in addition to the obvious patient safety benefit, is that maneuvers involving CPAP or alternative ventilation patterns of the operative lung can be instituted at the onset of OLV in a controlled fashion and will not require interruption of surgery and emergent reinflation of the nonventilated lung at a time that may be extremely disadvantageous.

BILATERAL PULMONARY SURGERY

Because of mechanical trauma to the operative lung, the gas exchange in this lung will always be temporarily impaired after OLV. Also HPV offset may be delayed after reinflation of the first lung collapsed. Desaturation during bilateral lung procedures is particularly a problem during the second period of OLV (i.e., during OLV of the lung that has already had surgery).[161] Thus, for bilateral procedures it is advisable to operate first on the lung that has better gas exchange and less propensity to desaturate during OLV. For the majority of patients, this means operating on the right side first.

ANESTHETIC MANAGEMENT FOR COMMON SURGICAL PROCEDURES

FLEXIBLE FIBEROPTIC BRONCHOSCOPY

Flexible fiberoptic bronchoscopy is a diagnostic and therapeutic procedure of great value in the clinical practice of thoracic surgery and anesthesia. In many centers, it is common practice to perform flexible fiberoptic bronchoscopy before lung resections to reconfirm the diagnosis (if a tumor compresses the airway) or to determine the invasion and obstruction of the distal airway (in relation to the extension of the bronchial resection).

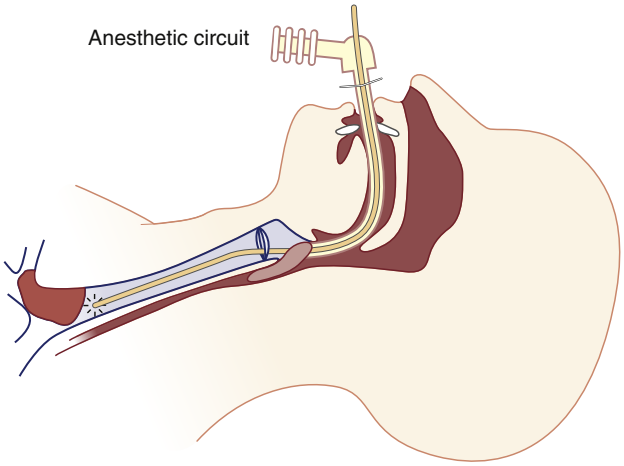

Figure 66-36. Diagram of fiberoptic bronchoscopy performed via a laryngeal mask airway (LMA) during general anesthesia in a spontaneously breathing patient with a carinal tumor, in this case for diagnosis and Nd:YAG laser tumor excision. The LMA permits visualization of the vocal cords and subglottic structures with the bronchoscope, which is not possible when fiberoptic bronchoscopy is performed via an endotracheal tube.

Anesthetic Management

There are multiple techniques for flexible fiberoptic bronchoscopy. Options include awake versus general anesthesia and oral versus nasal approaches. Options for local anesthesia include: topical anesthesia via a nebulizer, handheld aerosol, or soaked pledgets; nerve blocks (laryngeal and/or glossopharyngeal nerves); and direct administration of local anesthetic through the bronchoscope (spray-as-you-go technique)[162] with/without sedation/opioid or antisialogogues. Options during general anesthesia include spontaneous versus positive-pressure ventilation with/without muscle relaxation. Airway management during general anesthesia can be done with an endotracheal tube or a laryngeal mask airway (LMA). A Portex swivel connector (Smiths Medical, Ashford, Kent, UK) with a self-sealing valve is used to facilitate the ventilation and manipulation of the bronchoscope; at the same time inhalation and/or intravenous agents can be used for anesthesia. Patients who have copious secretions in the preoperative period should receive anticholinergic medication to ensure a dry field, which provides optimal visualization with the use of a flexible bronchoscope.

The advantages of an LMA technique include visualization of the vocal cords and subglottic structures as well as a lower airway resistance versus an ETT when the bronchoscope is inserted (Fig. 66-36). This is particularly useful in a patient with a difficult airway, when maintaining spontaneous respiration may be the safest method of anesthetic management.[163] Self-expanding flexometallic tracheal and bronchial stents can be placed with fiberoptic or rigid bronchoscopy (Fig. 66-37). However, silastic airway stents require rigid bronchoscopy for placement.

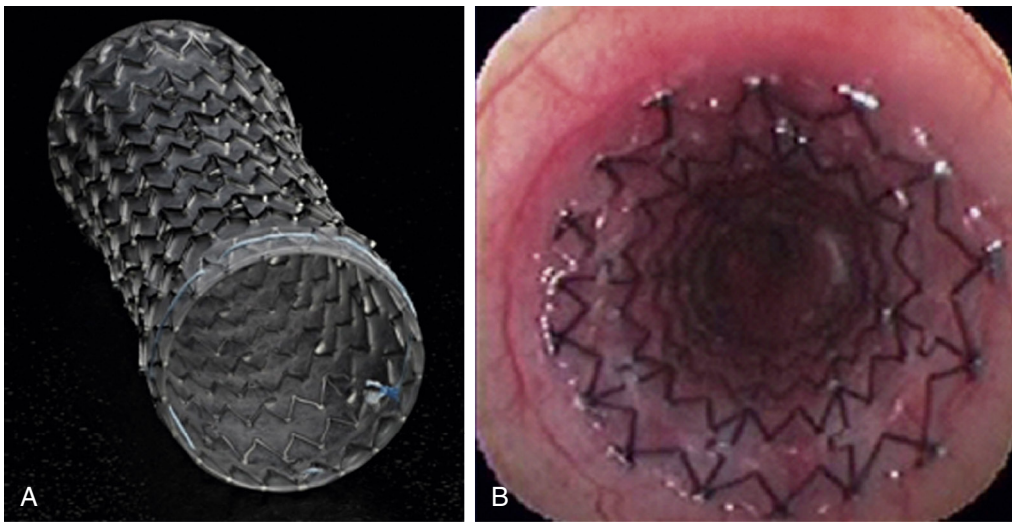

Figure 66-37. A, A self-expanding flexometallic airway stent. **B,** Fiberoptic bronchoscopic view of the proximal end of a flexometallic tracheal stent.

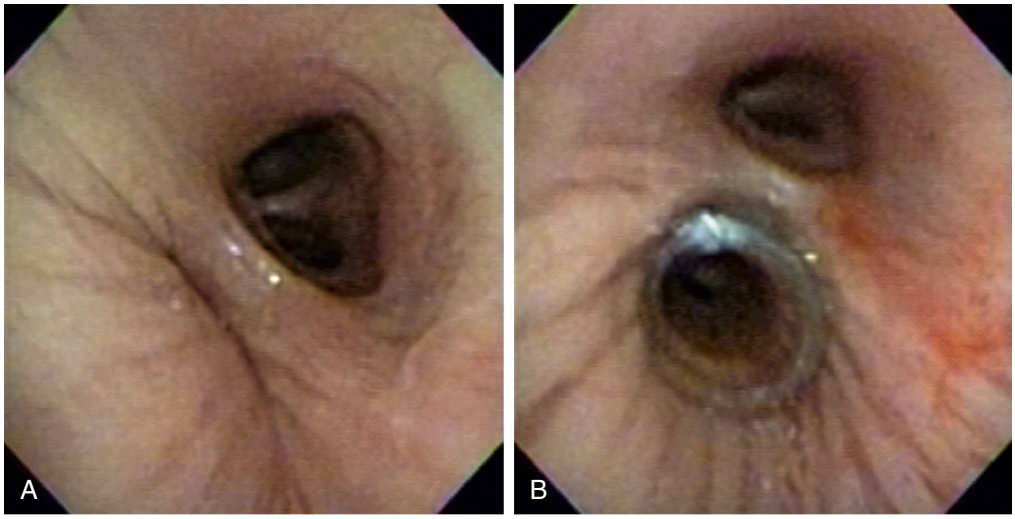

Figure 66-38. A, Photograph of a patient with a collapse of the left lower lobe bronchus post lung transplantation. **B,** A silastic stent has been placed in the left lower lobe bronchus with rigid bronchoscopy.

RIGID BRONCHOSCOPY

Rigid bronchoscopy has traditionally been considered the technique of choice for the preoperative diagnostic assessment of an airway obstruction involving the trachea and in the therapy of massive hemoptysis and foreign bodies in the airway. The role of interventional bronchoscopy with laser, bronchial dilation, or stent insertion is well established for the treatment of malignant and benign central airway and endobronchial lesions (Fig. 66-38).[164] Rigid bronchoscopy is the procedure of choice for operative procedures such as dilation of tracheal stenosis.

Anesthetic Management

Patients undergoing rigid bronchoscopy should have a complete preoperative evaluation including radiologic studies. Chest radiographs and chest CT scans should be reviewed in the preoperative evaluation. If time permits, it is recommended that patients with severe stridor receive pharmacologic interventions for temporary stabilization of the condition. Treatments may include inspired cool saline mist, nebulized racemic epinephrine, and the use of systemic steroids.[165]

There are four basic methods of ventilation management for rigid bronchoscopy:

1. *Spontaneous ventilation.* The addition of topical anesthesia or nerve blocks to the airway decreases the tendency to breath-hold and cough when volatile anesthetics are used.
2. *Apneic oxygenation (with/without insufflation of oxygen).* This requires thorough preoxygenation, and the anesthesiologist will have to interrupt surgery to ventilate the patient before desaturation occurs. This should allow the surgeon working intervals of 3 minutes or longer depending on the underlying condition of the patient.
3. *Positive-pressure ventilation via a ventilating bronchoscope* (Fig. 66-39). This allows the use of a standard anesthetic circuit but may cause significant air leaks if there is a discrepancy between the size of a smaller bronchoscope and a larger airway.
4. *Jet ventilation.* This can be performed with a handheld injector such as the Sanders injector (Sulz, Germany)[166] or with a high-frequency ventilator. These techniques

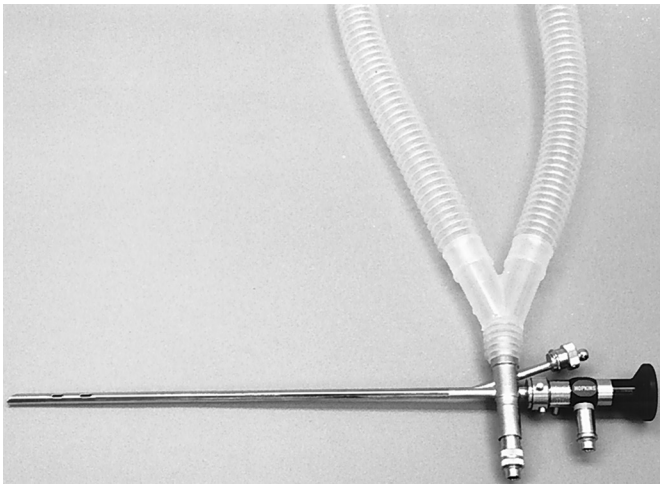

Figure 66-39. Photograph of a ventilating rigid bronchoscope with an anesthetic circuit attached to the side arm. This photograph also shows a telescopic lens sealing the proximal end of the bronchoscope. *(From Kaplan J, Slinger P, editors:* Thoracic anesthesia, *ed 3, Philadelphia, 2003, Churchill Livingstone.)*

are most useful with intravenous anesthesia because they entrain gas from either the room air or an attached anesthetic circuit, and the dose of any volatile agent delivered will be very uncertain.

The use of anticholinergic agents (e.g., 0.2 mg intravenous [IV] glycopyrrolate) before manipulation of the airway will decrease secretions during the bronchoscopic examination. For a patient undergoing rigid bronchoscopy, the surgeon must be at the bedside for the induction of anesthesia and be prepared to establish airway control with the rigid bronchoscope. Anesthesia in children for rigid bronchoscopy is most commonly done with spontaneous ventilation and a volatile anesthetic. In adults, IV anesthesia and the use of muscle relaxants is more common.

In cases for which the use of neuromuscular blocking drugs is not contraindicated, succinylcholine can be used initially to facilitate intubation with either a small SLT or the rigid bronchoscope. Nondepolarizing neuromuscular blocking drugs (see Chapter 34) may be needed for prolonged procedures such as stent placement or tumor resection. Mouthguards should be used to protect the upper and lower teeth and gums from the pressure of the bronchoscope. Remifentanil and propofol infusions can be administered if an IV regimen is the planned anesthetic.[167] This is a useful technique if the surgeon needs repeated access (for suction or instrumentation) to the open airway because it maintains the level of anesthesia and avoids contaminating the operating room with exhaled anesthetic vapors.

For cases in which a neodymium-doped yttrium aluminium garnet (Nd:YAG) laser is used, the inspired fraction of oxygen should be maintained in the lowest acceptable range (i.e., <30% if possible) according to patient oxygen saturation, to avoid the potential for fire in the airway. Because any common material (including porcelain and metal) can be perforated by the Nd:YAG laser, it is best to avoid any potentially combustible substance in the airway when the Nd:YAG laser is used.[168] Because of its high energy and short wavelength, the Nd:YAG laser has several advantages for distal airway surgery over the CO_2 laser, which is used in upper airway surgery. The Nd:YAG laser penetrates tissue more deeply so it causes more coagulation in vascular tumors, and it can be refracted and passed in fibers through a flexible or rigid bronchoscope. However, there is a higher potential for accidental reflected laser strikes and there is more delayed airway edema.

Rigid bronchoscopes have different sizes, commonly from 3.5- to 9-mm diameters, with a ventilating side port to facilitate ventilation when the bronchoscope is placed into the airway. If excessive leak of tidal volume occurs around the bronchoscope with positive-pressure ventilation, it may be necessary to place throat packs to facilitate ventilation. Continuous communication with the surgeon or pulmonologist is necessary in case desaturation occurs. If desaturation does occur, it must be corrected by stopping surgery and allowing the anesthesiologist to ventilate and oxygenate the patient, either via the rigid bronchoscope or by removing the bronchoscope and ventilating with a mask, LMA, or ETT.

Pulse oximetry is vital during rigid bronchoscopy because there is a high risk of desaturation. There is no simple way to monitor end-tidal CO_2 or volatile anesthetics because the airway remains essentially open to atmosphere. For prolonged procedures, it is useful to perform repeated arterial blood gas analysis to confirm the adequacy of ventilation. An alternative is to interrupt surgery and ventilate the patient with a standard circuit and a mask or ETT to assess the end-tidal CO_2.

Unlike during fiberoptic bronchoscopy via an ETT, with rigid the bronchoscopy the airway is never completely secure and there is always the potential for aspiration in patients at increased risk, such as those with a full stomach, hiatal hernia, morbid obesity, and so on. It is always best to defer rigid bronchoscopy to decrease the aspiration risk if possible in these patients. When there is no benefit to be gained by deferring and/or the airway risk is acute (e.g., aspiration of an obstructing foreign body), there is no simple solution and each case will need to be managed on an individual basis depending on the context and weighing the competing risks.

Other uses of the rigid bronchoscope that require anesthesia include dilation for benign airway stenosis, coring-out of malignant lesions in the trachea, laser ablation of endobronchial and carinal tumors, and therapeutic bronchoscopic interventions before surgical resection of lung cancer. In addition, interventional bronchoscopy is often used for the management of airway complications after lung transplantation.

Complications of rigid bronchoscopy include airway perforation, mucosal damage, hemorrhage, postmanipulation airway edema, and potential airway loss at the end of the procedure. In some situations, it may be necessary to keep the patient intubated with a small (i.e., 6.0-mm ID) SLT after a rigid bronchoscopy if an edematous airway is suspected or if the patient is not able to be extubated. These patients may require the use of steroids, nebulized racemic epinephrine, or helium-oxygen mixtures to treat stridor in the postoperative period.

MEDIASTINOSCOPY

Mediastinoscopy is the standard method for the evaluation of mediastinal lymph nodes in the staging of NSCLC. In addition, mediastinoscopy is used to aid in the diagnosis of anterior/superior mediastinal masses.[169] The most common mediastinal diagnostic procedure is a cervical mediastinoscopy, in which a small transverse incision (2 to 3 cm) is made in the midline of the lower neck in the suprasternal notch. The pretracheal fascial plane is dissected bluntly and the mediastinoscope inserted toward the carina. An alternative procedure is a parasternal (or anterior) mediastinoscopy with a small incision made through the interchondral space or the space of the excised second costal cartilage.

Morbidity related to mediastinoscopy ranges from 2% to 8%. The most severe complication of mediastinoscopy is major hemorrhage, which may require emergent thoracotomy. Other potential complications include airway obstruction, compression of the innominate artery, pneumothorax, paresis of the recurrent laryngeal, phrenic nerve injury, esophageal injury, chylothorax, and air embolism.[170]

Anesthetic Management

For patients undergoing cervical mediastinoscopy, the chest radiograph and CT scan should be reviewed for the presence of a mass that might obstruct the airway during the preoperative evaluation. It is possible to perform mediastinoscopy (particularly anterior mediastinoscopy) with local anesthesia. This may be an option with an anterior mediastinal mass in a cooperative adult with a compromised airway. However, patient coughing or movement could result in surgical complications. The majority of these patients require general anesthesia with placement of an SLT. An arterial line is not necessarily used in these cases. However, it is mandatory to monitor the pulse in the right arm (pulse oximeter on the right hand, arterial line, or anesthesiologist's finger) because compression of the innominate artery by the mediastinoscope may occur and the surgeon usually is not aware that this is happening. The innominate artery supplies blood not only to the right arm but also to the right common carotid. Patients who do not have good cerebral collateral circulation (it is generally not possible to predict who these patients are) are at risk for cerebrovascular ischemia with innominate compression. A noninvasive blood pressure cuff is placed on the left arm to confirm the correct systolic pressure in case of suspected innominate compression.

Mild mediastinal hemorrhage may respond to conservative measures: the patient can be placed in the head-up position, the systolic pressure kept in the 90s, and tamponading the wound with surgical sponges. However, massive hemorrhage requires an emergent sternotomy or thoracotomy to stop the bleeding (Box 66-10). A bronchial blocker can be passed through the lumen of the existing lung isolation device if lung isolation is required because it is often difficult to change to a DLT while the surgeon is tamponading the wound. An arterial line should be placed (if it was not placed previously) to measure arterial blood pressure. If hemorrhage originates from a tear in the superior vena cava, volume replacement and drug treatment may be lost into the surgical field unless they are administered through a peripheral IV catheter placed in the lower extremity.

BOX 66-10 *Anesthetic Management of Mediastinoscopy Hemorrhage*

1. Stop surgery and pack the wound. There is a serious risk that the patient will approach the point of hemodynamic collapse if the surgery-anesthesia team does not realize soon enough that there is a problem.
2. Begin the resuscitation and call for help, both anesthetic and surgical.
3. Obtain large-bore vascular access in the lower limbs.
4. Place an arterial line (if not placed at induction).
5. Prepare for massive hemorrhage with blood warmers and rapid infusers.
6. Obtain cross-matched blood in the operating room.
7. Place a double-lumen tube or bronchial blocker if the surgeon believes that thoracotomy is a possibility.
8. Once the patient is stabilized and all preparations are made, the surgeon can reexplore the cervical incision.
9. Convert to sternotomy or thoracotomy if indicated.

Pneumothorax is an infrequent complication of mediastinoscopy. Pneumothorax that occurs intraoperatively (as evidenced by increased peak inspiratory pressure, tracheal shift, distant breath sounds, hypotension, and cyanosis) requires immediate treatment by chest tube decompression. All patients must have a chest radiograph taken in the postanesthesia care unit after mediastinoscopy to rule out pneumothorax.

When mediastinoscopy causes injury to the recurrent laryngeal nerve, it can be permanent in approximately 50% of the cases. If injury to the recurrent laryngeal nerve is suspected, the vocal cords should be visualized while the patient is spontaneously breathing. If the vocal cords do not move or are in a midline position, consideration has to be given to the problem of postoperative laryngeal obstruction.

During mediastinoscopy, the tip of the mediastinoscope is located intrathoracically and therefore it is directly exposed to pleural pressure. A venous air embolus can occur if venous bleeding occurs and patients are breathing spontaneously because of the development of negative intrathoracic pressure during inspiration. Autonomic reflexes may result from compression or stretching of the trachea, vagus nerve, or great vessels. With an uncomplicated mediastinoscopy, the patient can be extubated in the operating room and discharged home the same day.

ENDOBRONCHIAL ULTRASOUND–GUIDED BIOPSY

Various alternative techniques are available for obtaining pathology specimens from the mediastinal lymph nodes. These include CT-guided percutaneous needle aspiration, conventional bronchoscopy with transbronchial needle aspiration, and endobronchial ultrasound–guided biopsy. Endobronchial ultrasonography (EBUS) using a radial probe through a working channel of the flexible fiberoptic bronchoscope can be used to identify mediastinal and hilar lymph nodes.[171] Under direct EBUS

TABLE 66-10 COMPARISON OF SURGICAL APPROACHES FOR PULMONARY RESECTIONS

Incision	Pro	Con
Posterolateral thoracotomy	Excellent exposure to entire operative hemithorax	Postoperative pain with or without respiratory dysfunction (short and long term)
Lateral muscle-sparing thoracotomy	Decreased postoperative pain	Increased incidence wound seromas
Anterolateral thoracotomy	Better access for laparotomy, resuscitation, or contralateral thoracotomy, especially in trauma	Limited access to posterior thorax
Axillary thoracotomy	Decreased pain Adequate access for first rib resection, sympathectomy, apical blebs, or bullae	Limited exposure
Sternotomy	Decreased pain Bilateral access	Decreased exposure of left lower lobe and posterior thoracic structures
Transsternal bilateral thoracotomy ("clamshell")	Good exposure for bilateral lung transplantation	Postoperative pain and chest wall dysfunction
Video-assisted thoracoscopic surgery or robotic surgery	Less postoperative pain and respiratory dysfunction	Technically difficult with central tumors and chest wall adhesions

guidance with fine-needle aspiration for mediastinal staging, an ultrasound puncture bronchoscope can be used to assist with the safe and accurate diagnostic interventional bronchoscopy of the mediastinal and hilar lymph nodes. Management of these patients is often done at a satellite location, either in the bronchoscopy facility or a CT suite. In general, these patients are managed with topical anesthesia (aerosolized lidocaine) and conscious sedation (e.g., fentanyl and/or midazolam). EBUS may replace mediastinoscopy as the standard method of staging lung cancer before resection.

PULMONARY SURGERY

Any given pulmonary resection can be accomplished by a variety of different surgical approaches. The approach used in an individual case will depend on the interaction of several factors that include the site and pathology of the lesion(s) and the training and experience of the surgical team. Common thoracic surgical approaches and their generally accepted advantages and disadvantages are listed in Table 66-10.

MINIMALLY INVASIVE THORACOSCOPIC SURGERY

VATS is the procedure of choice for the diagnosis and management of diseases of the pleura, nondiagnosed peripheral pulmonary nodules, and interstitial lung disease. Since the start of the modern era of thoracoscopic surgery in the early 1990s, VATS has been proposed as a less invasive approach than open procedures. Today it is a well-accepted and established procedure and has become the first-choice technique for lung biopsies, pleurectomies, sympathectomies, and other various pulmonary disorders.[172]

In addition, VATS may be used in a variety of other surgical procedures. Some centers routinely perform the majority of lobectomies under VATS. The outcomes for VATS lobectomy in patients with limited respiratory reserve seem superior to that for open thoracotomy. The spirometry threshold for increased risk for VATS seems to be a ppoFEV_1 of 30% versus 40% for open thoracotomy (Fig. 66-40); however, it was not possible to define a threshold for ppo$D_L$co.[173] Other surgeries, such as spinal fusion and scoliosis, have been performed with VATS. The advantage of VATS, when compared with open thoracotomy, include: (1) reduced hospital length of stay, (2) less blood loss if no mishaps occur, (3) less pain, (4) improvement in pulmonary function when compared with open thoracotomy,[174] (5) early patient mobilization with early recovery and rapid return to work and daily activities, and (6) less inflammatory reaction, as measured by cytokine response in patients undergoing VATS lobectomy compared with open thoracotomy.[175]

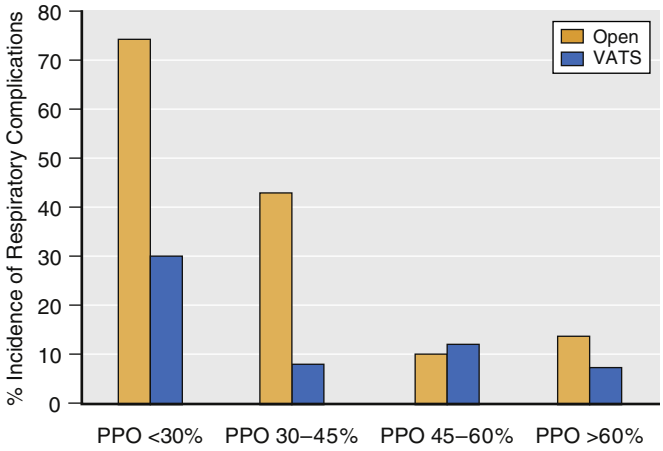

Figure 66-40. Incidence of major postoperative respiratory complications after lobectomy compared with the predicted postoperative (ppo) FEV_1% for open thoracotomy versus VATS. The threshold for increased risk appears to be increased only if the ppoFEV_1 is <30% for VATS. *(Based on data from Kaseda S, Aoki T, Hangai N, et al. Better pulmonary function and prognosis with video-assisted thoracic surgery than with thoracotomy,* Ann Thorac Surg *70:1644, 2000.)*

VATS lobectomy has been demonstrated to be a safe and effective procedure to treat early-stage NSCLC.[176] Thoracoscopic lobectomy is performed with a limited number of ports (1-3) and an access incision of approximately 5 cm in length.[177] The advantage of the VATS

Figure 66-41. Robotic surgery. The operating surgeon is on the far left, seated at the robot console. Note the limited access to the patient for the anesthesiologist after the robot has been docked.

BOX 66-11 *Anesthetic Considerations for Robotic Thoracic Surgery*

- A protocol for rapid emergency undocking (<60 s) of the robot must be developed and practiced in advance.
- Limit access to the patient. The position of lung isolation device needs to be confirmed before docking the robot.
- Extensions to monitoring lines and anesthesia circuit may be required.
- There is an increased need for intrathoracic CO_2 insufflation with possible venous return and hemodynamic compromise.
- Take precautions so that the operating room table cannot be moved while the robot is docked.
- Potentially prolonged procedures therefore increase risk of positional neuropathies; fluid restriction advisable.

technique is that the ribs are not spread open. VATS procedures are commonly performed in the lateral decubitus position; however, bilateral VATS procedures, such as bilateral wedge resections or lung volume reduction, can be performed in the supine position.

Robotic thoracic surgery has been suggested as the logical advancement of VATS because of the perceived better three-dimensional vision and increased range of motion in the chest for the surgeon with robotic techniques (Fig. 66-41).[178] Important points in anesthetic management are outlined in Box 66-11.

ANESTHETIC TECHNIQUE

Thoracoscopic surgery can be performed under local, regional, or general anesthesia with OLV or TLV.[179] For minor diagnostic procedures, VATS can be done in the awake patient. Intercostal nerve blocks performed at the level of the incision and two interspaces above and below provide adequate analgesia. Partial collapse of the lung on the side of surgery occurs when air enters the pleural cavity. When using local anesthesia with the patient awake, it is hazardous to insufflate gases under pressure into the hemithorax in an attempt to increase visualization of the pleural space. Although many patients suffer from advanced pulmonary disease, changes in PaO_2, $PaCO_2$, and cardiac rhythm are usually minimal during the procedure when it is performed under local anesthesia and the patient is breathing spontaneously.[180] However, it is recommended that a high FiO_2 is delivered via a facemask to overcome the shunt because of the loss in lung volume caused by the unavoidable pneumothorax.

For most invasive procedures, VATS is performed under general anesthesia with a DLT or a bronchial blocker to achieve OLV. If the procedure is short in duration and the lung needs to be deflated for only a brief period, blood gases are not routinely monitored during the procedure. However, for patients undergoing prolonged VATS procedures such as lobectomy or for patients with marginal pulmonary status, an arterial line and measurement of arterial blood gases is required. Paravertebral blocks have been used with a single dose of local anesthetic and have been shown to reduce pain after thoracoscopic surgery for 6 hours.[181]

Anesthetic complications are rare during this procedure, although it is possible that any structure that the surgeon has to manipulate may be damaged. The anesthesiologist needs to be aware of the potential for conversion to open thoracotomy if massive bleeding ensues or if the surgeon is unable to localize the lung nodule to be biopsied. The majority of thoracoscopic surgery requires placement of a chest tube postoperatively. It is important to have a functional chest tube with underwater seal drainage so that extubation can be performed safely.

LOBECTOMY

Lobectomy is the standard operation for the management of lung cancer because local recurrence of the tumor is reduced compared with lesser resections. Lobectomy is commonly performed via open thoracotomy or VATS. Sometimes, if the clinical staging of the lung cancer is advanced, an elective lobectomy is converted to a bilobectomy (right lung) or pneumonectomy during the operation. Although a posterolateral thoracotomy is the classic incision for lobectomies, anterolateral and muscle-sparing lateral incisions have also been used.

Postoperative analgesia is commonly performed with TEA or paravertebral analgesia (see Postoperative Analgesia later in the chapter). An arterial line for management of arterial blood gases and measurement of systemic blood pressure is used in all patients requiring an open thoracotomy or major VATS surgery. In addition, a large-bore IV catheter should be placed to facilitate rapid transfusion if necessary. Patients undergoing a lobectomy must be kept normothermic and normotensive and have an acceptable PaO_2 and oxygen saturation, particularly during OLV. Patients should have a thermal blanket covering the lower extremities to prevent hypothermia and its deleterious effects during HPV. After the lobe and blood vessels have been dissected, a test maneuver is performed with the surgeon clamping the surgical bronchus to confirm that the specific lobe is extirpated. This maneuver is accomplished by unclamping the limb of the DLT connector of the respective side, or in the case of a bronchial blocker, by deflating the blocker balloon, and reexpanding the lung with manual ventilation. During

VATS lobectomy, because of the interference to the surgical field caused by reinflating the residual lobe, the anesthesiologist may be asked to fiberoptically inspect the bronchial tree to confirm patency of the bronchus of the noninvolved lobe(s). Once the lobectomy has been performed, the bronchial stump is usually tested with 30 cm H_2O positive pressure in the anesthetic circuit to detect the presence of air leaks. A patient undergoing an uncomplicated lobectomy can usually be extubated in the operating room provided preoperative respiratory function is adequate (see Preoperative Assessment earlier in the chapter) and the patient is alert, warm, and comfortable ("AWaC").

Pancoast tumors are carcinomas of the superior sulcus of the lung and can invade and compress local structures including the lower brachial plexus, subclavian blood vessels, stellate ganglion (causing Horner syndrome), and vertebrae. Lobectomy may require a two-stage procedure with an initial operation for posterior instrumentation/stabilization of the spine. During lobectomy, extensive chest wall resection may be required and massive transfusion is a possibility. Peripheral lines and monitoring should be in the contralateral arm to accommodate the frequent compression of the ipsilateral vessels during surgery.

SLEEVE LOBECTOMY

Bronchial sleeve resections are performed for neoplasms or benign strictures. Bronchogenic carcinoma is the most frequent indication for a sleeve lobectomy, followed by carcinoid tumors, endobronchial metastases, primary airway tumors, and bronchial adenomas. Sleeve lobectomy involving parenchyma-sparing techniques in patients with a limited pulmonary reserve, is an alternative procedure for patients who cannot tolerate a pneumonectomy. The sleeve technique involves mainstem bronchial resection without parenchymal involvement and possibly resection of pulmonary arteries to avoid pneumonectomy (Fig. 66-42).

Patients undergoing sleeve lobectomy require lung isolation with a contralateral DLT or endobronchial tube (i.e., use a right-sided DLT for a left sleeve lobectomy). High-frequency jet ventilation can be used for resections done close to the tracheal carina. For a sleeve lobectomy involving resectioning of vessels, heparinization is necessary. In these cases, thoracic epidural catheters should not be manipulated for 24 hours after heparin administration. During pulmonary arterioplasty, uncontrollable bleeding may occur. For this reason, large-bore intravenous catheters should be used. Patients undergoing sleeve lobectomy are usually extubated in the operating room before transfer to the postanesthesia recovery room. Immediate and long-term survival is better after sleeve lobectomy compared with right pneumonectomy for comparable stages of right upper lobe cancer.[182]

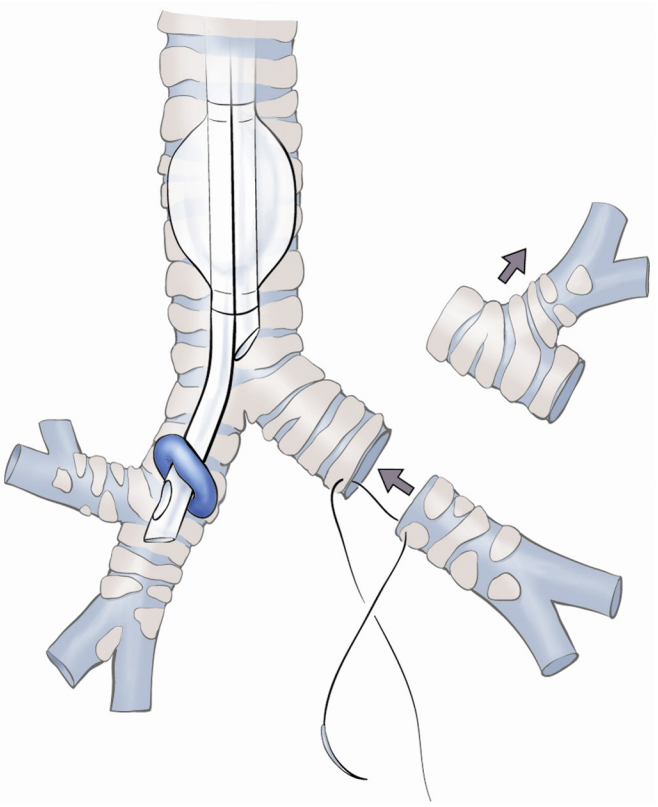

Figure 66-42. Diagram of the surgical procedure for a left upper sleeve lobectomy. Airway management is done with a right-sided double-lumen endobronchial tube. It will not be possible to position an endobronchial tube or bronchial blocker in the ipsilateral mainstem bronchus during this procedure.

PNEUMONECTOMY

Complete removal of the lung is required when a lobectomy or its modifications is not adequate to remove the local disease and/or ipsilateral lymph node metastases. Atelectasis and pneumonia occur after pneumonectomy as they do after lobectomy, but they may be less of a problem because of the absence of residual parenchymal dysfunction on the operative side. However, the mortality rate after pneumonectomy exceeds that for lobectomy because of postoperative cardiac complications and acute lung injury. The overall operative mortality for the first 30 days after pneumonectomy ranges from 5% to 13% and correlates inversely with the surgical case volume.[183] The risk of complications increases fivefold in patients aged 65 and older.[184]

Thoracotomy for pneumonectomy is usually performed through a standard posterolateral incision. After all vessels are stapled, stapling of the bronchus occurs and the entire lung is taken from the chest. A test for air leaks is generally performed at this point and reconstruction of the bronchial stump is completed. The bronchial stump should be as short as possible to prevent a pocket for the collection of secretions.

There is no consensus among thoracic surgeons on the best method of management of the postpneumonectomy space. If suction is applied to an empty hemithorax or a chest drain is connected to a standard underwater-seal system, it may cause a mediastinal shift with hemodynamic collapse. Some thoracic surgeons do not place a chest drain after a pneumonectomy; some thoracic surgeons prefer to use a temporary drainage catheter to add or remove air. The removal of air, ranging from 0.75 to

1.5 L, is necessary to empty the chest and to keep the mediastinum and the trachea in the midline ("balanced"). Some surgeons place a specifically designed postpneumonectomy chest drainage system with both high- and low-pressure underwater relief valves to balance the mediastinum.[185] A chest radiograph is mandatory after the patient arrives in the postanesthesia care unit or in the surgical intensive care unit to assess the mediastinal shift.

The patient scheduled to undergo a pneumonectomy is considered at high risk for perioperative morbidity and mortality. The placement of large-bore intravenous lines is necessary in case blood products need to be administered. An invasive arterial line is placed for measurement of beat-to-beat blood pressure and to monitor arterial blood gases. A CVP catheter is recommended to help guide intravascular fluid management and to administer vasopressors if needed, specifically in the postoperative period.

A major lung resection, such as pneumonectomy, decreases ventilatory function and has significant effects on right ventricular function.[186] Immediately after pneumonectomy, the right ventricle may dilate and the right ventricular function decreases. Increased right ventricular afterload is caused by an increase in pulmonary artery pressure and pulmonary vascular resistance. This is considered to be one of the main causes of right ventricular dysfunction after a major lung resection.

Management of lung isolation in a pneumonectomy patient can be achieved with a DLT, bronchial blocker, or SLT. When using a DLT for a pneumonectomy patient, it is optimal to use a device that does not interfere with the ipsilateral airway (i.e., for a right pneumonectomy use a left-sided DLT). If a left-sided DLT or bronchial blocker is used for a left pneumonectomy, it must be withdrawn before stapling the bronchus to avoid accidental inclusion into the suture line.

Specific areas of concern in the management of the patient undergoing pneumonectomy include: (1) fluid management, (2) intraoperative tidal volume, and (3) acute lung injury post surgery. Fluid administration after major lung resection continues to be an issue. In a retrospective report by Zeldin and associates,[187] the risk factors that were identified for the development of acute lung injury ("postpneumonectomy pulmonary edema") were a right-sided pneumonectomy, increased perioperative IV fluid administration, and increased urine output in the postoperative period. A more recent study by Licker and colleagues has shown that the excessive administration of intravenous fluids in thoracic surgical patients (more than 3 L in the first 24 hours) is an independent risk related to an acute lung injury.[188] There is reasonable clinical evidence that excessive fluid administration is associated with the development of an acute lung injury, which has a high mortality rate after pneumonectomy. Consequently, pneumonectomy patients should have restricted intraoperative fluid administration while preserving renal function. Some cases may require the use of inotropes/vasopressors to maintain hemodynamic stability while restricting fluids (see Box 66-8).

Respiratory failure is a leading cause of postoperative morbidity and mortality in patients undergoing pneumonectomy. A retrospective report[189] involving 170 pneumonectomy patients showed that patients who received median tidal volumes greater than 8 mL/kg had a greater risk of respiratory failure in the postoperative period after pneumonectomy. In contrast, patients who received tidal volumes less than 6 mL/kg were at lower risk for respiratory failure. Schilling and colleagues[190] have shown that a tidal volume of 5 mL/kg during OLV significantly reduces the inflammatory response to alveolar cytokines. Considering these factors, it is prudent to use lower tidal volumes (i.e., 5-6 mL/kg ideal body weight) in the pneumonectomy patient and limit peak and plateau inspiratory pressures (i.e., <35 and 25 cm H_2O, respectively) during OLV.

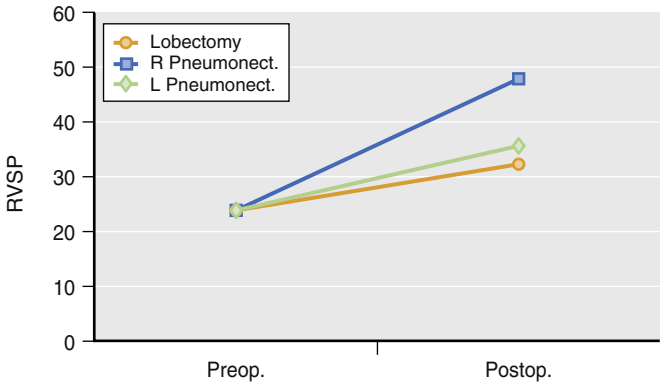

Figure 66-43. Comparison of right ventricular systolic pressure (RVSP) measured by echocardiography in patients before (Preop.) and at 6 months after (Postop.) pulmonary resections. *L Pneumonect.*, left pneumonectomy; *R Pneumonect.*, right pneumonectomy. Note the elevated RVSP, and therefore pulmonary artery pressure, after a right pneumonectomy. *(Based on data from Iglesias M, Martinez E, Badia JR, Macchiarini P: Extrapulmonary ventilation for unresponsive severe acute respiratory distress syndrome after pulmonary resection,* Ann Thorac Surg *85: 237, 2008.)*

The incidence of acute lung injury (postpneumonectomy pulmonary edema) after pneumonectomy is only 4%. However, the mortality rate is 30% to 50%. The etiology seems multifactorial. One study[190] has identified four independent risk factors for acute lung injury after pulmonary resection: (1) pneumonectomy; (2) excessive administration of fluids in the intraoperative period; (3) high intraoperative ventilatory pressure index (combined airway pressure and time); and (4) preoperative alcohol abuse. The incidence of an acute lung injury is greater for a right- versus a left-sided pneumonectomy. This may be related to the higher postoperative pulmonary artery pressures after a right versus a left pneumonectomy (Fig. 66-43).[191] Currently, only symptomatic management is appropriate for this lung injury. This includes fluid restrictions, diuretic administration, low ventilatory pressures and tidal volumes (if mechanical ventilation is used), and measures to decrease the pulmonary artery pressure. Extracorporeal techniques of ventilatory assist may be useful in managing this complication.[192]

EXTRAPLEURAL PNEUMONECTOMY

Extrapleural pneumonectomy is a therapeutic option for selected patients with malignant pleural mesothelioma.[193]

Significant improvement in survival has been achieved in patients who have an advanced malignant pleural mesothelioma with extrapleural pneumonectomy and high-dose radiotherapy in the postoperative period. Extrapleural pneumonectomy involves an extensive resection that may include lymph nodes, pericardium, diaphragm, parietal pleura, and the chest wall. The anesthetic management of the extrapleural pneumonectomy patient is characterized by significant loss of blood caused by chest wall vessel involvement. In these patients, it is recommended that a CVP catheter be used to guide intravascular fluid administration and ensure large-bore IV access. During tumor dissection, venous return to the heart may be compromised owing to multiple factors including blood loss, compression effect by the tumor in superior vena cava, or surgical causes. If there is an excessive loss of blood, it must be replaced to maintain an acceptable hematocrit level and the coagulation profile kept within normal limits. Because of extensive tumor resection and the potential for a pericardial resection in right-sided surgery, cardiac herniation or hemodynamic instability can appear postoperatively after the patient is turned from the lateral decubitus to the supine position. It is common to ventilate these patients for a short period postoperatively because of the extended duration of the surgery and the large fluid shifts. If a DLT is used intraoperatively, the DLT is usually replaced at the end of the case with an SLT.

SLEEVE PNEUMONECTOMY

Tumors involving the most proximal portions of the mainstem bronchus and the carina may require a sleeve pneumonectomy. These are most commonly performed for right-sided tumors and can usually be performed without cardiopulmonary bypass via a right thoracotomy. A long SLT can be advanced across into the left mainstem bronchus during the period of tracheo-bronchial anastomosis. High-frequency positive-pressure ventilation (HFPPV) has also been used for this procedure and the combined use of HFPPV and a DLT has been described.[194] Because the carina is surgically more accessible from the right side, left sleeve pneumonectomies are commonly performed as a two-stage operation. First is a left thoracotomy and pneumonectomy, and a right thoracotomy for the carinal excision follows. The complication and mortality rates are higher, and the 5-year survival (20%) is significantly lower than for other pulmonary resections. Postpneumonectomy pulmonary edema is particularly a problem after right sleeve pneumonectomy.

LIMITED PULMONARY RESECTIONS: SEGMENTECTOMY AND WEDGE RESECTION

A limited pulmonary resection is one in which less than a complete lobe is removed. The two procedures fitting this definition are *segmentectomy* and *wedge resection*. Segmentectomy is an anatomic pulmonary resection of the pulmonary artery, vein, bronchus, and parenchyma of a particular segment of the lung. Segmentectomy is usually performed as surgical therapy for patients with primary lung cancer and limited cardiorespiratory reserves. In contrast, a wedge resection is a nonanatomic removal of a portion of the lung parenchyma with a 1.5- to 2.0-cm margin and can be accomplished by open thoracotomy or VATS. Wedge resections are most commonly performed for diagnosis of lung lesions with unknown histology or for palliation in patients with metastatic lesions in the lungs from distant primary tumors. Lung cancers that are considered for limited resection are usually smaller than 3 cm and are located in the periphery of the lung with regional lymph nodes free of metastatic cancer.

A group of patients considered for limited pulmonary resection are those who develop a new primary lesion after a previous lobectomy or pneumonectomy. The patient with compromised lung function presents a greater risk in the intraoperative period (hypoxemia during OLV or prolonged intubation after surgery). Cerfolio and associates[195] reported that lung cancer patients with compromised pulmonary function can safely undergo limited pulmonary resection if selected appropriately. Segmentectomies and wedge resections can be performed with any of the standard thoracotomy or VATS incisions. Segments that are most commonly resected are in the upper lobes or the superior segments of the lower lobes.

Anesthetic technique and monitoring are essentially the same as for larger pulmonary resections. To facilitate surgical exposure and achieve OLV, it is necessary to use either a DLT or a bronchial blocker. If the patient had a previous contralateral lobectomy or a pneumonectomy, selective lobar collapse with the use of a bronchial blocker will facilitate surgical exposure while maintaining oxygenation. In selected cases, the combined use of a DLT and a bronchial blocker will allow selective lobar collapse/ventilation in the ipsilateral lung.[196] It is very important to use low tidal volumes (i.e., 3-5 mL/kg) during selective lobar ventilation, particularly in patients with previous pneumonectomy to prevent overinflation in the remaining lobes.

Segmentectomy plays a significant role in the management of patients with a second primary lung cancer. Many of these patients have previously undergone thoracic surgery, including previous lobectomy or pneumonectomy; therefore the potential for increased intraoperative bleeding is always a risk. In addition, because many of these patients have compromised lung function, early extubation may not be feasible. A common complication after surgery is an air leak. Chest tubes are placed to maximize postoperative expansion and minimize space complications. Suction and underwater-seal chest drainage is used in the postoperative period.

ANESTHETIC MANAGEMENT FOR SPECIFIC SURGICAL PROCEDURES

ESOPHAGEAL SURGERY

Esophageal surgery is performed for both malignant and benign disease and may be curative or palliative. General

considerations that apply to almost all esophageal surgery patients include an increased risk of aspiration caused by esophageal dysfunction and the possibility of malnutrition.

Esophagectomy

Esophagectomy is a palliative and potentially curative treatment for esophageal cancer and may occasionally be required for some benign obstructive lesions that do not respond to conservative therapy. It is a major surgical procedure and is associated with high morbidity and mortality rates (10%-15%). There is an inverse correlation between perioperative mortality and surgical volume, and the cure rate of esophageal cancer with esophagectomy is between 10% and 50%. There are multiple surgical procedures for esophageal cancer (Table 66-11) that combine some or all of three fundamental approaches: (1) a transthoracic approach, (2) a transhiatal approach, and (3) minimally invasive surgery (laparoscopic/thoracoscopic or robotic esophagectomy).[197] The incidence of respiratory complications has been reported to be between 18% and 26% for both the transthoracic and transhiatal esophagectomy approaches.[198] One study showed that the development of acute respiratory distress syndrome occurred in 14.5% of patients and acute lung injury occurred in 24%.[199] Complications associated with the gastroesophageal anastomosis are: anastomotic leakage/dehiscence (5%-26%) and stenosis (12%-40%). Outcomes are improved with a multimodal anesthetic management protocol using fluid restriction, early extubation, thoracic epidural analgesia, and vasopressor/inotrope infusions to support blood pressure.[200] Hypotension decreases the blood flow to the esophagogastric anastomosis. The use of vasopressors or inotropes, in normovolemic patients, restores the systemic pressure and the anastomotic blood flow.[201] Fluid management for esophageal surgery is essentially the same as for pulmonary resection surgery.

Transthoracic Approach. Transthoracic esophagectomy is commonly a two-phase procedure. The first phase involves a laparotomy performed with the patient in the supine position and the creation of a neoesophagus tube using the stomach. The second phase involves a right-sided thoracotomy in the left lateral position and esophageal reconstruction through the thoracic route. Some surgeons may perform this procedure through an extended left thoracoabdominal incision.

The anesthetic management for these patients includes the use of standard monitors, an invasive arterial line, and a CVP catheter to accommodate the large fluid shifts. Access to the right internal jugular is not a problem, but there is always the possibility of a surgical esophageal anastomosis in the left neck contraindicating access to the left internal jugular. A thoracic epidural catheter is usually placed to provide postoperative analgesia. Because of the wide number of dermatomes that must be covered for both incisions by the epidural infusion, it is best to use hydrophilic opioids (such as hydromorphone) in combination with local anesthetics in preference to lipophilic opioids. Most patients with an esophageal carcinoma have gastric reflux; for this reason, precautions (including a rapid-sequence induction with cricoid pressure) should be taken to protect the airway against aspiration.

During the second phase (right thoracotomy), a left-sided DLT or a right-sided bronchial blocker is required to facilitate lung collapse. Because esophagectomy requires a prolonged period of OLV, this procedure is marked by an important inflammatory response. Michelet and colleagues[202] have shown that the use of protective ventilatory strategies during OLV decreases the proinflammatory systemic response. This decreased response can be achieved by delivering 5 mL/kg of tidal volume and a PEEP of 5 cm H_2O to the dependent lung, instead of the 9 mL/kg of tidal volume that is conventionally used during esophagectomy.

TABLE 66-11 **SURGICAL APPROACHES FOR ESOPHAGECTOMY AND ESOPHAGOGASTRECTOMY**

Surgery	Incisions	Anesthetic Considerations
Laparotomy and right thoracotomy ("Ivor Lewis")	Two incisions: upper abdominal midline, right thoracotomy at ≈5th or 6th intercostal space	One-lung ventilation necessary Repositioning of patient intraoperatively from supine to right lateral
Transhiatal ("Orringer") (lower-third lesions; may be used for mid-third in some centers)	Two incisions: upper abdominal midline and left neck	Hemodynamic instability from cardiac compression during blunt intrathoracic dissection Possibility of occult perforation of tracheobronchial tree during blunt dissection (leave endotracheal tube uncut in case of need to advance into bronchus) No vascular access in left neck
Left thoracoabdominal (lower esophageal lesions only)	One incision: left lateral thoracotomy extended to left upper lateral abdominal	One-lung ventilation desirable
Combined chest, abdominal, and neck ("three hole"; upper and mid esophageal lesions)	Three incisions: right thoracotomy, laparotomy, left neck	One-lung ventilation necessary Repositioning lateral to supine intraoperatively No vascular access in left neck
Thoracoscopy plus laparotomy or laparoscopy	One or two incisions plus video port access Thoracoscopy to avoid blunt dissection in chest; neck incision at end	One-lung ventilation necessary Potentially prolonged surgery

Manipulation of the esophagus during thoracotomy may compromise venous return, which can cause hypotensive episodes. Early extubation in the operating room is encouraged if the patient meets the standard criteria for extubation. If extubation is not possible, the DLT should be replaced with an SLT and mechanical ventilation used in the postoperative period.

Transhiatal Approach. Airway management is done with an SLT. Apart from this, anesthetic management is essentially the same as for a transthoracic approach. Of special concern is that the blunt/blind manual dissection of the thoracic esophagus by the surgeon through the hiatus during this approach is often associated with cardiac compression and sudden severe hypotension. In addition, this blind dissection can cause vascular or distal airway injuries if the tumor is adherent.[203] It is good practice to not cut the endotracheal tube for this procedure in case of surgical perforation of the trachea or bronchus necessitating advancement of the endotracheal tube into a mainstem bronchus for emergent OLV.

Minimally Invasive Approach. Minimally invasive esophagectomy involves the use of laparoscopic, thoracoscopic, or robotic surgical approaches. For a laparoscopic approach, distention of the peritoneum may produce hemodynamic changes because of the intragastric pressure generated by carbon dioxide insufflation. In these cases, it is important to adjust ventilatory parameters to achieve an optimal $Paco_2$. For the thoracoscopic approach, a left-sided DLT or a bronchial blocker is required. During robotic surgery, the use of a lung isolation device is required to achieve OLV. Special considerations for robotic surgery include protecting the patients against any injury related to the robot and not moving the operating room table while the robot is being used. The thoracoscopic-assisted esophagectomy has several advantages including less blood loss, less pain, and a shorter length of hospitalization. This method does, however, require a prolonged duration of surgery.

All patients undergoing esophagectomy require a nasogastric tube, which must be well-secured at the end of the operation. Respiratory complications, including the development of an acute lung injury, may be present after an esophagectomy. Intrathoracic anastomotic leakage is a feared major complication after esophageal surgery and carries a high mortality rate of 4% to 30%.[204] To treat this potential complication, nasogastric decompression and nutritional support should be used. Severe leakage usually occurs in the early postoperative period as a consequence of gastric necrosis, and it may present with respiratory symptoms and signs of shock. Even though there is a very high mortality rate, prompt surgical intervention is recommended. Patients older than 80 years have an increased risk of mortality after esophagectomy, independent of comorbidity.[205]

Esophageal Surgery for Benign Disease

Hiatal Hernia. Although most patients with gastroesophageal reflux have a hiatal hernia, most patients with a hiatal hernia do not have significant reflux.[206] Patients with heartburn have a lowered barrier pressure and may be at increased risk for regurgitation of gastric contents. Two types of hiatal hernia have been described. Type I hernias, also called "sliding hernias," make up approximately 90% of esophageal hiatal hernias. In this type, the esophagogastric junction and fundus of the stomach have herniated axially through the esophageal hiatus into the thorax (Fig. 66-44). The term *sliding* refers to the presence of a sac of parietal peritoneum. The lower esophageal sphincter is cephalad to the diaphragm and may not respond appropriately to increased abdominal pressure. Thus a reduced barrier pressure during coughing or breathing leads to regurgitation. The type II or "paraesophageal hiatal hernia," is characterized by portions of the stomach herniating into the thorax next to the esophagus. In the presence of a type II hernia, the esophagogastric junction is still located in the abdomen. The most common complications from type II hernias are blood loss, anemia, and gastric volvulus.

The goal of surgical repair of a sliding hernia is to obtain competence of the gastroesophageal junction. Because restoration of the normal anatomy is not always successful in preventing subsequent reflux, several antireflux operations have been developed, such as the Nissen fundoplication. Repair of a hiatal hernia can be performed via a thoracotomy or laparotomy, or minimally invasively.

Benign Esophageal Stricture. Chronic reflux of acidic gastric contents can lead to ulceration, inflammation, and eventually stricture of the esophagus. The pathologic

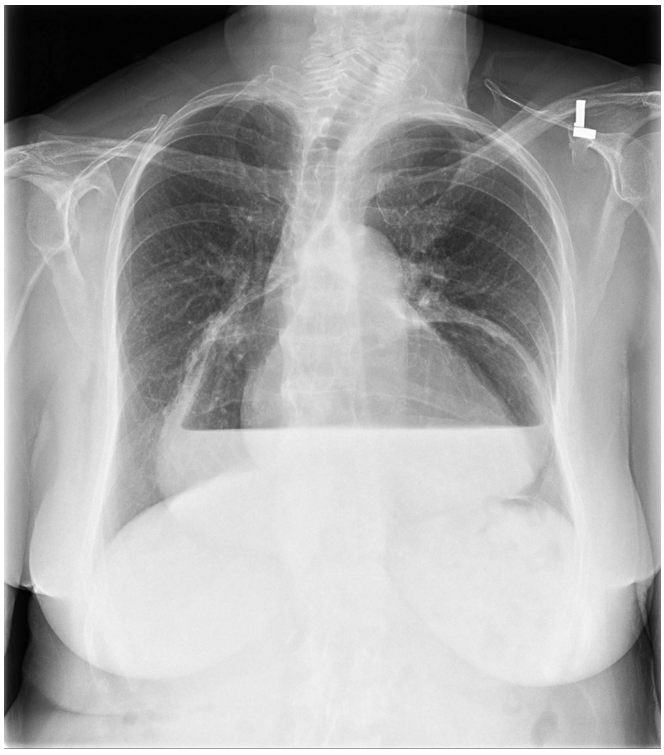

Figure 66-44. Chest radiograph of a patient with a hiatal hernia and a dilated intrathoracic stomach, scheduled for hiatal hernia repair via a left thoracotomy. An air-fluid level can be seen in the stomach behind the heart. These patients are at high risk for aspiration on induction of anesthesia.

changes are reversible if the acidic gastric contents cease their contact with the esophageal mucosa. Surgery may be necessary if medical treatment and dilatations are inadequate. There are two types of surgical repair, both of which are usually approached via a left thoracoabdominal incision. Gastroplasty after esophageal dilatation interposes the fundus of the stomach between the esophageal mucosa and the acidic milieu of the stomach. The remaining fundus may be sewn to the lower esophagus to create a valvelike effect. The second type of repair is resection of the stricture and the creation of a thoracic end-to-side esophagogastrostomy. Vagotomy and antrectomy are performed to eliminate stomach acidity, and a Roux-en-Y gastric drainage procedure is performed to prevent alkaline intestinal reflux.

Esophageal Perforation and Rupture. There are multiple causes of esophageal perforation, including foreign bodies, endoscopy, bougienage, traumatic tracheal intubation, gastric tubes, and oropharyngeal suctioning. Iatrogenic causes are the most common, with upper gastrointestinal endoscopy being the most frequent cause. A rupture is a burst injury often caused by uncoordinated vomiting, straining associated with weight-lifting, childbirth, defecation, and crush injuries to the chest and abdomen. The rupture is usually located within 2 cm of the gastroesophageal junction on the left side. Rupture is the result of a sudden increase in abdominal pressure with a relaxed lower esophageal sphincter and an obstructed esophageal inlet. In contrast to a perforation, in the presence of a rupture, the stomach contents enter the mediastinum under high pressure and the patient becomes symptomatic much more abruptly.

In addition to chest and/or back pain, patients with intrathoracic esophageal perforation or rupture may develop hypotension, diaphoresis, tachypnea, cyanosis, emphysema, and hydrothorax or hydropneumothorax.[207] Radiologic studies may reveal subcutaneous emphysema, pneumomediastinum, widening of the mediastinum, pleural effusion, and pneumoperitoneium. Minor perforations can in some cases be managed conservatively. Major injuries will rapidly develop mediastinitis and sepsis if not treated surgically, so repair and drainage is an emergency procedure usually performed via a left or right thoracotomy.

Achalasia. Achalasia is a disorder in which there is a lack of peristalsis of the esophagus and a failure of the lower esophageal sphincter to relax in response to swallowing. Clinically, the patients have esophageal distention that may lead to chronic regurgitation and aspiration. The goal of treatment is to alleviate the distal obstruction. This can be done by either esophageal dilatation or by surgery. Dilatation, which carries with it the risk of perforation, can be achieved by mechanical, hydrostatic, or pneumatic means. The surgical repair consists of a Heller myotomy, which is an incision through the circular muscle of the esophagogastric junction. The myotomy is often combined with a hiatal hernia repair to prevent subsequent reflux. This can be performed via thoracotomy, laparotomy, or laparoscopy.[208] The Dor operation is a modification of the Heller procedure in which a stent is inserted into the muscular defect created by the myotomy to prevent muscular reapposition and thus recurrent dysphagia.[209]

Esophagorespiratory Tract Fistula. Esophagorespiratory tract fistula in an adult is most often a result of malignancy. Sometimes the fistula is benign and may be caused by injury from a tracheal tube, trauma, or inflammation. Of the malignant fistulas, approximately 85% are secondary to esophageal cancer. In contrast to the pediatric patient with esophagorespiratory tract fistula, which usually connects the distal esophagus to the posterior tracheal wall, these fistulas may connect to any part of the respiratory tract.[210] In most cases, the fistula can be seen on esophagoscopy or bronchoscopy. In malignant cases, the goal of surgery is usually palliation. The technique of lung isolation will depend on the location of the fistula. One option in adults with a distal tracheal fistula is the use of bilateral small (5-6 mm ID) endobronchial tubes.[211]

Zenker Diverticulum. Zenker diverticulum is actually a diverticulum of the lower pharynx that arises from a weakness at the junction of the thyropharyngeus and cricopharyngeus muscles just proximal to the esophagus. It is commonly considered an esophageal lesion because of its proximity to the upper esophagus and because the underlying cause may be a failure of relaxation of the upper esophageal sphincter during swallowing. Early symptoms may be nonspecific such as dysphagia or complaints of food being stuck in the throat. As the diverticulum enlarges, patients describe noisy swallowing, regurgitation of undigested food, and coughing spells while supine. Recurrent aspiration and pneumonia may develop.

The major concern for anesthesia is the possibility of aspiration on induction of general anesthesia for excision of the diverticulum.[212] Even prolonged fasting does not ensure that the diverticulum will be empty. The best method to empty the diverticulum is to have the patient express and regurgitate the contents immediately before induction. Many of these patients will be used to doing this on a regular basis at home. Because the diverticulum orifice is almost always above the level of the cricoid cartilage, cricoid pressure during a rapid-sequence induction does not prevent aspiration and may contribute to aspiration by causing the sac to empty into the pharynx. Surgical excision is usually done through a lower left neck incision.

The safest method of managing the airway for these patients may be awake fiberoptic intubation. However, intubation has been managed without incident using a modified rapid-sequence induction without cricoid pressure and with the patient supine and in a head-up position of 20 to 30 degrees. Other considerations in these patients include the possibility of perforation of the diverticulum when passing an orogastric or nasogastic tube or an esophageal bougie.

ANESTHESIA FOR TRACHEAL RESECTION

Tracheal resection and reconstruction is indicated in patients who have a tracheal obstruction as a result of a tracheal tumor, previous tracheal trauma (most

commonly because of postintubation stenosis), congenital anomalies, vascular lesions, and tracheomalacia. For patients who have operable tumors, approximately 80% undergo segmental resection with primary anastomosis, 10% undergo segmental resection with prosthetic reconstruction, and the remaining 10% undergo placement of a T-tube stent.

Diagnostic studies are reviewed as part of the preoperative evaluation. The CT scan is a useful diagnostic tool to evaluate the degree, level, and length of the lesion. Bronchoscopy is one of the definitive diagnostic tests for tracheal obstruction. Bronchoscopy for a patient with tracheal stenosis should be carried out in the operating room where the surgical and anesthesia teams are present and ready to intervene should loss of airway occur. An advantage of rigid bronchoscopy over flexible bronchoscopy is that it can bypass the obstruction and provide a ventilation pathway if complete obstruction occurs. During surgery, all patients should have an invasive arterial catheter placed to facilitate measurement of arterial blood gases, as well as to measure arterial blood pressure. CVP catheters are only used if the patient requires cardiopulmonary bypass (CPB).

A variety of methods for providing adequate oxygenation and elimination of CO_2 have been used during tracheal resection. The different alternatives include (1) standard orotracheal intubation, (2) insertion of a sterile SLT into the opened trachea or bronchus distal to the area of resection, (3) high-frequency jet ventilation (HFJV) through the stenotic area, (4) high-frequency positive-pressure ventilation (HFPPV), and (5) the use of CPB.

Induction of anesthesia in patients with a compromised airway requires good communication between the surgical team and the anesthesiologist. The surgeon should always be in the operating room during induction and available to manage a surgical airway if this becomes necessary.[213] A rigid bronchoscope must be immediately available. The patient should be thoroughly preoxygenated with 100% oxygen before induction. The airways of patients with congenital or acquired tracheal stenosis are unlikely to collapse during induction of anesthesia. However, intratracheal masses may lead to airway obstruction with induction of anesthesia and should be managed similarly to anterior mediastinal masses (discussed later). One airway management technique is to begin the case with rigid bronchoscopy and tracheal dilation and then to pass an SLT through the stenosis. This tube is withdrawn into the proximal trachea once the distal trachea is opened and a second sterile SLT is placed into the distal trachea by the surgeon. Ventilation is done via a sterile anesthetic circuit passed across the drapes into the surgical field. With a low tracheal lesion, a right thoracotomy provides the optimal surgical exposure. A sterile SLT is used to provide ventilation to the lung distal to the resection. After the posterior anastomosis is completed, the endobronchial tube is removed and the original SLT is advanced past the site of resection (Fig. 66-45). This technique can also be used for carinal resection.

A third technique for airway management during tracheal resection includes HFJV through a small-bore endotracheal tube or catheter.[214] With this technique, a small-bore uncuffed catheter is placed through the stenotic area, and ventilation is accomplished by intermittently exposing the lung to a high flow of fresh gas through the catheter. Other techniques that have been used for oxygenation during distal airway resections include HFPPV, helium-oxygen mixtures, and CPB.

After the tracheal resection is completed, most patients are kept in a position of neck flexion to reduce tension on the suture line. Replacement of the SLT by an LMA for emergence facilitates bronchoscopy if required. A thick chin-sternum suture may be placed for several days to maintain neck flexion, or a cervical splint may be used.[215] A T-tube with the upper limb 0.5 to 1 cm above the vocal cords may be inserted at the end of surgery in cases where glottic edema is a concern, or for patients requiring

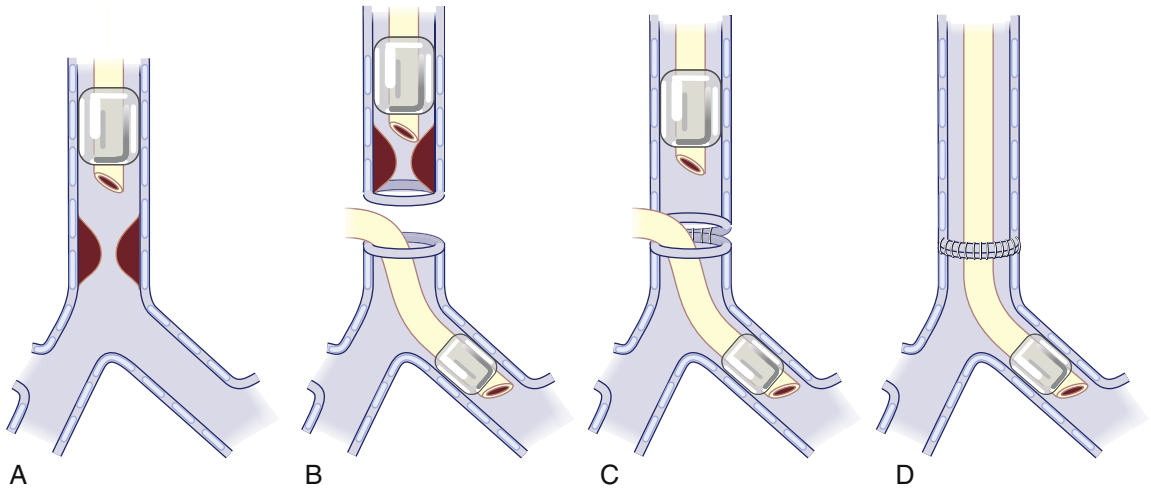

Figure 66-45. Airway management and surgical procedure for resection of a low tracheal lesion. **A,** Initial intubation above the lesion. **B,** Left endobronchial intubation distal to the lesion after the trachea has been opened. **C,** Placement of sutures for the posterior anastomosis. **D,** The endobronchial tube has been removed, and the original endotracheal tube has been advanced distal to the anterior anastomosis into an endobronchial position. *(Modified from Geffin B, Bland J, Grillo HC: Anesthetic management of tracheal resection and reconstruction,* Anesth Analg *48:884, 1969.)*

ventilatory support. If a tracheostomy is performed, it will be done distal to the anastomosis. Early extubation is highly desirable. If a patient requires reintubation, it should be performed with a flexible fiberoptic bronchoscope by advancing an SLT under direct vision over the bronchoscope and then placing it in the patient's trachea. The patient is kept in a head-up position to diminish swelling. Steroids may be useful in these cases to decrease airway edema.

One of the complications in the postoperative period is tetraplegia, with hyperflexion of the neck having been implicated as a potential cause. In these cases, it is necessary to cut the chin stitch. An infusion of propofol and remifentanil, with fiberoptic bronchoscopy guidance and full patient cooperation, can aid extubation.[216]

BRONCHIECTASIS/LUNG ABSCESS/ EMPYEMA

Bronchiectasis is a disease that causes localized, irreversible dilatation of part of the bronchial tree. Involved bronchi are inflamed and easily collapsible, resulting in airflow obstruction and impaired clearance of secretions. Bronchiectasis is associated with a wide range of disorders, but it usually results from necrotizing bacterial infections. Bronchiectasis may require surgery if it causes hemoptysis or recurrent pneumonia. An abscess is a nonanatomic area of liquefactive necrosis of the lung, often distal to an obstruction or after a bout of pneumonia (Fig. 66-46). An empyema is a collection of pus between the visceral and parietal pleural layers, often a complication of pneumonia or surgery. Empyema complicating lung resections occurs in 2% to 16% of cases and with a 40% increase in the associated perioperative mortality rate. Mortality further increases when the empyema is associated with a bronchopleural fistula. Surgical interventions for patients with empyema include: decortication (the method of choice when the underlying lung is unable to expand because of a thick inflammatory coat) or open-window thoracostomy (the ideal method for drainage of the pleural cavity to control septic symptoms in patients with postpulmonary resection empyema).[217] In less severe cases, tube drainage, antibiotic irrigation, and debridement may be sufficient.

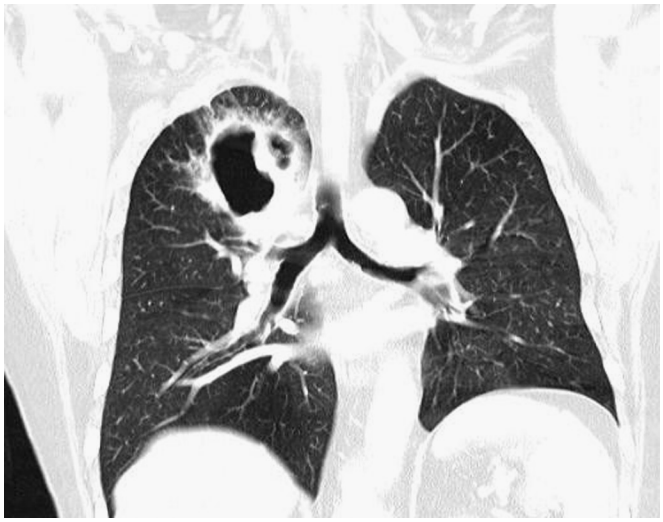

Figure 66-46. Computed tomographic scan of a patient with a lung abscess distal to an obstructing carcinoma of the right upper lobe. The diagnostic thick wall of the abscess and the air-fluid level can be appreciated in the right upper thorax. These patients are at risk for soiling of uncontaminated lung regions during repositioning for surgery from pus in the abscess. The optimal method of lung isolation is with a double-lumen endobronchial tube.

All of these infective indications for thoracic surgery are less common in the developed world since the introduction of antibiotics. Anesthetic considerations during surgery for these infective indications include the need for lung isolation to protect uninvolved lung regions from soiling by pus in the infected areas. The risk of soiling occurs if the patient is repositioned for surgery after induction of anesthesia before the lung is adequately isolated. Because of the inflammation, surgery is technically more difficult and there is a greater risk of massive hemorrhage.

Anesthetic Management

Some of these patients may present with sepsis at the time of surgery. In these patients, the placement of a thoracic epidural catheter is not recommended. They require lung isolation, preferably with a DLT. The DLT facilitates suctioning of debris and copious secretions that are present in the tracheobronchial tree. Patients undergoing a decortication may have massive blood loss. If the lung has been chronically collapsed, expansion should be done gradually to avoid the development of pulmonary edema upon reexpansion. Extubation in the operating room is encouraged if the patient meets the standard criteria for extubation.

BRONCHOPLEURAL FISTULA

A bronchopleural fistula may be caused by (1) rupture of a lung abscess, bronchus, bulla, cyst, or parenchymal tissue into the pleural space; (2) the erosion of a bronchus by carcinoma or chronic inflammatory disease; or (3) stump dehiscence of a bronchial suture line after pulmonary resection. Pneumonectomy patients have an incidence of bronchopleural fistula ranging from 2% to 11%,[218] with a mortality ranging from 5% to 70%.

The diagnosis of bronchopleural fistula is usually made clinically. After pneumonectomy, the diagnosis is based on the sudden onset of dyspnea, subcutaneous emphysema, contralateral deviation of the trachea, and a decrease of fluid level on serial radiographs of the chest (Fig. 66-47). In lobectomy patients, persistent air leak, purulent drainage, and expectoration of purulent material are usually diagnostic indicators of a bronchopleural fistula. When the fistula appears after removal of a chest tube, the diagnosis of bronchopleural fistula is made on the basis of fever, purulent sputum, and a new air-fluid level in the pleural cavity on the chest radiograph.

The diagnosis is confirmed by bronchoscopic examination. In addition, bronchography and sinograms of the fistula may be used to confirm the diagnosis. Other diagnostic methods include the injection of an indicator, such as methylene blue, into the pleural space and subsequent recovery of the indicator from sputum.

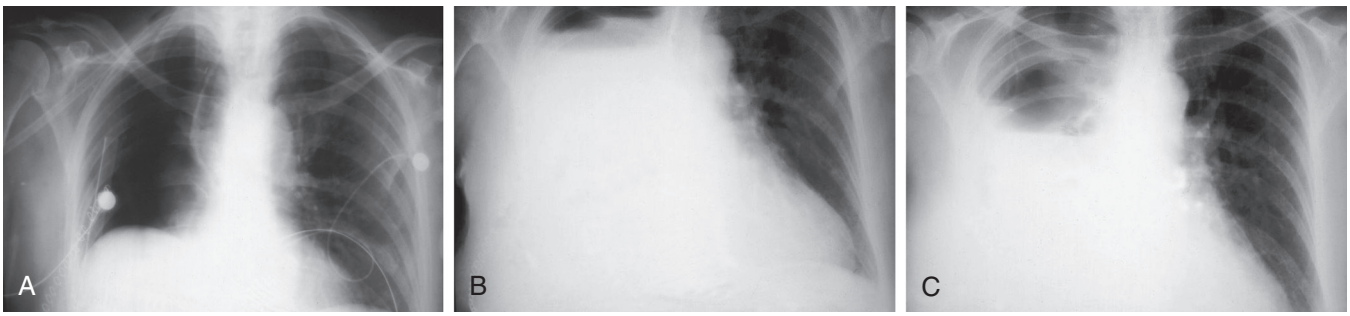

Figure 66-47. A, Chest radiograph of a patient immediately postoperatively after a right pneumonectomy. **B,** The same patient on postoperative day 6. This is a normal postpneumonectomy film. The right hemithorax is gradually filling with serous fluid. **C,** The same patient on postoperative day 7. The patient had the sudden onset of severe dyspnea, desaturation, and coughing. The chest radiograph reveals a decrease in the fluid level in the right hemithorax. This is diagnostic of a bronchopleural fistula caused by the dehiscence of the bronchial stump.

Accumulation of radionuclide in the pleural space after inhalation of xenon or a mixture of O_2 and N_2O to detect the presence of a bronchopleural fistula can also be used as indicators.[219]

If the disruption occurs early in postpneumonectomy patients it can be life threatening and it is possible to resuture the stump. Late or chronic postpneumonectomy bronchial disruption is managed with drainage or with the Clagett procedure, which includes open pleural drainage and the use of a muscle flap to reinforce the bronchial stump. In nonpneumonectomy cases, if the lung expands to fill the thoracic cavity, the air leak can usually be controlled with chest tube drainage alone. However, if the fistula is large and a significant leak through a large persistent pleural space occurs, it is unlikely that the fistula will close, and surgical resection is necessary

Anesthetic Management

The patient with a bronchopleural fistula presents several intraoperative challenges for the anesthesiologist, including: (1) the need for lung isolation to protect healthy lung regions, (2) the possibility of tension pneumothorax with positive-pressure ventilation, and (3) the possibility of inadequate ventilation caused by air-leak from the fistula.

Preoperatively, it is useful to estimate the loss of tidal volume through the bronchopleural fistula, which may be done in two ways. First, one should determine whether air bubbles flow intermittently or continuously through the chest tube. If air bubbles flow intermittently, then the fistula is small. In contrast, when a patient has a large bronchopleural fistula or bronchial rupture, air will bubble continuously through the water-seal chamber of the chest tube drainage system. Second, the size of the bronchopleural fistula may be quantified by the difference between inhaled and exhaled tidal volumes. In a nonintubated patient, this may be determined with a tight-fitting mask and a fast-responding spirometer. In an intubated patient, it is determined by direct attachment of the spirometer to the endotracheal tube. The larger the air leak, the greater the need to isolate the bronchopleural fistula with the use of a lung isolation device (a DLT or an independent bronchial blocker).

Several nonsurgical approaches (i.e., the use of various mechanical ventilation–chest tube drainage systems) have been used for the treatment of patients with a bronchopleural fistula. These approaches consist of OLV and differential lung ventilation, including HFV, PEEP to the pleural cavity equal to intrathoracic PEEP, and unidirectional chest tube values. One-way endobronchial valves have been used successfully in patients with bronchopleural fistula who were considered unfit for surgery.[220]

For patients undergoing operative repair, the ability to adequately deliver positive-pressure ventilation intraoperatively must be carefully considered before surgery. A chest drain should be placed before induction to avoid the possibility of tension pneumothorax with positive-pressure ventilation. A DLT is the best choice for delivering positive-pressure ventilation. The DLT can provide positive-pressure ventilation to the normal lung without loss of minute ventilation through the fistula and prevent the hazard of contamination of the uninfected lung with infected material when the patient is turned to the lateral decubitus position.

The safest method of obtaining lung isolation is awake fiberoptic intubation with a DLT.[221] However, this requires a cooperative patient and excellent topical anesthesia and is often not an option. Another option is to maintain spontaneous ventilation during induction and intubation until lung isolation is secured. This avoids the possibility of inadequate positive-pressure ventilation because of air-leak but is not well tolerated in older patients with significant comorbidity. If the patient has a postpneumonectomy fistula, the DLT or SLT must be guided under direct vision with the assistance fiberoptic bronchoscopy, and the tip of the endobronchial lumen should be placed in the noninvolved lung (i.e., for right-sided fistula, use a left-sided tube). Whatever anesthetic technique is used, the principle of anesthetic management for a bronchopleural fistula is: lung isolation before positive-pressure ventilation or repositioning the patient.

One option to avoid instrumentation of the airway in patients with bronchopleural fistula after pneumonectomy is the use of thoracic epidural anesthesia with intravenous sedation during minimally invasive surgery.[222] An alternative method of ventilating patients with multiple bronchopleural fistulas is the use of high-frequency oscillatory ventilation with permissive hypercapnia. This avoids barotrauma to the nonoperative lung, decreases bronchopleural fistula air-leak, and optimizes the operative outcome.[223] The advantage of high-frequency oscillatory ventilation over conventional mechanical ventilation is that it uses lower peak airway pressure and

higher minimum airway pressure and may decrease the air-leak across the fistula. Early extubation in the operating room should be considered in all patients undergoing fistula repair to avoid barotrauma to the surgical stump from positive-pressure ventilation in the postoperative period.

BLEBS, BULLAE, CYSTS, AND PNEUMATOCELES

BLEBS

A bleb is a subpleural collection of air under the visceral pleura caused by a ruptured alveolus. The air dissects through the pulmonary parenchyma and enlarges to form a bubble on the surface of the lung. Blebs most commonly occur at the apices of the lung and can rupture into the interpleural space, causing a pneumothorax. A single episode of spontaneous pneumothorax is usually treated conservatively with chest tube drainage until the air-leak has stopped. Resection of blebs is commonly indicated for recurrent pneumothoraces, bilateral pneumothoraces, or prolonged chest tube drainage. Resection of blebs after a single pneumothorax may be indicated if the patient's occupation exposes them to significant rapid fluctuations in atmospheric pressure (e.g., flight crews or scuba divers). Resection is most commonly combined with a procedure to obliterate the pleural space by partial pleurectomy or pleural abrasion. Resection of blebs is most often performed by VATS. Although VATS procedures per se are generally associated with a limited need for postoperative analgesia, pleurectomy or abrasion is very painful.

BULLAE

Bullae are thin-walled, air-filled intraparenchymal lung spaces caused by the loss of alveolar structural tissue (Fig. 66-48). These are usually associated with emphysema but their exact cause is unclear. Although there is some confusion over terminology in this area, bullous-like lesions of the lung associated with congenital malformations or secondary to trauma or infection are more correctly termed *pneumatoceles* or *cysts*. There are no universally accepted surgical indications for resection of lung bullae. A patient with symptomatic dyspnea and a giant bulla (or bullae) that occupies more than 30% of a hemithorax and in whom radiography and CT scans suggest that reasonably functional lung tissue can be restored to a more anatomically favorable position should be considered for bullectomy. Factors that support the effect of the bullae as a cause of a patient's dyspnea are a restrictive pattern of spirometry (proportional decrease of both FEV_1 and FVC) and a discrepancy in lung volume studies in which the FRC measured by plethysmography exceeds the FRC measured by helium dilution by more than 2 liters.

In the usual tidal volume range, bullae are more compliant than normal lung and fill preferentially during spontaneous ventilation. However, beyond the normal tidal volume range, bullae become much less compliant and the intrabulla pressure rises acutely as airway pressure increases. Measurement of in vivo intrabullae pressures in patients using fine needles both before and during anesthesia showed no evidence of a valve mechanism.[37] All bullae studied communicated with the central airways, although some did this very slowly. The typical compression pattern seen on radiographs or CT scans is most likely caused by secondary elastic recoil of normal lung regions (see Fig. 66-6). Intrabulla pressure at FRC corresponds with the mean airway pressure averaged over the respiratory cycle. Thus during spontaneous ventilation, the intrabulla pressure will be negative with respect to the surrounding lung tissue. However, whenever positive pressure is used, the intrabulla pressure will rise in relation to surrounding lung regions. There is a risk of hyperinflation and rupture whenever positive pressure is used. The complications of bulla rupture can be life threatening because of hemodynamic collapse from tension pneumothorax or inadequate ventilation owing to resultant bronchopleural fistula.

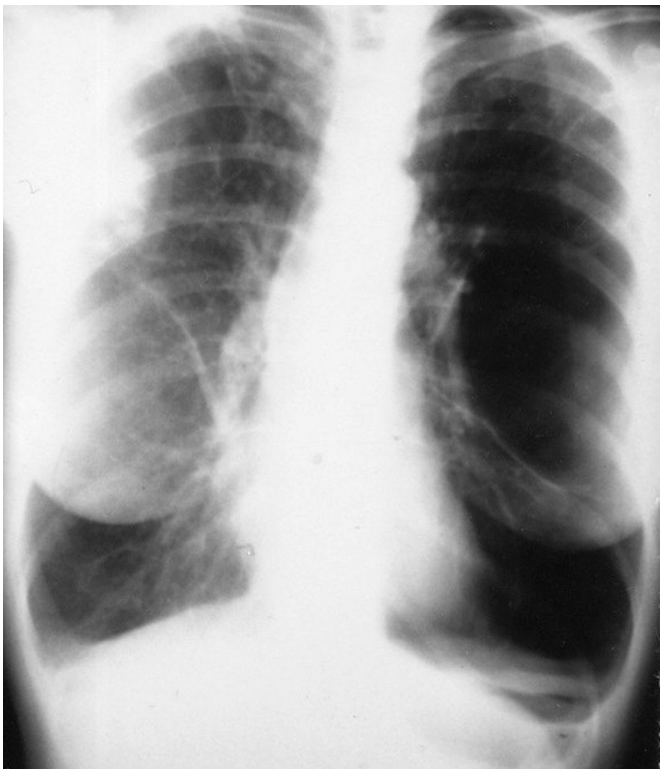

Figure 66-48. Chest radiograph of a patient with severe emphysema and multiple bullae including giant bullae of the left upper and lower lobes.

Relief of dyspnea symptoms and improved pulmonary function are well documented in patients after resection of giant bullae, with most patients showing an increase in FEV_1 of more than 0.3 L and excellent short-term improvement in quality of life, but with a decrease in improvement by 3 years.[224] Hypercapnia is not a contraindication for bulla resection. Lung infection must be meticulously treated preoperatively. Outcome depends on patient age, smoking history, and cardiac status. In the postoperative period, lung air-leaks are the major complication.

The surgical approach can be by traditional sternotomy or by VATS. Laser resection may decrease the incidence of air-leaks. Various nonsurgical thoracoscopic

and bronchoscopic procedures such as the subsegmental injections of fibrin glue have been used to deal with these air-leaks.

The anesthetic considerations for bullectomy are similar to those for a patient with a bronchopleural fistula, with the exception that it is best to not place a chest drain prophylactically because this may enter the bulla and create a fistula, and there is not the risk of soiling healthy lung regions from extrapleural fluid that there is with fistulas. For induction of anesthesia, it is optimal to maintain spontaneous ventilation until the lung or lobe with the bulla or bleb is isolated.[225] When there is a risk of aspiration or it is felt that the patient's gas exchange or hemodynamics may not permit spontaneous ventilation for induction, the anesthesiologist will have to use small tidal volumes and low airway pressures during positive-pressure ventilation until the airway is isolated.

CYSTS

Congenital bronchogenic cysts are products of abnormalities in the tracheobronchial budding process of lung organogenesis. They may occur peripherally within the lung parenchyma (70%) or centrally attached to the mediastinum or hilum. Bronchogenic cysts become problematic if they become enlarged, exerting a mass effect on functional lung or mediastinal structures; if they rupture and create a pneumothorax; or if they become infected. Small cysts without communication to a bronchus are asymptomatic and may be incidentally noted as round, clearly demarcated lesions on chest radiographs. Communicating cysts often produce air-fluid levels, are prone to recurrent infection, and may trap air by a ball-valve mechanism, risking rapid expansion or rupture. Infected cysts may be obscured by surrounding pneumonia, or they may be difficult to differentiate from an empyema. CT scans help differentiate cystic from solid lesions. Conservative surgical excision of bronchogenic cysts is generally recommended, regardless of whether a bronchial communication is evident.

Pulmonary hydatid cysts are watery, parasitic cysts containing larvae of the dog tapeworm *Echinococcus granulosus*.[226] *E. granulosus* is a relatively common cause of pulmonary cysts in endemic areas (e.g., Australia, New Zealand, South America, and some third-world regions). Hydatid cysts may grow in diameter by as much as 5 cm per year and become medically problematic in several ways. By mass effect, they may exert pressure on adjacent structures (e.g., bronchus, great vessels, esophagus). Spontaneous or traumatic rupture may occur, sending fluid, parasites, or laminated debris into adjacent tissue, bronchus, pleura, or the circulation (i.e., systemic emboli). Hypersensitivity reactions, bronchospasm, and anaphylaxis can result. Drainage into the bronchi may cause dramatic expulsion of fluid with respiratory distress or asphyxiation, depending on the amount of fluid involved. Rupture into the pleural space may result in a large hydropneumothorax, severe dyspnea, shock, suffocation, or anaphylaxis. Rupture becomes more dangerous and more likely as cysts become larger. It is recommended that any cyst larger than 7 cm should be removed.

Small, intact peripheral cysts are often easily enucleated without loss of lung parenchyma. Segmentectomy or lobectomy is indicated when single or multiple cysts occupy most of the segment or lobe. Patients with suppurative cysts should be prepared for surgery with postural drainage and antibiotics. Lung isolation and/or reduced airway pressure during dissection may be helpful in preventing herniation of the cyst. Increased airway pressure at the time of delivery may aid in removal of the cyst. The multiple bronchial openings in the residual cavity must then be identified and closed. Multiple "leak tests" with saline poured into the residual opening may be required to locate all bronchial openings. An alternative surgical strategy is to inject hypertonic saline into the cyst to sterilize it, followed by aspiration of the contents and removal of the evacuated cyst.

PNEUMATOCELE

Pneumatoceles are thin-walled, air-filled spaces generated by pulmonary infections or trauma. They usually appear in the first week of pneumonia and resolve spontaneously within 6 weeks. As with other lung cysts, potential complications of pneumatoceles include secondary infection and enlargement as a result of air entrapment, with possible rupture or displacement and compression of normal lung. Adverse hemodynamic consequences may result either from a tension pneumothorax or a tension pneumatocele. The latter is unusual and is presumed to result from a one-way valve mechanism, usually in the setting of positive-pressure mechanical ventilation.[227] Sometimes surgical decompression is required and is performed by percutaneous needle aspiration, catheter drainage, or chest tube drainage under CT or fluoroscopic guidance. Rarely is thoracoscopic or open surgical drainage or excision required.

LUNG TRANSPLANTATION

End-stage pulmonary disease is one of the most common causes of death. Lung transplantation is a definitive treatment for these patients. Indications and contraindications to lung transplantation are summarized in Box 66-12. Approximately 1500 lung transplants are performed annually worldwide; the number is limited by the supply of donor organs. Recipients fall into four major categories (by frequency of indication):

1. COPD
2. Cystic fibrosis (CF) (Fig. 66-49) and other congenital forms of bronchiectasis
3. Pulmonary fibrosis: idiopathic, associated with connective tissues disorders, other
4. Primary pulmonary hypertension

There are also several other, rarer indications such as primary bronchoalveloar lung cancer, lymphangioleiomyomatosis, and so on.[228] Depending on the patient's pathophysiology, there are several surgical options: single-lung transplantation, bilateral sequential (double) lung transplantation, heart-lung transplantation, and living-related lobar transplantation. An overall 5-year survival rate of 50% is the benchmark but depends on recipient age and diagnosis. Survival is generally better

BOX 66-12 ***Indications and Contraindications for Lung Transplantation***

INDICATIONS

- Untreatable end-stage pulmonary, parenchymal, or vascular disease
- Absence of other major medical illnesses
- Substantial limitation of daily activities
- Projected life expectancy less than 50% of 2- to 3-year predicted survival
- New York Heart Association Class III or IV functional level
- Rehabilitation potential
- Satisfactory psychosocial profile and emotional support system
- Acceptable nutritional status
- Disease-specific mortality exceeding transplant-specific mortality over 1 to 2 years

RELATIVE CONTRAINDICATIONS

- Age > 65 years
- Critical or unstable clinical conditions (e.g., shock, mechanical ventilation, extracorporeal membrane oxygenation)
- Severely limited functional status with poor rehabilitation potential
- Colonization with highly resistant or virulent bacteria, fungi, or mycobacteria
- Severe obesity defined as a body mass index greater than >30 kg/m^2
- Severe or symptomatic osteoporosis
- Other medical conditions not resulting in end-organ damage (e.g., diabetes mellitus, systemic hypertension, peripheral vascular disease, gastroesophageal reflux, patients with coronary artery disease s/p coronary artery stenting or percutaneous transluminal coronary angioplasty)

ABSOLUTE CONTRAINDICATIONS

- Untreatable advanced dysfunction of another major organ system (e.g., heart, liver, kidney)
- Active malignancy within the previous 2 years
- Noncurable chronic extrapulmonary infection
- Chronic active viral hepatitis B, hepatitis C, and HIV
- Significant chest wall or spinal deformity
- Documented nonadherence or inability to follow through with medical therapy, office follow-up, or both
- Untreatable psychiatric or psychological condition associated with inability to cooperate or comply with medical therapy
- Absence of a consistent or reliable social support system
- Substance addiction (e.g., alcohol, tobacco, narcotics) that is either currently active or was active within the previous 6 months

Based on Orens JB, Estenne M, Arcasoy S, et al: International guidelines for the selection of lung transplant candidates: 2006 update, J Heart Lung Transplant *25: 745, 2006.*

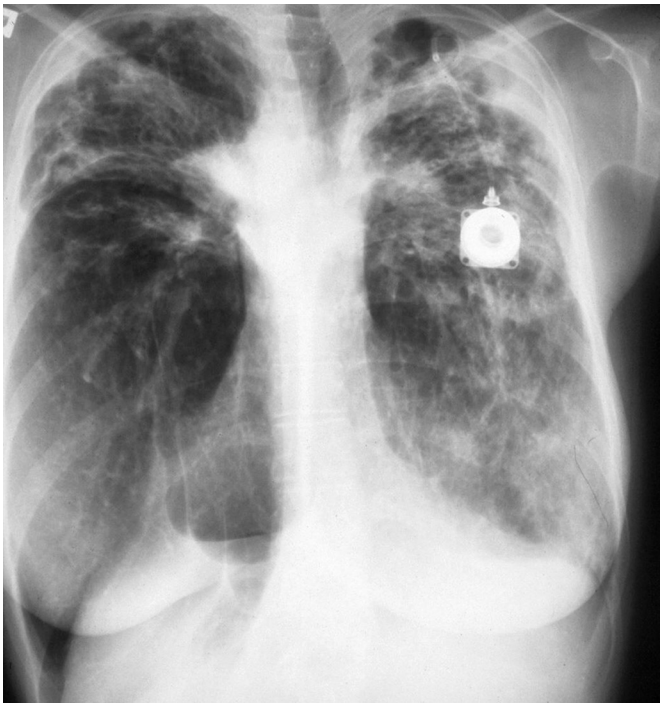

Figure 66-49. Chest radiograph of a patient with cystic fibrosis for bilateral lung transplantation. The chest image shows a typical pattern of bronchiectasis. A subcutaneous intravenous injection reservoir is seen over the upper left chest.

with double-lung than with single-lung transplants, with the exception of older pulmonary fibrosis patients, for whom there is no outcome difference between the two procedures.

Anesthetic airway management is most commonly done with a DLT. The advantage of using a DLT in transplantation is that it allows direct continuous access to both lungs for suctioning, oxygenation, and examination of the bronchial anastomoses. Several advances have allowed the use of DLTs for transplantation. The use of segmental bronchial lavage at induction via an SLT, before placement of the DLT facilitates suctioning via the DLT in patients with copious secretions. Monitoring includes invasive arterial and pulmonary catheters and transesophageal echocardiography in most centers. Anesthetic maintenance is based mainly on IV infusions because of the frequent need for airway access (suctioning, bronchoscopy), which causes problems in maintaining a stable level of inspired anesthetic vapor. Despite advances in lung preservation techniques, it is optimal to limit the donor lung ischemic period to 4 hours.

There are wide variations in the frequency of use of CPB during lung transplantation; some centers always use CPB and some centers almost never use it. CPB temporarily decreases postoperative gas exchange, increases intraoperative blood loss, and increases the duration of postoperative mechanical ventilation. There is no net decrease in short- or long-term mortality attributable to CPB. Extracorporeal membrane oxygenation (ECMO) is used in some centers in place of CPB intraoperatively.[229] ECMO is also used increasingly for postoperative respiratory support.

The intraoperative anesthetic complications depend, in large part, on the underlying lung disease. Emphysema patients are prone to hypotension on induction from positive-pressure ventilation (see COPD in "Preoperative Evaluation," discussed earlier). Problems in patients with CF include the inability to both deal with thick bronchial secretions and adequately ventilate these patients. CF patients, because they have both increased inspiratory and expiratory flow resistances, may benefit from slow inspiratory phase ventilation with a high airway pressure.[230] Because of the severely

decreased lung compliance, this method of ventilation causes little hemodynamic compromise in this subgroup of patients, if air trapping is avoided. Other recipient disease-specific problems include: hemodynamic collapse on induction because of right-heart dysfunction in primary pulmonary hypertensives, the poor tolerance of pulmonary fibrosis patients for OLV, and the risk of pneumothoraces in patients with lymphangiomyomatosis.

SUBSEQUENT ANESTHESIA FOR THE PULMONARY TRANSPLANT RECIPIENT

Many lung transplant recipients subsequently require anesthesia for related or unrelated surgical problems.[231] The frequency with which they present for surgery may be caused by complications of immunosuppression (e.g., infection, tumor, renal failure) or complications of the transplantation (e.g., bronchial stenosis, bronchiolitis obliterans). Most transplant recipients can be managed according to routine anesthetic practice including optimal perioperative respiratory care, antibiotic prophylaxis, and maintenance of immune suppression. Results of recent blood gas analysis, chest radiographs, and CT scans are vital in managing these patients. Most adults with bronchial anastomoses have no problem with endotracheal intubation. If endobronchial intubation or a DLT is used, a bronchoscopy should be performed first to assess the bronchial anastomoses, and the intubation should be done with fiberoptic guidance.

Single-lung transplant recipients with native lung emphysema are a specific concern. They have a marked imbalance in pulmonary compliance, with the native lung highly compliant and the donor lung of normal or reduced (if there is rejection) compliance. However, the major proportion of the pulmonary blood flow is usually to the allograft. With standard methods of positive-pressure ventilation, dynamic hyperinflation of the emphysematous lung with hemodynamic instability and problems with gas exchange may develop in these patients. They may require the use of a DLT and independent lung ventilation techniques, reducing the airway pressure and minute ventilation in the native lung, if positive-pressure ventilation is required.

LUNG VOLUME REDUCTION

Although resection of bullae is a well-established thoracic surgical procedure, the use of multiple wedge resections to reduce lung volume and improve symptoms in severe emphysema (lung volume reduction) is a procedure in evolution. Depending on the patient and center, this procedure may be unilateral or bilateral and performed by thoracotomy, sternotomy, or VATS. The surgery is more effective in patients with heterogeneous lung disease, where the most severely affected areas (often apical) can be resected, than in patients with homogenous types of emphysema (e.g., α1-antitrypsin deficiency). Patients with extremely severe disease (FEV_1 or D_Lco <20% predicted) have poor survival after surgery.[232] This procedure is now most commonly seen as an option for patients with severe emphysema who have contraindications to transplantation.

Immediate postoperative improvements in symptoms and pulmonary function are common, and many patients are able to discontinue or reduce home oxygen therapy. These changes are the result of a decompression of the airways and a reduction of airflow resistance and work of breathing,[233] which results in a dramatic fall in auto-PEEP (intrinsic PEEP) with a corresponding increase in dynamic compliance. Despite the encouraging changes in early postoperative pulmonary function, the improvement in respiratory function as a result of this surgery is transient.[234] However, this must be viewed in the context of the short life expectancy of patients with this degree of emphysema and the potential for improvement in their quality of life from the operation.

Anesthetic management is similar to that for other patients with severe COPD having thoracic surgery (see COPD in Preoperative Evaluation, discussed earlier) with the risk of hypotension on induction caused by auto-PEEP and the need for excellent analgesia to avoid postoperative mechanical ventilation.[235] This procedure is now performed in some centers using one-way valves placed bronchoscopically in the most involved segments to cause collapse of severely emphysematous distal lung regions,[236] thus avoiding surgery.

PULMONARY HEMORRHAGE

Massive hemoptysis is defined as expectoration of more than 200 mL of blood in 24 to 48 hours. The commonest causes are carcinoma, bronchiectasis, and trauma (blunt, penetrating, or secondary to a pulmonary artery catheter). Death can occur quickly as a result of asphyxia. Management requires four sequential steps: lung isolation, resuscitation, diagnosis, and definitive treatment. The anesthesiologist is often called to deal with these cases outside of the operating room. There is no consensus on the best method of lung isolation for these cases. The initial method for lung isolation will depend on the availability of appropriate equipment and an assessment of the patient's airway. All three basic methods of lung isolation have been used: DLTs, SLTs, and bronchial blockers. Fiberoptic bronchoscopy is usually not helpful to position endobronchial tubes or blockers in the presence of torrential pulmonary hemorrhage, and lung isolation must be guided by clinical signs (primarily auscultation). DLTs will achieve rapid and secure lung isolation. Even if a left-sided tube enters the right mainstem bronchus, only the right upper lobe will be obstructed. However, suctioning large amounts of blood or clots is difficult through the narrow lumina of a DLT. An option is initial placement of the SLT for oxygenation and suctioning and then replacement with a DLT either by laryngoscopy or with an appropriate tube exchanger. An uncut single-lumen ETT can be advanced directly into the right mainstem bronchus or rotated 90 degrees counterclockwise for advancement into the left mainstem bronchus.[237] A bronchial blocker will normally pass easily into the right mainstem bronchus and is useful for right-sided hemorrhage (90% of pulmonary artery catheter–induced hemorrhages are right-sided). Except for cases with blunt or penetrating trauma, after lung isolation and resuscitation

have been achieved, diagnosis and definitive therapy of massive hemoptysis are now most commonly performed by coiling of the pulmonary artery false aneurysm in interventional radiology.[238]

PULMONARY ARTERY CATHETER–INDUCED HEMORRHAGE

Hemoptysis in a patient with a pulmonary artery catheter must be assumed to be caused by perforation of a pulmonary vessel by the catheter until proven otherwise. The mortality rate may exceed 50%. This complication seems to be occurring less than previously, possibly related to stricter indications for the use of pulmonary artery catheters and more appropriate management of the catheters with less reliance on wedge measurements. Therapy for pulmonary artery catheter–induced hemorrhage should follow an organized protocol with some variation depending on the severity of the hemorrhage (Box 66-13).

BOX 66-13 *Management of the Patient With a Pulmonary Artery Catheter*

Induced Pulmonary Hemorrhage

- Initially position the patient with the bleeding lung dependent.
- Perform endotracheal intubation, oxygenation, airway toilet.
- Isolate the lung by endobronchial double- or single-lumen tube or bronchial blocker.
- Withdraw the pulmonary artery catheter several centimeters, leaving it in the main pulmonary artery. Do not inflate the balloon (except with fluoroscopic guidance).
- Position the patient with the isolated bleeding lung nondependent. Administer positive end-expiratory pressure to the bleeding lung if possible.
- Transport the patient to medical imaging for diagnosis and embolization if feasible.

During Weaning From Cardiopulmonary Bypass

Weaning from CPB is one of the situations in which pulmonary artery catheter–induced hemorrhage is most likely to occur. Management of the pulmonary artery catheter during CPB by withdrawal from a potential wedge depth and observing the pulmonary artery pressure waveform to avoid wedging during CPB may decrease the risk of this complication. When hemoptysis does occur in this situation, there are several management options available (Fig. 66-50). The anesthesiologist should resist the temptation to rapidly reverse the anticoagulation to quickly discontinue CPB, because this can lead to fatal asphyxiation from hemorrhage. Resumption of full CPB ensures oxygenation while the tracheobronchial tree is suctioned and then visualized with fiberoptic bronchoscopy. The use of a pulmonary artery vent may be required to decrease the pulmonary blood flow sufficiently to define the bleeding site (usually the right lower lobe). The pleural cavity should be opened to assess the lung parenchymal damage. Conservative management with lung isolation, to avoid lung resection, is optimal therapy if possible. In patients with persistent hemorrhage who are not candidates for lung resection, temporary lobar pulmonary artery occlusion with a vascular loop during and after weaning from CPB may be an option.

Posttracheostomy Hemorrhage

Hemorrhage in the immediate postoperative period after a tracheostomy is usually from local vessels in the incision such as the anterior jugular or inferior thyroid veins. Massive hemorrhage 1 to 6 weeks postoperatively is most commonly caused by tracheoinnominate artery fistula.[239] A small sentinel bleed occurs in most patients before a massive bleed. The management protocol for tracheoinnominate artery fistula is outlined in Box 66-14.

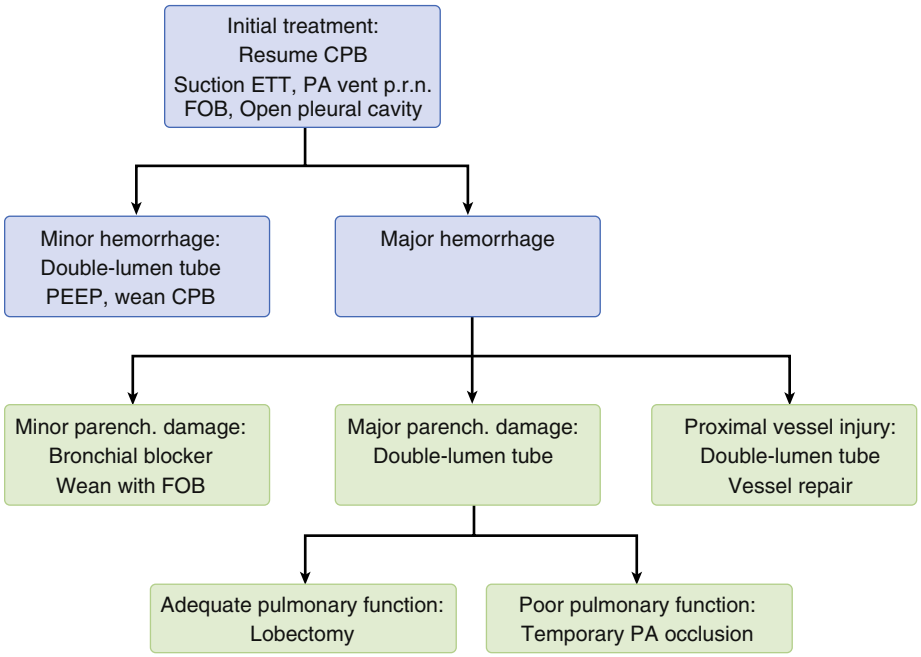

Figure 66-50. Flow diagram of management of massive hemoptysis during weaning from cardiopulmonary bypass. *CPB*, cardiopulmonary bypass; *ETT*, endotracheal tube; *PA*, pulmonary artery; *FOB*, fiberoptic bronchoscopy; *Parenc.*, lung parenchyma.

PULMONARY THROMBOENDARTERECTOMY

Pulmonary thromboendarterectomy is a potentially curative procedure for chronic thromboembolic pulmonary hypertension (CTEPH). CTEPH is a progressive disorder that responds poorly to conservative therapy, and pulmonary thromboendarterectomy is its most appropriate treatment, with a perioperative mortality of approximately 4%, which is less than lung transplantation. The majority of patients with CTEPH present for medical evaluation late in the disease because many have not had an obvious episode of deep venous thrombosis or pulmonary embolus, and the progression of the disease is insidious. Patients present with severe dyspnea on exertion and signs of right-sided heart failure. Surgical candidates have hemodynamically significant pulmonary vascular obstruction (pulmonary vascular resistance >300 dynes/sec/cm^{-5}), with potentially accessible proximal areas of thromboemboli.

An inferior vena cava filter is often placed prophylactically before surgery. Surgery is performed via a midline sternotomy with CPB with or without periods of deep hypothermic circulatory arrest (DHCA). Anesthetic management is essentially the same as for a patient with primary pulmonary hypertension for lung transplantation, with the exception that there is no need for lung isolation, so airway management is done with a standard ETT. Monitoring includes femoral and pulmonary artery catheters, TEE, processed electroencephalography, and rectal/bladder thermometers.[240]

These patients are at risk of hemodynamic collapse because of right ventricular failure from hypotension during induction of general anesthesia. Induction may be performed with etomidate or ketamine to avoid hypotension. Support of systemic vascular resistance with noradrenaline or phenylephrine is usually required. If DHCA is used, it is preceded by mannitol and methylprednisolone to try to decrease cerebral cellular edema and to improve free-radical scavenging. The speed of warming and cooling is controlled on CPB to maintain a temperature gradient less than 10° C between the blood and bladder/rectal temperatures. Periods of DHCA are usually limited to 20 minutes. Massive pulmonary hemorrhage occurs rarely during CPB in these cases. Management of pulmonary hemorrhage is done according to the algorithm outlined in Figure 66-50. The instillation of phenlyephrine 10 mg and vasopressin 20 U diluted in 10 mL saline via the ETT may be beneficial. Postoperatively, the patients are kept sedated, intubated, and ventilated for at least 24 hours to decrease the risk of reperfusion pulmonary edema. Noradrenalin or vasopressin infusions may be used to elevate the systemic vascular resistance and decrease cardiac output to decrease pulmonary blood flow.

BOX 66-14 *Management of Tracheoinnominate Artery Fistula Hemorrhage*

- Overinflate the tracheostomy cuff to tamponade the hemorrhage.
- If this fails:
  - Replace the tracheostomy tube with an oral endotracheal tube. Position the cuff with fiberoptic bronchoscopic guidance just above the carina.
  - Apply digital compression of the innominate artery against the posterior sternum using a finger passed through the tracheostomy stoma.
- If this fails:
  - Slowly withdraw the endotracheal tube and overinflate the cuff to tamponade.
  - Proceed with definitive therapy: sternotomy and ligation of the innominate artery.

BRONCHOPULMONARY LAVAGE

Bronchopulmonary lavage (BPL) is a treatment during which up to 10 to 20 L of normal saline is instilled and then drained in 500- to 1000-mL aliquots through one side of a DLT into one lung under general anesthesia until the effluent is clear.[241] It may then be performed on the contralateral lung during the same anesthetic or during a subsequent anesthetic after a period of several days for recovery. It is the most effective treatment modality for symptomatic pulmonary alveolar proteinosis. This lung disease results from accumulation in the alveoli of a lipoprotein material similar to surfactant.[242] This disease seems to have an immune component, and some patients respond to conservative medical therapy with granulocute-macrophage colony-stimulating factor.[243] Other pathologic states that have been treated by bronchopulmonary lavage include cystic fibrosis, asthma, radioactive dust inhalation, lipoid pneumonitis, and silicosis, all without convincing success.

General anesthesia is induced and maintained with intravenous infusions as for lung transplantation. Airway management is done with a left-sided DLT.[244] The patient is kept in the supine position during the procedure.

Because of transmitted hydrostatic pressure from the lavage lung to the pulmonary circulation, oxygenation increases during the filling phase and decreases during the emptying phase in synchrony with changes in the pulmonary blood flow distribution. These changes are usually transient and well tolerated. In severely hypoxemic patients presenting for BPL a variety of maneuvers have been used (such as inflation of a PA catheter balloon in the pulmonary artery (PA) of the lavage lung while adding NO to the ventilated lung[245] or the use of ECMO) to maintain oxygenation.

Usually 10 to 15 L is instilled and more than 90% is recovered, leaving a deficit of less than 10%. At the end of the procedure, the lavaged lung is thoroughly suctioned. A dose of furosemide (10 mg) is administered to increase diuresis of absorbed saline. If the plan is to proceed to a lavage of the contralateral lung, there is a period of at least 1 hour of TLV to allow recovery of the lavaged lung, during which arterial blood gases are monitored. If there is a persistent large alveolar-arterial oxygen gradient, the procedure is terminated at this stage and the patient will undergo lavage of the other lung at a later date. The postprocedure, after reintubation with an SLT, is a fiberoptic bronchoscopic inspection performed for suctioning. Conventional ventilation with PEEP is continued, usually for less than 2 hours. Observation in the intensive care

unit for 24 hours is part of the routine procedure. Some patients require lavage every few months, whereas others remain in remission for years.

MEDIASTINAL MASSES

Patients with mediastinal masses, particularly masses in the anterior or superior mediastinum, or both, present unique problems for the anesthesiologist. Patients may require anesthesia for biopsy of these masses by mediastinoscopy or VATS, or they may require definitive resection via sternotomy or thoracotomy. Tumors of the mediastinum include thymoma, teratoma, lymphoma, cystic hygroma, bronchogenic cyst, and thyroid tumors. Mediastinal masses may cause obstruction of major airways, main pulmonary arteries, atria, and the superior vena cava. During induction of general anesthesia in patients with an anterior or superior mediastinal mass, airway obstruction is the most common and feared complication. It is important to note that the point of tracheobronchial compression usually occurs distal to an endotracheal tube (Fig. 66-51), and it is not possible to forcibly pass an endotracheal tube through the airway once it has collapsed. A history of supine dyspnea or cough should alert the clinician to the possibility of airway obstruction on induction of anesthesia. Life-threatening complications may occur in the absence of symptoms in children. The other major complication is cardiovascular collapse secondary to compression of the heart or major vessels. Symptoms of supine presyncope suggest vascular compression.

Anesthetic deaths have mainly been reported in children. These deaths may be the result of the more compressible cartilaginous structure of the airway in children or because of the difficulty in obtaining a history of positional symptoms in children. The most important diagnostic tool for the patient with a mediastinal mass is the CT scan of the trachea and chest. Children with tracheobronchial compression noted to be greater than 50% on CT scan cannot be safely given general anesthesia.[246] Flow-volume loops, specifically the exacerbation of a variable intrathoracic obstructive pattern (expiratory plateau) when supine, are unreliable[247] for predicting which patients will have intraoperative airway collapse.[248] Transthoracic echocardiography is indicated for patients with vascular compression symptoms.

MANAGEMENT

General anesthesia will exacerbate extrinsic intrathoracic airway compression in three ways. First, reduced lung volume occurs during general anesthesia and tracheobronchial diameters decrease according to lung volume. Second, bronchial smooth muscle relaxes during general anesthesia, allowing greater compressibility of large airways. Finally, third, paralysis eliminates the caudal movement of the diaphragm seen during spontaneous ventilation. This eliminates the normal transpleural pressure gradient that dilates the airways during inspiration and minimizes the effects of extrinsic intrathoracic airway compression.

Management of these patients is guided by their symptoms and the CT scan (Boxes 66-15 and 66-16). Patients with "uncertain" airways should have diagnostic procedures performed under local or regional anesthesia whenever possible. Patients with "uncertain" airways requiring general anesthesia need a step-by-step induction of anesthesia with continuous monitoring of gas exchange and hemodynamics. This "NPIC" (*noli pontes ignii consumere*; i.e., "don't burn your bridges") anesthetic induction can be an inhalation induction with a volatile anesthetic such as sevoflurane or IV titration of propofol with or without ketamine, maintaining spontaneous ventilation until either the airway is definitively secured or the procedure is completed.[249] Awake intubation of the trachea before induction is a possibility in some adult patients if the CT scan shows an area of noncompressed distal trachea to which the endotracheal tube can be advanced before induction. If muscle relaxants are required, ventilation should first be gradually taken over manually to ensure that positive-pressure ventilation is possible, and only then can a short-acting muscle relaxant be administered (Box 66-17).

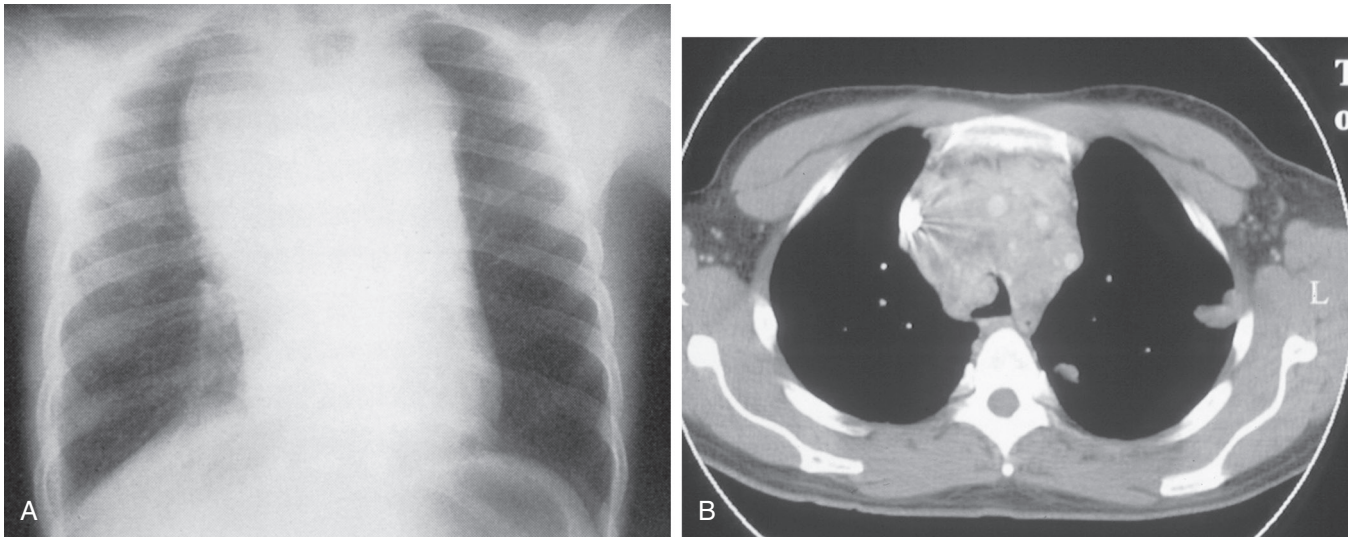

Figure 66-51. A, Chest radiograph of an adult patient with an anterosuperior mediastinal mass. This mass was a lymphoma. **B,** A thoracic CT scan with contrast just above the level of the carina shows partial compression of the carina and right mainstem bronchus. This patient has an "Uncertain" airway.

BOX 66-15 *Grading Scale for Symptoms in Patients with an Anterior or Superior Mediastinal Mass*

- Asymptomatic
- Mild: Can lie supine with some cough/pressure sensation
- Moderate: Can lie supine for short periods but not indefinitely
- Severe: Cannot tolerate supine position

BOX 66-16 *Stratification of Patients with Mediastinal Masses Regarding Safety for General Anesthesia*

- Safe: (I) Asymptomatic adult with CT minimal tracheal/bronchial diameter >50% of normal
- Unsafe: (I) Severely symptomatic adult or child; (II) children with CT tracheal/bronchial diameter <50% of normal, regardless of symptoms
- Uncertain: (I) Mild/moderate symptomatic child with CT tracheal/bronchial diameter >50% of normal; (II) mild/moderate symptomatic adult with CT tracheal/bronchial diameter <50% of normal; (III) adult or child unable to give history

CT, Computed tomography.

BOX 66-17 *Management for All Patients with a Mediastinal Mass and an Uncertain Airway for General Anesthesia*

- Determine optimal positioning of patient preoperatively.
- Secure airway beyond stenosis when patient is awake, if feasible.
- Have rigid bronchoscope and surgeon available at induction of anesthesia.
- Maintain spontaneous ventilation if possible (noli pontes ignii consumere).
- Monitor for airway compromise postoperatively.

Development of airway or vascular compression requires that the patient be awakened as rapidly as possible and then other options for the procedure be explored. Intraoperative life-threatening airway compression usually has responded to one of two therapies: either repositioning of the patient (it must be determined before induction if there is a position that causes less compression and fewer symptoms) or rigid bronchoscopy and ventilation distal to the obstruction (this means that an experienced bronchoscopist and equipment must always be immediately available in the operating room for these cases). The rigid bronchoscope, even if passed into only one mainstem bronchus, can be used for oxygenation during resuscitation (see Rigid Bronchoscopy, discussed earlier).[250] Once adequate oxygenation has been restored, the rigid bronchoscope can be used to position an airway exchange catheter, over which an ETT is passed after the bronchoscope is withdrawn. An alternative technique to secure the airway with rigid bronchoscopy is to first mount an ETT over a small rigid bronchoscope (e.g., 6 mm) and then perform rigid bronchoscopy using the bronchoscope to deliver the ETT distal to the obstruction.[251]

BOX 66-18 *Predictors of Airway Compromise in Children with a Mediastinal Mass*

- Anterior location
- Histologic diagnosis of lymphoma
- Superior vena cava syndrome
- Radiologic evidence of major vessel compression or displacement
- Pericardial or pleural effusion

Based on Lam JCM, Chui CH, Jacobsen AS, et al: When is a mediastinal mass critical in a child? An analysis of 29 patients, Pediatr Surg Int *20:180, 2004.*

Institution of femorofemoral CPB before induction of anesthesia is a possibility for some adult patients who are "unsafe" for NPIC general anesthesia. The concept of CPB "standby" during attempted induction of anesthesia is fraught with danger[252] because there is not enough time after a sudden airway collapse to establish CPB before hypoxic cerebral injury occurs.[253] Other options for "unsafe" patients include local anesthetic biopsy of the mediastinal mass or biopsy of another node (e.g., supraclavicular), preoperative radiotherapy with a nonradiated "window" for subsequent biopsy, preoperative chemotherapy or short-course steroids, and CT-guided biopsy of a mass or drainage of a cyst. The salient points in managing a patient with an anterior or superior mediastinal mass include[254]:

1. In virtually all children and adults with a mediastinal mass, diagnostic procedures and imaging can be performed, if necessary, without subjecting the patient to the risks of general anesthesia.[255]
2. An extrathoracic source of tissue for diagnostic biopsy (pleural effusion or extrathoracic lymph node) should be sought as an initial measure in every patient.
3. Regardless of the proposed diagnostic or therapeutic procedure, the flat, supine position is never mandatory.
4. In the high-risk child (Box 66-18) without extrathoracic lymphadenopathy or a pleural effusion, prebiopsy steroid therapy is justifiable.[256] In this case, coordination with oncology, surgery, and anesthesiology is essential to organize timing of the biopsy. An alternative to preoperative steroids in the cooperative high-risk patient includes irradiating the tumor while leaving a small area covered with lead for subsequent biopsy.

With improved awareness of the risk of acute intraoperative airway obstruction in these patients, life-threatening events are now less likely to occur in the operating room. In children, these events now tend to occur preoperatively if the patient is forced to assume a supine position for imaging. In adults, acute airway obstruction is now more likely to occur postoperatively in the recovery room.[257] Vigilance must be maintained throughout the entire perioperative period.

THYMECTOMY FOR MYASTHENIA GRAVIS

Myasthenia gravis is a disease of the neuromuscular junction; affected patients have weakness caused by a decreased number of acetylcholine receptors at the motor

end plate.[258] Patients may or may not have an associated thymoma. Thymectomy is frequently performed to induce clinical remission, even in the absence of a thymoma. The effects of muscle relaxants are modified by this disease; myasthenic patients are resistant to succinylcholine and are extremely sensitive to nondepolarizing blockers. Thymectomy may be performed via full or partial sternotomy, or with a minimally invasive approach via a transcervical incision or VATS. For thymectomy with a thymoma, a sternotomy is used. In the absence of an identifiable tumor, minimally invasive techniques are commonly used. Ideally, the use of neuromuscular relaxation is avoided. Induction of anesthesia with propofol, remifentanil, and topical anesthesia of the airway facilitates intubation without the use of muscle relaxants. Alternatively, inhalational induction with a halogenated agent such as sevoflurane may be performed.[259] For sternotomy, combined general and thoracic epidural anesthesia is a useful technique.

Most patients take pyridostigmine, an oral anticholinesterase, and many patients take immunosuppressive medication (e.g., corticosteroids). On the day of surgery, pyridostigmine dosing should ensure that the patient's usual regimen is provided during the immediate perioperative period. A few patients require IV dosing with neostigmine until they are able to resume oral intake of pyridostigmine. A scoring system was devised for prediction of the need for prolonged mechanical ventilation after thymectomy via sternotomy.[260] Among the criteria that contributed to the predicted need for support were disease duration longer than 6 years, chronic respiratory illness, pyridostigmine dosage greater than 750 mg/day, and vital capacity less than 2.9 L. The relevance of this score has diminished with better preoperative preparation and minimally invasive surgery.[261] Referral for surgery early in the course of the disease and stabilization of symptoms with medication and plasmapheresis, combined with an increased use of minimally invasive approaches, have made the need for postoperative ventilation infrequent. In optimized patients, mean hospital length of stay can be reduced to 1 day after minimally invasive, and 3 days after transsternal thymectomy.[262] Patients should remain on their full medical regimen postoperatively. The remission from myasthenia gravis after thymectomy occurs slowly over a period of months to years.

POSTOPERATIVE MANAGEMENT

EARLY MAJOR COMPLICATIONS

There are multiple potential major complications that can occur in the immediate postoperative period after thoracic surgery, such as torsion of a remaining lobe after lobectomy, dehiscence of a bronchial stump, or hemorrhage from a major vessel. Fortunately, these are infrequent and when they do occur, the principles of management are as outlined earlier for common and specific procedures. Among these possible complications, two will be discussed in more detail: (1) respiratory failure, because it is the most common cause of major morbidity after thoracic surgery; and (2) cardiac herniation, because, although it is rare, it is usually fatal if it is not quickly diagnosed and appropriately treated.

Respiratory Failure

Respiratory failure is a leading cause of postoperative morbidity and mortality in patients undergoing major lung resection. Acute respiratory failure after lung resection is defined as the acute onset of hypoxemia (PaO_2 <60 mm Hg) or hypercapnia ($Paco_2$ >45 mm Hg), or the use of postoperative mechanical ventilation for more than 24 hours or reintubation for controlled ventilation after extubation. The incidence of respiratory failure after lung resection is between 2% and 18%. Patients with decreased respiratory function preoperatively are at increased risk of postoperative respiratory complications. In addition, age, the presence of coronary artery disease, and the extent of lung resection play major roles in predicting postoperative morbidity and mortality. Crossover contamination, because of the failure of lung isolation intraoperatively during lung resection in patients with contaminated secretions, can result in contralateral pneumonia and postoperative respiratory failure.[263] Mechanical ventilation during the postoperative period after lung resection is associated with the risk of acquired nosocomial pneumonia and bronchopleural fistula.

Decreased pulmonary complications in high-risk patients are associated with the use of thoracic epidural analgesia during the perioperative period.[2] The prevention of atelectasis and secondary infections have been attributed to better preservation of the functional residual volume, efficient mucociliary clearance, and alleviation of the inhibiting reflexes acting on the diaphragm in patients receiving epidural analgesia.[264] Chest physiotherapy, incentive spirometry, and early ambulation are crucial to minimize pulmonary complications after lung resection. For an uncomplicated lung resection, early extubation is desirable to avoid potential complications that can arise as a result of prolonged intubation and mechanical ventilation. Current therapy to treat acute respiratory failure is supportive therapy attempting to provide better oxygenation, treat infection, and provide vital organ support without further damaging the lungs.

Cardiac Herniation

Acute cardiac herniation is an infrequent but well described complication of pneumonectomy, where the pericardium is incompletely closed or the closure breaks down.[265] It usually occurs immediately or within 24 hours after chest surgery and is associated with a more than 50% mortality rate. Cardiac herniation may also occur after a lobar resection with pericardial opening, or in other chest tumor resections involving the pericardium or in trauma.[266] When cardiac herniation occurs after a right pneumonectomy, the clinical presentation is caused by impairment of the venous return to the heart with a concomitant increase in CVP, tachycardia, profound hypotension, and shock. An acute superior vena cava syndrome ensues because of the torsion of the heart.[267] In contrast, when the cardiac herniation occurs after a left-sided pneumonectomy, there is less cardiac rotation, but the edge of the pericardium compresses the myocardium.

This may lead to myocardial ischemia, the development of arrhythmias, and ventricular outflow tract obstruction. Cardiac herniation occurs after chest closure because of the pressure difference between the two hemithoraces. This pressure difference may result in the heart being extruded through a pericardial defect.

Management for a patient with a cardiac herniation should be considered as dire emergent surgery. The differential diagnosis should include massive intrathoracic hemorrhage, pulmonary embolism, or mediastinal shift from improper chest drain management. Early diagnosis and immediate surgical treatment by relocation of the heart to its anatomic position with repair of the pericardial defect or by the use of analogous or prosthetic patch material is key to patient survival. Because these patients have undergone a previous thoracotomy, all precautions should be taken for a "redo" exploration. This includes the use of large-bore intravenous catheters and an arterial line. Maneuvers to minimize the cardiovascular effects include positioning the patient in the full lateral position with the operated side up. Because time is crucial, an SLT is used. Vasopressors or inotropes, or both, are required to support the circulation while exploration takes place. The use of TEE intraoperatively and after resuscitation and relocation of the heart can be considered during pericardial patch repair to prevent excessive compression of the heart by the repair.[268] In general, patients undergoing an emergency thoracic reexploration remain intubated and are transferred to the intensive care unit postoperatively.

POSTOPERATIVE ANALGESIA
(See Chapter 98)

Studies before 1990 consistently report a 15% to 20% rate of major respiratory complications (i.e., atelectasis, pneumonia, respiratory failure) within the first 3 days after thoracic surgery.[1] This time of onset may relate to the unique pattern of recovery of pulmonary function after thoracotomy, which shows a delay in the initial 72-hour postoperative period that is not seen with other major surgical incisions.[269] The incidence of postthoracotomy respiratory complications has shown an overall decline to less than 10%, whereas the cardiac complication rate has not changed.[2] Improvements in postoperative care, specifically pain management, are the major cause of this decline.

There are multiple sensory afferents that transmit nociceptive stimuli after thoracotomy (Fig. 66-52). These include the incision (intercostal nerves T4-T6), chest drains (intercostal nerves T7-T8), mediastinal pleura (vagus nerve, CN X), central diaphragmatic pleura (phrenic nerve, C3-C5),[270] and ipsilateral shoulder (brachial plexus). There is no one analgesic technique that can block all of these various pain afferents, so analgesia should be multimodal. The optimal choice for an individual patient depends on patient factors (i.e., contraindications, preferences), surgical factors (i.e., type of incision), and system factors (i.e., available equipment, monitoring, nursing support). The ideal postthoracotomy analgesic technique will include three classes of drugs: opioids, antiinflammatory agents, and local anesthetics.

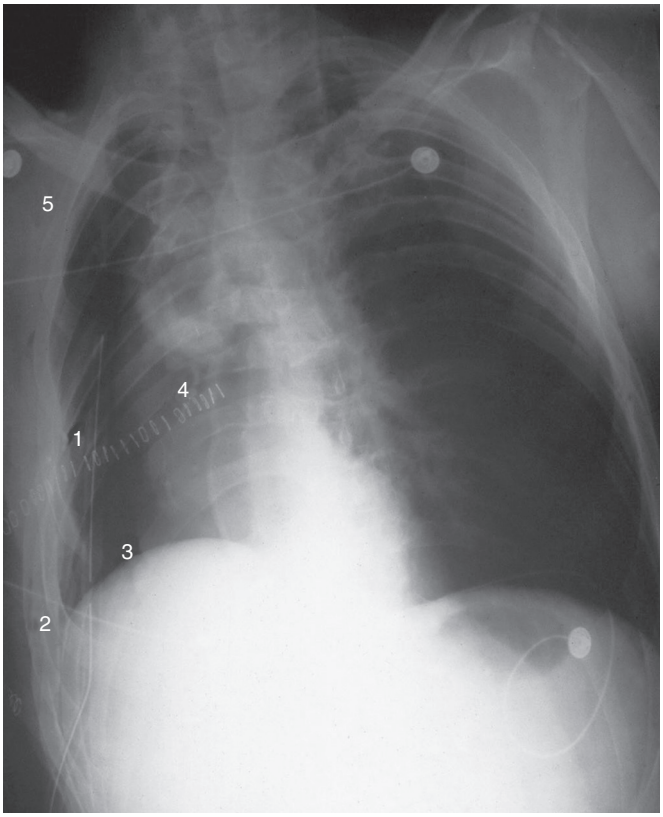

Figure 66-52. Multiple sources of afferent transmission of pain sensations after thoracotomy. *1*, Intercostal nerves at the site of the incision (usually T4-T6); *2*, intercostal nerves at the site of chest drains (usually T7-T8); *3*, phrenic nerve afferents from the dome of the diaphragm; *4*, vagal nerve innervation of the mediastinal pleura; *5*, brachial plexus.

SYSTEMIC ANALGESIA

Opioids

Systemic opioids alone are effective in controlling background pain, but the acute pain component associated with cough or movement requires plasma levels that produce sedation and hypoventilation in most patients. Even when administered by patient-controlled devices, pain control is generally poor[271] and patients have interrupted sleep patterns when serum opioid levels fall below the therapeutic range.

Nonsteroidal Antiinflammatory Drugs

NSAIDs can reduce opioid consumption more than 30% after thoracotomy and are particularly useful in treating the ipsilateral shoulder pain that is often present postoperatively and is poorly controlled with epidural analgesia. NSAIDs act through reversible inhibition of cyclooxygenase (COX), which has antiinflammatory and analgesic effects but can also be associated with decreased platelet function, gastric erosions, increased bronchial reactivity, and decreased renal function. Acetaminophen is an antipyretic/analgesic with weak COX inhibition and can be administered orally or rectally in doses of up to 4 g/day. It is effective against shoulder pain and has a low toxicity compared with more potent COX-inhibiting NSAIDs.[272]

Ketamine

Low-dose intramuscular ketamine (1 mg/kg) is equivalent to the same dose of meperidine and causes less respiratory depression. Ketamine can also be administered as a low-dose intravenous infusion and may be useful in patients who are refractory to other therapies or if there is a contraindication to more common techniques.[273] The possibility of psychomimetic effects with ketamine is always a concern but is rarely seen with analgesic, subanesthetic doses.

Dexmedetomidine

Dexmedetomidine, a selective adrenergic α_2-receptor agonist, has been reported as a useful adjunct for postthoracotomy analgesia and can significantly decrease the requirement for opioids when used in combination with epidural local anesthetics. Maintenance infusion doses for analgesia in children and adults are in the range of 0.3 to 0.4 μg/kg/h.[274] It is associated with some hypotension, but it seems to preserve renal function.

LOCAL ANESTHETICS/NERVE BLOCKS

Intercostal Nerve Blocks

Regional blocks of the intercostal nerves supplying the dermatomes of the surgical incision can be an effective adjunct to methods of postthoracotomy analgesia. These can be done percutaneously or under direct vision when the chest is open. The duration of analgesia is limited to the duration of action of the local anesthetic used, and the blocks will need to be repeated to have any useful effect on postoperative lung function. Indwelling intercostal catheters are an option but they can be difficult to position reliably percutaneously. Nerve blocks are useful supplements for the pain associated with the multiple small-port incisions and chest drains after VATS. It is important to avoid injection into the intercostal vessels, which are adjacent to the nerve in the intercostal groove. It is also important to place the block near the posterior axillary line to be certain to block the lateral cutaneous branch of the intercostal nerve. Total bupivacaine dose for a single session of blocks should not exceed 1 mg/kg (e.g., for a 75-kg patient: 3 mL bupivacaine 0.5% with epinephrine 1:200,000 at each of 5 levels).

Intrapleural Analgesia

Intrapleural local anesthetics produce a multilevel intercostal block. The analgesia is extremely dependent on patient position, infusion volume, chest drains, and the type of surgery. Despite occasional successes, most clinicians have not found the reliability of intrapleural techniques adequate to justify their use on a routine basis.[275]

Epidural Analgesia

The routine use of neuraxial analgesia for postthoracotomy patients is a relatively recent concept. Spinal injection of opioids can have a duration of analgesia that approaches 24 hours after thoracotomy. Because of the concerns of possible infection with subarachnoid catheters and the need to repeat spinal injections, investigation and therapy have focused on epidural techniques.

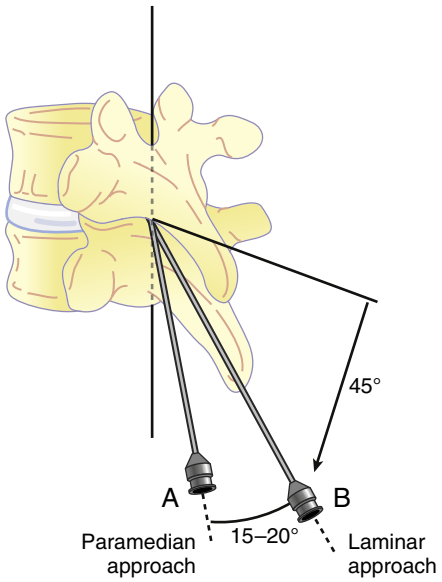

Figure 66-53. A, The paramedian approach to the epidural space is now favored by most anesthesiologists at the midthoracic levels. The needle is inserted 1 cm lateral to the superior tip of the spinous process and the advanced perpendicular to all planes to contact the lamina of the vertebral body immediately below. The needle is then "walked" up the lamina at an angle rostrally (45 degrees) and medially (20 degrees) until the rostral edge of the lamina is felt. The needle is then advanced over the edge of the lamina seeking a loss of resistance on entering the epidural space after traversing the ligamentum flavum. **B,** The laminar approach is favored by some practitioners. The needle is inserted next to the rostral edge of the spinous process and advanced straight without any angle from the midline. *(Reprinted with permission from Ramamurthy S: Thoracic epidural nerve block. In Waldman SD, Winnie AP, editors:* Interventional pain management. *Philadelphia, 1996, Saunders.)*

A meta-analysis of respiratory complications after various types of surgery has shown that epidural techniques reduce the incidence of respiratory complications.[276] Lumbar epidural analgesia has been replaced by thoracic epidural analgesia for thoracic surgery, with infusions of local anesthetic and opioid. These combinations provide better analgesia at lower doses than either drug will alone.[277] The use of epidural infusions has an excellent record for patient safety when used on routine postoperative surgical wards.[278] The use of a paramedian approach to the epidural space in the midthoracic levels (Fig. 66-53) has improved the success rate for many clinicians. Ultrasonographic guidance has not yet proved to be as useful for thoracic epidural catheter placement as it has for other types of regional blockade.[279]

Research has shed light on the pharmacology that underlies the synergy between local anesthetics and opioids to produce segmental epidural analgesia. In a double-blind randomized study, Hansdottir and associates[280] compared epidural infusions of lumbar sufentanil, thoracic sufentanil, and thoracic sufentanil plus bupivacaine for postthoracotomy analgesia. Infusions were titrated for equianalgesia at rest. Thoracic sufentanil plus bupivacaine provided significantly better analgesia with movement and less sedation than the other infusions. Although sufentanil dosages and serum levels were significantly lower

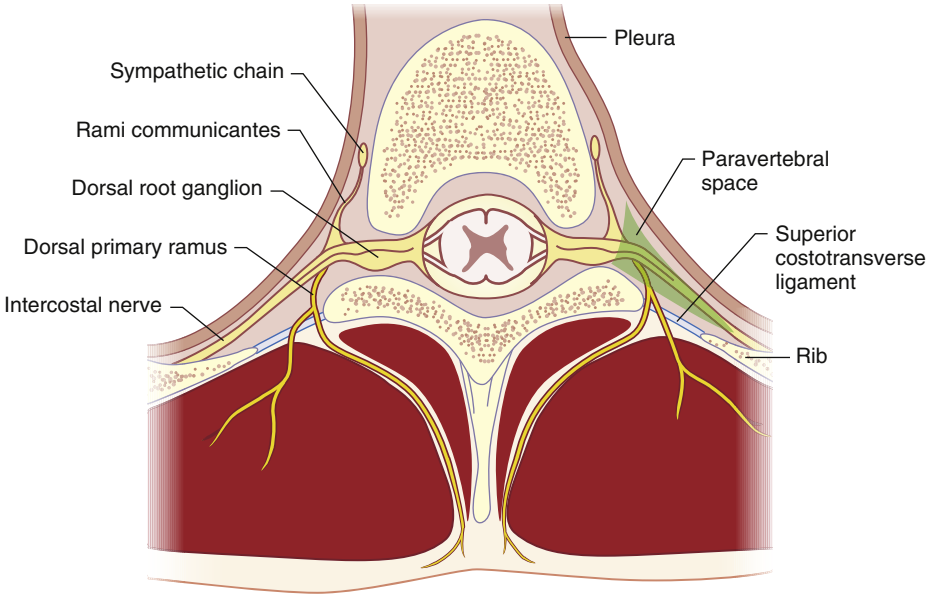

Figure 66-54. Diagram of the paravertebral space. The space is bound medially by the vertebral body, posteriorly by the costotransverse ligaments and the heads of the ribs, and anteriorly by the endothoracic fascia and parietal pleura. *(From Conacher ID, Slinger PD: Post-thoracotomy Analgesia. In Kaplan J, Slinger P, editors:* Thoracic anesthesia, *ed 3, Philadelphia, 2003, Churchill Livingstone.)*

in the combined sufentanil plus bupivacaine group than in the other two groups, lumbar cerebrospinal fluid levels of sufentanil at 24 and 48 hours were higher in the combined group than in the thoracic sufentanil group. This suggests that the local anesthetic facilitates entry of the opioid from the epidural space into the cerebrospinal fluid.

In patients with severe emphysema, thoracic epidural analgesic doses of bupivacaine do not cause any significant reduction in lung mechanics or increase in airway resistance.[281] In volunteers, a thoracic level of epidural blockade increases FRC.[282] This increase is largely caused by an increase in thoracic gas volume caused by a fall in the resting level of the diaphragm without a fall in tidal volume. Differences in lipid solubility that create relatively minor clinical differences in the effects of opioids when used systemically cause major differences in the effects of these same opioids when used neuraxially. The highly lipid-soluble agents (e.g., fentanyl, sufentanil) are associated with narrow dermatomal spread, rapid onset, and low incidence of pruritis/nausea, and can be potentiated by epinephrine. However, these lipid-soluble agents have significant absorption and systemic effects when used as epidural infusions.[283] For incisions that cover many dermatomes (e.g., sternotomy) or for procedures that have combined abdominal and thoracic incisions (e.g., esophagectomy), the hydrophilic opioids (e.g., morphine, hydromorphone) are preferable.

Paravertebral Block

The paravertebral space is a potential space deep to the endothoracic fascia that the intercostal nerve traverses as it passes from the intervertebral foramen en route to the intercostal space (Fig. 66-54). A catheter can be placed in the thoracic paravertebral space either percutaneously or by approaching the space anteriorly and directly when the chest is open intraoperatively.

There is also a combined percutaneous/direct-vision method in which the tip of the Tuohy needle is advanced percutaneously into the paravertebral space under direct vision either during open thoracotomy or VATS. The tip of the needle is seen to enter the paravertebral space and the pleura is not punctured. Saline is injected via the Tuohy needle to hydrodissect the paravertebral space, and an epidural catheter is passed into the pocket that has been created in the paravertebral space and then secured at the skin. The use of ultrasonographic guidance has been a major advance for percutaneous paravertebral injections and catheter placement (Fig. 66-55).[284]

Paravertebral local anesthetics provide a reliable multilevel intercostal blockade that tends to be unilateral, with a low tendency to spread to the epidural space. Clinically the analgesia is comparable with that from epidural local anesthetics.[285] Studies comparing paravertebral versus thoracic epidural analgesia for thoracotomies have suggested the following advantages for paravertebral blockade[286]: comparable analgesia; fewer failed blocks; decreased risk of neuraxial hematoma; and less hypotension, nausea, or urinary retention. Because there is an option to place the paravertebral catheter under direct vision, this may contribute to the lower incidence of failed blocks versus thoracic epidural analgesia.

Paravertebral infusions in combination with NSAIDs and systemic opioids are a reasonable alternative to epidural techniques in children or patients with contraindications to neuraxial blockade.[57] Using common therapeutic doses (e.g., 0.1 mL/kg/h of bupivacaine 0.5%), serum bupivacaine levels can approach toxic levels by 4 days.[287] An alternative regime for paravertebral infusions is lidocaine 1% (1 mL/10 kg/h; maximum 7 mL/h). It has not yet been demonstrated whether paravertebral analgesia can contribute to a decrease in respiratory morbidity in high-risk cases, which has been shown for thoracic epidural analgesia.[288]

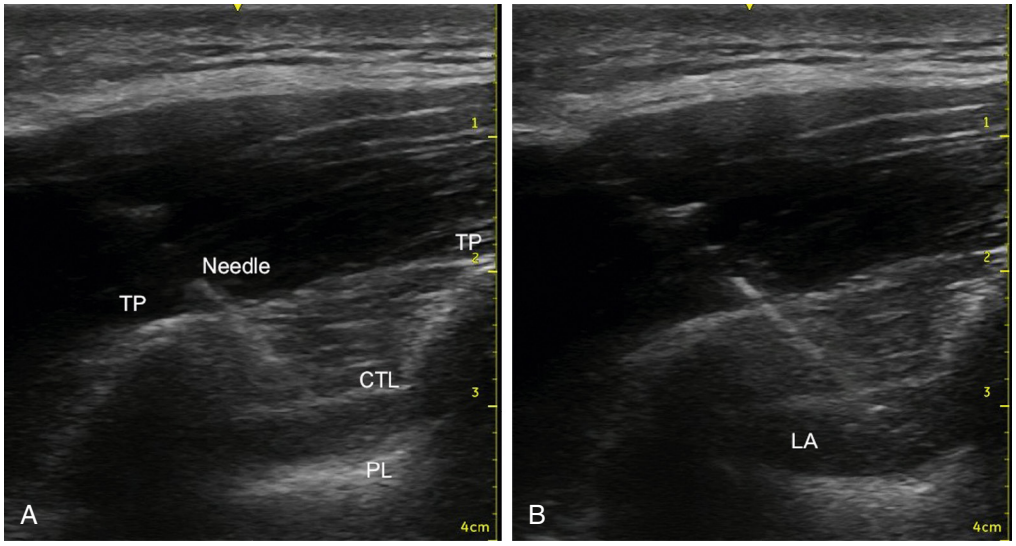

Figure 66-55. Ultrasound-guided paravertebral blockade. **A,** With the ultrasound probe in the parasagittal plane, a needle has been advanced from the cephalad border of the probe directed caudally passing under the transverse process *(TP)* of the thoracic vertebra. The paravertebral space is between the costotransverse ligament *(CTL)* and the parietal pleura *(PL)*. **B,** A bolus of local anesthetic *(LA)* has been injected into the paravertebral space, so a catheter can then be passed into the space. *(Courtesy Dr. M. Fiegel.)*

POSTOPERATIVE PAIN MANAGEMENT PROBLEMS

Shoulder Pain

After thoracotomy, as much as 80% of patients with a functioning epidural describe ipsilateral shoulder pain. Shoulder pain occurs after both thoracotomy and VATS and is thought to be primarily referred pain of diaphragmatic irritation transmitted by phrenic nerve afferents.[274] Other factors, including patient position during operation and major bronchus transection, have been incriminated, although the mechanisms are not clear. Several other causes of shoulder pain should be considered when evaluating a patient with shoulder pain postoperatively:

1. A chest drain placed too far into the apex of the hemithorax will irritate the parietal pleura and cause shoulder pain. The postoperative chest radiograph should be reviewed and the chest drain partially withdrawn if this is suspected as the cause.
2. The posterior end of a large posterolateral thoracotomy incision may not be well blocked by a functioning thoracic epidural, and this may be described as shoulder pain. The extent of the sensory block should be determined on the skin. If inadequate block is a possibility, the thoracic epidural analgesia can be "topped-up."
3. Patients with chronic arthralgia of the shoulder may experience an exacerbation from the intraoperative positioning of the ipsilateral arm. It is important to ask about shoulder problems preoperatively and to position the arms in a manner that does not exacerbate shoulder problems.

Shoulder pain is refractory to thoracic epidural analgesia and requires antiinflammatory agents with or without opioids. Shoulder pain is usually transient and is often resolved completely by the second postoperative day. There are several reports of the use of nerve blocks to treat postthoracotomy shoulder pain. Phrenic nerve infiltration and interscalene brachial plexus block[289] have had some success but carry a risk of causing diaphragm dysfunction.

Postthoracotomy Neuralgia and Chronic Incisional Pain

The transition of acute pain syndromes, associated with thoracic surgery, to chronic ones such as postthoracotomy neuralgia, may be partially preventable with analgesic regimens that prophylactically block nerves and desensitize peripheral nerve endings and dorsal horn cells of nerves that are damaged by surgery.[290]

MANAGEMENT OF OPIOID-TOLERANT PATIENTS

The opioid-tolerant patient requiring thoracic surgery presents a significant challenge. Patients may be using physician-prescribed opioids for pain related to their thoracic pathology or other chronic pain syndromes. Active abusers of narcotics or those in a rehabilitation program who are receiving daily methadone are also included in this group. Whenever possible, patients should take their regular analgesia or methadone preoperatively; otherwise substitute opioids must be provided. The opioid doses required to produce adequate postoperative analgesia are increased.

A multimodal analgesic regimen is optimal. A choice must be made regarding the method of increased opioid delivery, either systemically or through an epidural solution. An increased narcotic dose may be provided in the epidural solution, or standard narcotic concentrations may be used in the epidural with additional systemic narcotic. DeLeon-Casasola and Yarussi[291] report that higher epidural doses of opioids are able to curtail the appearance of narcotic withdrawal in most patients. More frequently, the patient receives a standard or slightly increased concentration of opioid in the epidural infusion and additional systemic opioid to minimize the occurrence of withdrawal. A convenient way to provide drug delivery in patients not immediately able to take oral medication is in the form of a transdermal fentanyl patch. Systemic

opioids can be provided as a continuous IV infusion or in oral form.

Patient-controlled analgesic techniques are often difficult to manage in these patients and they may be best managed with fixed dosage regimens that are modified as needed. Ultimately, after dose titration the patient may be receiving both increased epidural opioid and greater than preoperative doses of systemic opioid, without significant side effects. Patients in whom epidural bupivacaine-morphine analgesia is inadequate may respond to a switch to bupivacaine-sufentanil.[292] Patients in drug rehabilitation programs with methadone may be reluctant to modify their methadone dose perioperatively, having struggled to establish a stable dose in the past. They frequently can take their full methadone dose throughout the perioperative period.

Supplemental therapies to be considered for these patients include adding epinephrine 5 μg/mL to the epidural infusion solution and the addition of low-dose continuous IV ketamine infusions.[293] All opioid-tolerant patients require frequent adjustment of analgesic doses. Despite this, pain scores of 4 to 5 out of 10 with movement are often the lowest that are achievable. The increased analgesic requirements of opioid-tolerant patients are for a longer duration postoperatively than the usual need for analgesia in opioid-naive patients.

Chapter 67

Anesthesia for Cardiac Surgical Procedures

NANCY A. NUSSMEIER • MUHAMMAD F. SARWAR • BRUCE E. SEARLES • LINDA SHORE-LESSERSON • MARC E. STONE • ISOBEL RUSSELL

Acknowledgment: The editors and publisher would like to thank Drs. Michael C. Hauser and Alina M. Grigore for contributing a chapter on this topic to the seventh edition of this work. It has served as the foundation for the current chapter.

Key Points

- Common cardiac surgical procedures in adults include coronary revascularization with either cardiopulmonary bypass (CPB) or off pump, as well as cardiac valve repair or replacement for valvular regurgitation or stenosis, surgical management of heart failure (e.g., ventricular assist devices, extracorporeal membrane oxygenation, cardiac transplantation), initial repair of or reoperation for congenital heart disease, surgical ablation of atrial fibrillation, pericardiocentesis or pericardiectomy, and repair of traumatic injuries to the heart or thoracic aorta.
- Patients undergoing "redo" cardiac surgery (i.e., those who have previously had a median sternotomy) warrant special concern about the possibility of sudden, massive hemorrhage (see also Chapter 61). At least 2 units of blood should be immediately available for all such cases.
- The choice of anesthetic drugs and techniques for inducing anesthesia should include consideration of the patient's cardiac pathophysiology and other comorbid conditions. Hypotension may result from vasodilation secondary to decreased sympathetic tone induced by anesthetics, particularly in patients with poor left ventricular function. Conversely, hypertension may occur from preinduction anxiety or sympathetic stimulation caused by laryngoscopy and endotracheal intubation.
- During the prebypass period, hemodynamic and metabolic stability of the patient should be achieved while making preparations for CPB. The degree of surgical stimulation varies markedly during this period.
- CPB activates the extrinsic and intrinsic coagulation pathways and alters platelet function through the influence of hemodilution, hypothermia, and contact activation by bypass circuit materials (see also Chapter 62).
- Problems that may occur during the postbypass or postoperative time periods include hypotension resulting from surgical or technical failure, left or right ventricular dysfunction, vasoplegic syndrome, or left ventricular outflow tract obstruction. Other potential problems include dysrhythmias, pulmonary complications (e.g., atelectasis, bronchospasm, mucus or blood plugging of the endotracheal tube, pulmonary edema, hemothorax, pneumothorax), the potential for awareness, metabolic disturbances (e.g., hypokalemia, hyperkalemia, hypocalcemia, hypomagnesemia, hyperglycemia), and bleeding and coagulopathy.
- In 2007, with an update in 2011, the Society of Thoracic Surgeons (STS) and the Society of Cardiovascular Anesthesiologists published a joint statement on practice guidelines for transfusion and blood conservation in cardiac surgery. The guidelines include recommendations regarding the following: (1) use of drugs that decrease postoperative bleeding, including antifibrinolytic drugs; (2) techniques for conserving blood, including cell saver sequestration, retrograde priming of the pump, and normovolemic hemodilution; and (3) implementation of transfusion algorithms supported with point-of-care testing (see also Chapters 61 and 63).
- The incidence of overt postoperative stroke after isolated coronary artery bypass grafting surgery has decreased significantly to 1.2% despite the more frequent and current prevalence of diabetes mellitus and hypertension. The major risk factor

KEY POINTS—cont'd

for central nervous system injury or dysfunction is particulate and microgaseous emboli; other factors include cerebral hypoperfusion and the inflammatory response to surgery and CPB.

- Current STS guidelines state that blood glucose levels should be maintained at less than 180 mg/dL throughout the perioperative period, although many centers treat cardiac surgical patients somewhat more aggressively with continuous insulin infusions in an attempt to keep glucose levels lower than 150 mg/dL. Hypoglycemia should be avoided.
- Postoperative pain after median sternotomy or thoracotomy causes enhanced sympathetic tone and may lead to myocardial ischemia secondary to increased heart rate, pulmonary vascular resistance, myocardial work, and myocardial oxygen consumption. Furthermore, pain may cause "splinting" that interferes with the patient's ability to cough and clear secretions and leads to postoperative respiratory insufficiency.
- Common procedures performed in "hybrid" operating rooms or cardiac interventional suites include electrophysiology procedures, percutaneous management of valvular lesions, placement of occlusion or umbrella devices to close atrial or ventricular septal defects, insertion of percutaneous ventricular assist devices, and stenting of thoracic or abdominal aortic aneurysms.

CARDIOVASCULAR DISEASE IN THE TWENTY-FIRST CENTURY

AGE, GENDER, AND RACE

An estimated 82,600,000 U.S. adults (<1 in 3) have one or more types of cardiovascular disease (CVD), of whom approximately half are 60 years old or older.[1] The prevalence of CVD will likely increase because of the "graying" of the United States (i.e., the aging of our population) and the increasing incidences of obesity and hypertension.[2] Although mortality from coronary artery disease (CAD) specifically has decreased since the 1970s, CVD remains the leading cause of death for both men and women in the United States (Fig. 67-1). Furthermore, approximately 7,453,000 inpatient cardiovascular operations and procedures are performed yearly in the United States, with direct and indirect costs totaling approximately $300 billion.[1] As the current health care reforms expand treatment coverage, these costs will probably increase.[2]

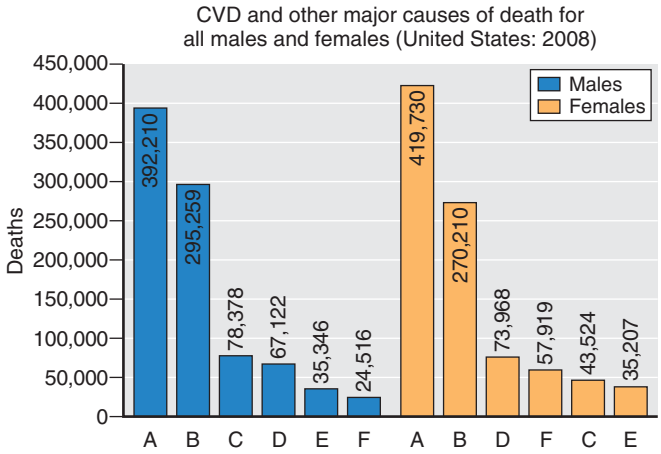

Figure 67-1. Cardiovascular disease (CVD) and other major causes of death for all male and female members of the U.S. population in 2008. *(From Roger VL, Go AS, Lloyd-Jones DM, et al: Heart disease and stroke statistics—2012 update: a report from the American Heart Association,* Circulation *2012;225:e2-e220.)*

Despite the common perception that CVD affects mainly men, this is true only in younger age groups. The sex distribution of CVD changes with age; CVD becomes equally prevalent between the sexes by the age of 60 years, and by the age of 80 years, more women than men are affected.[1] The impact of CVD on the health status of U.S. women has gained recognition and is the focus of public education efforts such as the "Go Red for Women" campaign sponsored by the American Heart Association (AHA) and the "Red Dress" project sponsored by the Department of Health and Human Services, the National Institutes of Health, and the National Heart Lung and Blood Institute.[3] Furthermore, a series of editorials and articles in the *Journal of Thoracic and Cardiovascular Surgery*[4] and gender-specific practice guidelines for coronary artery surgery in the *Annals of Thoracic Surgery*[5] have emphasized sex differences that affect patients who undergo cardiac surgical procedures. For example, using internal mammary artery (IMA) grafts significantly reduces mortality in patients of both sexes, but, until more recently, these grafts were underused in women.[5] Although some studies have shown that women's short-term survival is worse than men's after coronary artery bypass grafting (CABG) surgery,[6] others have found that 5-year post-CABG survival is actually better in women than in men.[7]

Mortality resulting from CVD has been consistently more frequent in black than white patients.[1] In 2008, the overall CVD-related death rate per 100,000 persons was 390.4 for black male patients, 287.2 for white male patients, 277.4 for black female patients, and 200.5 for white female patients. Furthermore, racial disparities have been reported in outcomes after CABG: both unadjusted mortality rates and mortality rates adjusted for patient-related characteristics are higher in black patients than in

white patients.[8] In fact, as an unfortunate consequence of the public release of quality information through CABG "report cards" in certain states, institutions and individual surgeons may use "racial profiling" in selecting patients for CABG.[9] For example, in New York State, physicians' avoidance of racial and ethnic minorities, who may be at a higher risk for poor outcomes, may have temporarily widened the disparity in CABG use among white versus black and Hispanic patients.

GENETIC INFLUENCES

Evolving rapidly beyond racial considerations (which are increasingly losing their medical and scientific meaning in the "melting pot" of the United States), *perioperative genomics* is the study of the unique biologic makeup of surgical patients. This field holds promise for uncovering the biologic reasons that patients with similar risk factors can have dramatically different perioperative clinical outcomes.[10] Patients with complex comorbid conditions are exposed to controlled trauma in the cardiac surgical operating room (Fig. 67-2). The hope is that preoperative risk assessment and outcome prediction will soon include testing for genetic markers related to individual differences in inflammatory, thrombotic, and vascular responses to stress related to cardiopulmonary bypass (CPB) and to the operation itself.

One example is the prevention of perioperative myocardial infarction (MI). Mechanisms in the pathogenesis of myonecrosis include the complex acute inflammatory response to surgery and CPB. Functional genetic variants in cytokine and leukocyte-endothelial interaction pathways are independently associated with the severity of myonecrosis after cardiac surgery.[11] Increased concentrations of the most extensively studied inflammatory marker, C-reactive protein (CRP), are associated with increased mortality in patients who undergo CABG.[12] Both increased baseline plasma CRP levels and acute phase increase in postoperative plasma CRP levels are genetically determined.[13] Another pathophysiologic process in perioperative MI is coagulation variability with a tendency toward thrombosis. Polymorphisms in platelet activation[14] and thrombin formation[15] have been associated with myocardial injury and with mortality after cardiac surgery.

Genetic factors have been associated with other postoperative complications. Common genetic variants of CRP and interleukin-6 (IL-6) are significantly associated with the risk of stroke[16] and cognitive decline after cardiac surgery.[17] Angiotensin-converting enzyme (ACE) gene polymorphisms predict a patient's risk of respiratory complications that necessitate prolonged mechanical ventilation after cardiac surgery.[18]

In summary, researchers are just beginning to discover genetic and molecular determinants that predispose patients to adverse events after cardiac surgery.[10] Rapid metabolic phenotyping approaches to diagnostic testing may soon be available for use in preoperative risk stratification, as well as real-time intraoperative diagnosis that affects decisions regarding monitoring and surgical and critical care.[19,20]

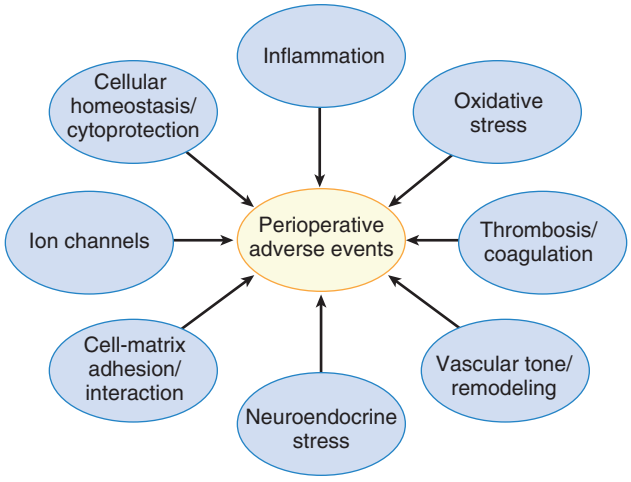

Figure 67-2. Biologic systems and mechanistic pathways genetically associated with perioperative adverse events. *(Redrawn from Podgoreanu MV, Schwinn DA: New paradigms in cardiovascular medicine: emerging technologies and practices: perioperative genomics,* J Am Coll Cardiol *46:1965-1977, 2005.)*

APPROACH TO ANESTHESIA FOR THE ADULT CARDIAC PATIENT

PREOPERATIVE EVALUATION, PREPARATION, AND MONITORING

Heart and Vascular System

Electrocardiography. Standard monitoring of cardiac surgical patients by electrocardiography (ECG) involves using the five-lead electrode system (see Chapter 47). An electrode is placed on each extremity, and one precordial electrode is placed in the V_5 position (on the left anterior axillary line at the fifth intercostal space). Ischemia detection is greatest (75%) with the V_5 lead. This sensitivity increases to 80% when lead II is paired with a V_5 lead.[21] The addition of a second precordial lead, V_4, increases the sensitivity, thus making it possible to detect nearly 100% of ischemic episodes.[22] Currently, most ECG monitors can perform ST-segment analysis automatically with high sensitivity and specificity for detecting ischemia.

Despite appropriate lead selection and the use of automated ST-segment monitoring, perioperative ECG monitoring has important limitations. Visual inspection of the ECG on the monitor has low sensitivity in diagnosing ischemic changes, and automated ST-segment analysis depends on the computer's ability to set the isoelectric and J-point reference points accurately. During cardiac surgical procedures, the set points should be checked before and after bypass, especially persistent changes in heart rate, because the reference points chosen at the beginning of the case may not be accurate under conditions that may arise later.[23]

Arterial and Central Venous Pressure Monitoring. Invasive arterial cannulation and monitoring comprise a standard of care for cardiac surgical patients (see also Chapter 45). Patients' comorbidities often include labile hypertension, atherosclerotic CVD, or both. Furthermore, cardiac surgical technique frequently causes sudden, rapid changes in arterial blood pressure resulting from factors such as direct compression of the heart, impaired venous return caused by retraction and cannulation of the great

vessels, and arrhythmias resulting from mechanical stimulation.[24] In addition, sudden, significant blood loss may induce hypovolemia and hypotension. Finally, during nonpulsatile CPB, noninvasive blood pressure recordings are not accurate. Intraarterial monitoring provides continuous, real-time, beat-to-beat assessment of arterial perfusion pressure and waveform throughout the cardiac surgical procedure. Having an indwelling arterial catheter also enables the frequent drawing of arterial blood for laboratory analyses.[24]

Although the radial artery is the most commonly accessed site, the femoral, brachial, ulnar, dorsalis pedis, posterior tibial, and axillary arteries can also be used. The pressures measured in the peripheral arteries are different from the central aortic pressure because the arterial waveform becomes progressively more distorted as the signal is transmitted down the arterial system.[24] Although the mean arterial pressure (MAP) measured in the peripheral arteries is usually similar to the central aortic pressure, this may change after CPB is initiated.[25] When cannulating a radial artery, one should consider the native state of the collateral circulation in the hand and the possible surgical use of a radial artery free graft as an arterial conduit. If a radial arterial graft is to be harvested, it is usually taken from the nondominant hand or arm; thus, the arterial line should be placed on the dominant side.

Central venous access is also standard of care during cardiac surgery. In addition to monitoring central venous pressure (CVP), central venous access provides a portal for intravascular volume replacement, pharmacologic therapy, and the insertion of other invasive monitors, such as pulmonary artery (PA) catheters. In addition, a CVP catheter can be used to measure the filling pressure of the right ventricle and estimate intravascular volume status.[24] Although the CVP does not directly reflect left-sided heart filling pressure, it may be used as an estimate of left-sided pressures in patients with good left ventricular (LV) function. Following trends is more useful than relying on an individual measurement.[24] In many patients, using a central venous catheter may offer a better risk-to-benefit ratio than using a PA catheter.[26] For the accurate measurement of pressure, the distal end of the catheter must lie within one of the large intrathoracic veins or the right atrium.[24]

An internal jugular vein is most commonly selected for catheterization because it provides ease of approach and optimal distance from the operative field. A femoral or subclavian vein can be considered as well, but groin access can be challenging in obese patients and may be inappropriate if femoral bypass cannula placement or vein graft harvesting is necessary. The subclavian approach is also imperfect because it is associated with an increased risk of catheter obstruction during sternal retraction.

The use of ultrasound is being rapidly adopted throughout the United States for facilitating the placement of central venous catheters and reducing the complications associated with them.[27] Although ultrasound-guided central catheter placement is easily accomplished and appears to improve patients' outcomes, concerns regarding the associated costs of the required hardware and training are reasons for the lack of universal adoption of this technique (Box 67-1).

BOX 67-1 ***Some of the Recognized Benefits of and Concerns About Ultrasound-Guided Central Venous Cannulation***

BENEFITS*

Greater success rate on first attempt
Fewer overall attempts
Better access in patients with difficult neck anatomy (e.g., resulting from obesity or prior surgery)
Fewer complications (e.g., carotid artery puncture, anticoagulant-enhanced bleeding)
Visible vessel patency, anatomic variants
Relatively inexpensive technology

CONCERNS

Need for personnel to be trained to maintain aseptic technique when using sterile probe sheaths
Requirement for additional training
Inability to show surface anatomy
Potential loss of landmark-guided skills when needed for emergency central venous catheterization

Modified from Kaplan JA, Reich DL, Savino JS, editors: Kaplan's cardiac anesthesia: the echo era, *ed 6, St. Louis, 2011, Saunders, p 426.*
*Ultrasonic guidance of internal jugular vein cannulation can be particularly advantageous in patients with difficult neck anatomy (e.g., short neck, obesity) or prior neck surgery, anticoagulated patients, and infants.

BOX 67-2 ***Conditions Resulting in Discrepancies Between Pulmonary Capillary Wedge Pressure and Left Ventricular End-Diastolic Pressure***

PCWP > LVEDP

Positive-pressure ventilation
PEEP
Increased intrathoracic pressure
Non-West lung zone III PAC placement
Chronic obstructive pulmonary disease
Increased pulmonary vascular resistance
Left atrial myxoma
Mitral valve disease (e.g., stenosis, regurgitation)

PCWP < LVEDP

Noncompliant left ventricle (e.g., ischemia, hypertrophy)
Aortic regurgitation (premature closure of the mitral valve)
LVEDP > 25 mm Hg

Modified from Tuman KJ, Carroll CC, Ivankovich AD: Pitfalls in interpretation of pulmonary artery catheter data, Cardiothorac Vasc Anesth Update *2:1, 1991.*

PULMONARY ARTERY CATHETERIZATION. The PA catheter is a flow-directed catheter typically placed through an introducer in the central venous compartment via the internal jugular, subclavian, or femoral vein (see also Chapter 45). This catheter can measure PA pressure (PAP), CVP, and pulmonary capillary wedge pressure (PCWP). However, the PCWP can both overestimate and underestimate LV filling pressure (Box 67-2). Some PA catheters are designed with a thermistor to register blood temperature changes, which are used to calculate right-sided heart cardiac output (CO)

or ejection fraction (EF) by thermodilution. PA catheters may also have oximetric capabilities to measure mixed venous oxygen saturation ($S\bar{v}O_2$). Thus, a PA catheter can be used to assess intravascular volume status, measure CO, measure $S\bar{v}O_2$, and derive hemodynamic parameters.[24]

The CO, the amount of blood delivered to the tissues by the heart, is of particular interest to cardiac anesthesiologists. The product of stroke volume and heart rate, CO is affected by preload, afterload, heart rate, and contractility. PA catheters capable of measuring CO continuously were introduced into clinical practice in the 1990s.[24] The correlation of continuous CO measurements with those measurements obtained by using the intermittent thermodilution method is good in physiologically and thermally stable prebypass and postbypass periods.

Continuous monitoring of $S\bar{v}O_2$ provides a means to estimate the adequacy of oxygen delivery relative to oxygen consumption.[24] Decreases in $S\bar{v}O_2$ may indicate decreased CO, increased oxygen consumption, decreased arterial oxygen saturation, or decreased hemoglobin concentration. If it is assumed that oxygen consumption and arterial oxygen content are constant, changes in $S\bar{v}O_2$ should reflect changes in CO.[24] However, London and colleagues found that continuous $S\bar{v}O_2$ monitoring did not lead to better outcomes than standard PA catheter monitoring.[28]

Pacing PA catheters are also commercially available. Electrode PA catheters include five electrodes for atrial, ventricular, or atrioventricular (AV) sequential pacing. Paceport PA catheters (Edwards Lifesciences, Irvine, CA) have a port for the insertion of a ventricular wire or of both atrial and ventricular wires for temporary pacing.

The risk-to-benefit ratio involved in using PA catheters has been a subject of controversy since the 1990s. Complications of PA catheter placement include those mentioned in the section on CVP placement, as well as transient arrhythmias, complete heart block, pulmonary infarction, endobronchial hemorrhage, thrombus formation, catheter knotting and entrapment, valvular damage, and thrombocytopenia.[24] In addition, a common complication is incorrect interpretation of the data obtained from the PA catheter, with resultant incorrect treatment of the patient.[29] Schwann and colleagues published a large, international, prospective observational study showing that using a PA catheter was associated with a more frequent risk of a composite mortality and morbidity outcome than using a CVP alone in patients undergoing CABG surgery.[26] Smaller observational trials have also associated the PA catheter with increased morbidity and decreased survival in cardiac surgical patients.[30,31]

Currently, the trend in the United States is to be selective in deciding which patients may benefit from a PA catheter, especially with the widespread use of transesophageal echocardiography (TEE). Absolute contraindications to PA catheter placement include tricuspid or pulmonic valvular stenosis, right atrial (RA) or right ventricular (RV) masses, and tetralogy of Fallot.[24] Relative contraindications include severe arrhythmias and newly inserted pacemaker wires (which may be dislodged by the catheter during insertion). Clearly, patients undergoing low-risk cardiac surgical procedures can be managed safely without PA catheter placement.[24] However, many cardiac surgeons and anesthesiologists still use the device in high-risk cardiac operations and in patients with right-sided heart failure (HF) or pulmonary hypertension, particularly to assist in postoperative management (Box 67-3).

BOX 67-3 ***Possible Clinical Indications for Pulmonary Artery Catheter Monitoring***

Major procedures involving large fluid shifts or blood loss in patients with

Right-sided heart failure, pulmonary hypertension
Severe left-sided heart failure not responsive to therapy
Cardiogenic or septic shock or multiple organ failure
Hemodynamic instability requiring inotropes or intraaortic balloon counterpulsation
Surgery of the aorta requiring suprarenal cross-clamping
Hepatic transplantation
Orthotopic heart transplantation

Transesophageal Echocardiography. TEE is used in many, if not most, cardiac surgical procedures in the current era. See Chapter 46 for a thorough discussion of this extraordinarily valuable diagnostic and monitoring modality.

Central Nervous System

Risk for Injury. The incidence of overt postoperative stroke after isolated CABG decreased significantly from 1.6% in the year 2000 to 1.2% in the year 2009, despite the greater prevalence of diabetes mellitus and hypertension in the current era.[32] A more subtle entity, postoperative cognitive decline (POCD), has also been described in numerous studies.[33] However, the measurement of POCD is complicated by variations in the tests used to assess cognitive function, the timing of these tests, and the diagnostic and statistical definitions of decline.[34] Furthermore, studies have shown that compared with nonsurgical and healthy controls, patients who undergo CABG have similar rates of cognitive decline 1 year postoperatively.[35,36]

Risk factors for CNS injury or dysfunction after cardiac surgery are listed in Box 67-4.[37] The most common cause is thought to be particulate or microgaseous emboli.[38,39] Other factors include cerebral hypoperfusion, particularly in patients with cerebrovascular disease, and the inflammatory response to surgery and CPB.[40,41]

Monitoring

Transesophageal and Epiaortic Echocardiography. TEE allows direct visualization of the first segment of the ascending aorta, the middle distal segment of the aortic arch, and a good portion of the descending thoracic aorta. However, the distal segment of the ascending aorta and the proximal midportion of the aortic arch cannot be visualized well because of the interposition of the trachea and bronchi between the TEE probe and these aortic structures. Instead, epiaortic imaging with a handheld, high-frequency probe placed over the ascending aorta or

Grade 4	Atheroma protruding ≥5 mm into the lumen
Grade 5	Atheroma of any size with a mobile component

Modified from Béique FA, Joffe D, Tousignant G, Konstadt S: Echocardiography-based assessment and management of atherosclerotic disease of the thoracic aorta, J Cardiothorac Vasc Anesth *12:206-220, 1998.*

aortic arch can be used to visualize aortic segments that are in the TEE probe's "blind spot."

The echocardiographic finding of atheromatous disease of the aorta has been linked to CNS injury in cardiac surgical patients.[42] Atherosclerosis of the ascending aorta is present in 20% to 40% of cardiac surgical patients, and the percentage increases with age. The severity of atheromatous disease of the aorta is a strong predictor of death and stroke after CABG (Table 67-1).[43] Using TEE to guide cannula placement or surgical technique significantly reduced the stroke rate in a series of 500 consecutive patients compared with controls in a statewide database.[44] Avoiding instrumentation of the ascending aorta (the "no touch technique") in patients with severe aortic atherosclerosis has been advocated.[45] The addition of epiaortic scanning of the ascending aorta increases the sensitivity of intraoperative echocardiography in identifying significant atheromatous disease in this segment of the aorta. Certainly, this combination of techniques is superior to surgical palpation in detecting such disease.[46]

CEREBRAL OXIMETRY. Cerebral oximetry uses near-infrared spectroscopy technology similar to that used in pulse oximeters (see also Chapter 49). Light-emitting electrodes are placed on the patient's forehead, lateral to the midline, and over both frontal cortices. Because the skull is translucent to infrared light, and because oxygenated blood and deoxygenated blood have different absorption characteristics when exposed to infrared light of two different wavelengths, regional cerebral oxygen saturation (rSO_2) can be computed from the returning signal. The design of the cerebral oximeter enables it to measure change from the patient's own established baseline and to monitor both frontal lobes simultaneously.

The use of near-infrared spectroscopy has been studied in the perioperative setting; a relative decrease in rSO_2 to less than 80% of the preoperative baseline or to absolute levels less than 50% increased the incidence of adverse postoperative outcomes.[47,48] These outcomes include POCD,[49] stroke,[50] organ dysfunction, mortality,[51,52] and length of hospital stay.[53] A physiologically derived treatment algorithm for management of perioperative cerebral oxygen desaturation has been proposed (Fig. 67-3).[54] As noted by Murkin,[37] an important confounder in evaluating the role of monitoring cerebral oximetry is the efficacy of treatment for cerebral desaturation.

A baseline rSO_2 that is low even though the patient is breathing supplemental oxygen (absolute value ≤50%) is an independent risk factor for 30-day and 1-year mortality.[55] A baseline rSO_2 could act as a refined marker for preoperative risk stratification and help clinicians identify patients who require more intensive monitoring and care in the postoperative period.[55,56]

TRANSCRANIAL DOPPLER. Transcranial Doppler (TCD) involves the ultrasonic interrogation of blood flow velocity through the middle cerebral or common carotid arteries as an indirect measure of cerebral blood flow.[47] The technology has been used extensively as a research tool. For example, in conjunction with cerebral oximetry, TCD has been used to delineate the limits of cerebral autoregulation during CPB.[57] TCD can also detect cerebral emboli. Contrary to previous information, an association between TCD-detected emboli and POCD is questionable.[58,59]

A primary limitation of TCD technology has been its inability to discern gaseous from solid emboli.[47,58] Other general limitations of TCD technology include the following: (1) the quality of information is heavily user dependent; (2) accuracy requires stable and precise probe placement, which can be quite cumbersome; and (3) information is affected by patient-related characteristics, such as skin thickness. These difficulties have limited use of this technology in the perioperative setting.[47]

ELECTROENCEPHALOGRAPHY AND BISPECTRAL INDEX MONITORING. The electroencephalogram (EEG), recorded from multiple adhesive or screw-in scalp electrodes, represents surface cerebral cortical activity (see also Chapters 13 and 14). Awake patients produce a pattern of EEG readings that differs from the pattern produced by patients who are under anesthesia. Establishing a baseline and monitoring the changes from that baseline form the premise of EEG monitoring. Changes in the frequency of EEG signals (slower brain waves) and the reduction of wave amplitude may indicate changes in cortical neuronal function that warrant concern.

Multichannel EEG monitoring is not routinely used in cardiac surgery. However, a resurgence of interest in single- or dual-channel processed EEG monitoring, such as the bispectral index (BIS), has occurred.[47,60,61] The BIS has been studied as a means to monitor for intraoperative awareness, to reduce overall anesthetic consumption, and to provide information on cerebral perfusion. However, controversy surrounds the usefulness of BIS monitoring in reducing intraoperative awareness.[47,62-64] Similarly, the effectiveness of BIS monitoring in either guiding the safe reduction of anesthetic dosing or contributing to the success of fast tracking has not been demonstrated by randomized clinical trials in cardiac surgical patients.[60]

With respect to cerebral ischemia, sudden EEG changes during cardiac surgery and CPB can be attributable to correctable problems such as superior vena cava (SVC) obstruction or severe decrease in CO.[60] The latest iteration of the BIS monitor incorporates bilateral frontal EEG channels, which may increase its ability to detect unilateral frontal ischemia, especially if anesthesia is stable, if the insult is sudden, extended, or located in the frontal area, and if the preoperative EEG was normal.[60,65] However, many variables may confuse EEG interpretation during cardiac surgery. These include hypothermia, the pharmacologic suppression of EEG signals, and interference produced by pump mechanics. In addition, the EEG measures only cortical activity, so ischemic or embolic injury that occurs below the level of the cortex may go undetected. Therefore, the EEG and derived indices are neither sensitive nor specific in detecting cerebral ischemia.[60]

Summary. Currently, evidence-based recommendations cannot be made regarding the efficacy of treatment for abnormal values. Although not yet recognized as a clinical standard of care, neuromonitoring will likely continue to be the subject of significant research effort.

Renal System

Acute kidney injury (AKI) after cardiac surgery remains a significant cause of postoperative morbidity, increased cost of care, later development of chronic kidney disease, and short-term as well as long-term mortality (see also Chapter 101).[66] Although the pathogenesis of AKI is multifactorial,

control of some specific factors may limit its incidence in cardiac surgical patients. Bellomo and associates identified six major injury pathways of cardiac surgery–associated AKI: toxins (both exogenous and endogenous), metabolic factors, ischemia-reperfusion injury, neurohormonal activation, inflammation, and oxidative stress.[67]

Randomized trials of specific potential preventive measures for AKI after cardiac surgery are few. Certainly, all potentially nephrotoxic drugs should be avoided in the perioperative period (Box 67-5).[66,68] Hydration is, of course, a universally accepted component of strategies to prevent contrast nephropathy.[68] Unfortunately, no pharmacologic strategy has definitive efficacy in preventing early AKI.[68] Atherosclerosis of the ascending aorta appears to be an independent risk factor for AKI.[67]

Intraoperative TEE should be used to identify patients at increased risk for thromboembolic phenomena.[67,68] Although observational studies have suggested a possible benefit of off-pump procedures and avoidance of aortic manipulation, definitive evidence is lacking.[67,68] For cardiac surgical cases that require CPB, the duration of aortic cross-clamping should be limited if possible, especially in patients who are at a higher-than-normal risk for renal complications, such as patients with preexisting renal insufficiency.[67] Hemodynamic instability should be addressed quickly, and intravascular volume should be maintained or rapidly restored.[67,68] Finally, perioperative hyperglycemia should be avoided.[67,68]

Clearly, definition of measures that may prevent AKI after cardiac surgery is needed.[67,68] The cost of this complication to the patient and to society is probably higher than previously thought.[66]

Endocrine System

Glucose Control. Hyperglycemia in surgical patients is a consequence of the inflammatory or stress response to the trauma of surgery. Components of this response include an endocrine response (i.e., increased production of counterregulatory hormones such as cortisol, growth hormone, glucagon, and catecholamines) (Fig. 67-4), an immune response resulting in increased cytokine production, an autonomic response resulting in increased sympathetic stimulation, and altered insulin signaling. These changes increase glucose production, decrease glucose elimination during CPB, and induce insulin resistance, thereby causing hyperglycemia.[69]

All patients are at risk for developing hyperglycemia during cardiac surgery. Older patients, diabetic patients, and patients with CAD are particularly prone to perioperative hyperglycemia. Although cardiac surgery without CPB initiates a stress response, CPB increases this response manyfold.[69] The degree of hyperglycemia depends on several variables associated with the use of CPB, such as the pump prime fluid selected and the degree of hypothermia induced. Epinephrine and other inotropic drugs may contribute to hyperglycemia after CPB by stimulating hepatic glycogenolysis and gluconeogenesis.

Impaired fasting glucose blood levels before cardiac surgery and persistently increased glucose levels during and immediately after surgical procedures are predictive of longer hospital stay and increased perioperative morbidity and mortality in both diabetic and nondiabetic patients.[70,71] However, in diabetic patients undergoing cardiac operations, hyperglycemia may only partly explain the increased risk for adverse outcomes.[71] Immunologic abnormalities common to diabetic patients, such as decreased chemotaxis, phagocytosis, opsonization, bacterial killing, and antioxidant defense, also promote adverse outcomes by increasing diabetic patients' risk of infection.[72]

Glucose blood levels should be controlled, beginning in the preoperative period and continuing until discharge.[73] However, in a classic study, patients were randomly assigned to intensive intraoperative insulin treatment (to maintain glucose levels at 80 to 100 mg/dL) or to standard insulin treatment (to keep glucose levels <200 mg/dL).[74] Surprisingly, the investigators reported a statistically nonsignificant increase in the incidence of death and stroke in the group receiving intensive insulin treatment. The precise value necessary for achieving glycemic control during surgical procedures is not well defined.[71,75] Current Society of Thoracic Surgeons (STS) guidelines state that blood glucose levels should be kept lower than 180 mg/dL throughout the perioperative period.[76] Some cardiac surgical centers more aggressively administer continuous insulin infusions in an attempt to keep glucose levels lower than 150 mg/dL.

Thyroid Hormone. Abnormal thyroid function ultimately affects cardiac function in many ways (Table 67-2). During cardiac surgery, the effect of CPB on thyroid hormone production is uncertain. Both increased and decreased levels of thyroid hormone can occur during or immediately after CPB. Free triiodothyronine (T_3), the biologically active form of the thyroid hormone, is frequently reduced in cardiac patients because of the reduced activity of the 5′-monodeiodinase responsible for converting thyroxine (T_4) into T_3 in peripheral tissues.[77] This low T_3 syndrome has been described in patients with impaired contractility and enhanced risk for MI and HF, as well as in adults and children after CPB.[78] Preexisting

thyroid dysfunction can occasionally be severely aggravated by CPB because of hypothermia, nonpulsatile blood flow, and reduced conversion of T_4 to T_3.

Notably, hypothyroidism is more common in female than in male patients undergoing CABG.[79] Zindrou and associates noted a 17% higher mortality rate in women who underwent CABG while receiving thyroxine replacement therapy for hypothyroidism.[80] A review of the literature by Edwards and colleagues concluded that ensuring a perioperative euthyroid state in women with hypothyroidism who were undergoing CABG could be helpful in reducing the perioperative mortality of these patients.[5] Although subclinical hypothyroidism and low T_3 syndrome have an effect on CABG outcome in both women and men, further studies are needed before routine preoperative evaluation of thyroid function can be recommended.[81]

Hematologic System

Bleeding is the primary complication of cardiac operations that require CPB (see also Chapter 62). In fact, 10% to 15% of blood product use in the United States is associated with cardiac surgery, and this fraction is increasing, largely because of the increasing complexity of cardiac surgical procedures.[82] Real-world data obtained from a large sample of patients and entered into STS Adult Cardiac Surgery Database suggest that 50% of patients who undergo cardiac surgical procedures receive a blood transfusion. Complex cardiac operations such as "redo" procedures, aortic operations, and the implantation of ventricular assist devices (VADs) require blood transfusion much more often than do simpler operations.[83,84] Donor blood is viewed as a scarce resource that is associated with increased health care costs and significant risk to patients (see also Chapters 61 to 63). Furthermore, perioperative blood transfusion is associated with worse short-term and long-term outcomes.[85,86] Hence, reducing bleeding and blood transfusions has become a major focus of quality improvement efforts in cardiac surgery.[82]

Heparin as an Anticoagulant

Overview of Heparin. Since its discovery by Jay McLean, MD, in 1915, heparin has stood the test of time and remains the primary anticoagulant used in cardiac operations that require CPB. The mechanism underlying heparin's anticoagulant effect centers on the heparin molecule's ability to bind simultaneously to antithrombin III and thrombin. Modern nomenclature refers to antithrombin III as antithrombin (AT). The binding process is mediated by a unique pentasaccharide sequence that binds to AT. The proximity of AT and thrombin, mediated by the heparin molecule, allows AT to inhibit the procoagulant effect of thrombin by binding to the active-site serine residue of the thrombin molecule.[87] The inhibitory effect of AT is increased 1000-fold in the presence of heparin. The heparin-AT complex can affect several coagulation factors, but factor Xa and thrombin are the most sensitive to inhibition by heparin, and thrombin is 10 times more sensitive to the inhibitory effects of unfractionated heparin than is factor Xa.[88]

Only approximately one third of the heparin molecules in a dose of heparin contain the critical pentasaccharide segment that is needed for high-affinity binding to AT.[89] Thus, relatively large doses are required to produce the anticoagulant effect necessary for CPB. In fact, dosing of heparin for CPB is somewhat empiric. After a baseline activated clotting time (ACT) is measured (the normal range is 80 to 120 seconds), a dose of 300 to 400 units/kg of heparin is given as an intravenous bolus. Commercially available assays are used for calculating the patient's dose-responsiveness to heparin in vitro. Some practitioners administer heparin at the dose that is indicated by such an in vitro dose-response assay. Subsequent heparin dosing for extracorporeal circulation (ECC) is targeted at maintaining ACT values longer than 480 seconds. Also available is a heparin concentration monitor that uses protamine titration analysis for ex vivo calculation of the whole blood heparin concentration. This result is often used as an adjunct to the ACT value of 480 seconds in confirming an adequate heparin concentration for CPB. Unfortunately, ACT test results vary substantially with clinical conditions and the particular platform used for measurement. Thus, the evidence supporting the use of a threshold of 480 seconds is almost entirely anecdotal.

The dose of heparin used in patients on CPB is based on early landmark work published by Bull and coauthors in 1975.[90] A small study that sought evidence of thrombin activity during CPB in nonhuman primates and pediatric patients found results supporting a safe lower limit for ACT of 400 seconds.[91] In 1979, Doty and colleagues proposed a simplified dosing regimen guided by ACT values without dose-response curves.[92] The data and recommendations from these few studies constitute the primary basis for current heparin dosing protocols.

Despite heparin's historic and continued role in anticoagulation for patients maintained on CPB, it is not a perfect anticoagulant. Intrinsic and extrinsic pathway coagulation occurs despite heparin administration, and platelets can still be activated by contact with bypass circuitry and by heparin directly.[93,94] Alternative anticoagulants are discussed briefly in the section on heparin-induced thrombocytopenia (HIT).

Monitoring of Anticoagulation. Using ACT to monitor the effectiveness of heparin is not an exact science (see also Chapter 62). Tremendous variability is observed in patients' anticoagulation responses to a given dose of heparin; reasons for this variability include variations in levels of heparin-binding proteins and AT. Hence, ACT values correlate poorly with actual heparin concentrations. Nevertheless, since the publication of Bull and colleagues' early work,[90] ACT has been the mainstay of anticoagulation monitoring in cardiac operations that require CPB.

Many different ACT measurement devices are commercially available, and each uses a different platform for clot detection and endpoint signaling. However, they all involve the addition of whole blood to a tube or channel containing a contact-phase activator. The activator can be celite, kaolin, glass, or any combination thereof. The sample is warmed to 37° C before the measurement technique is performed. Clot formation occurs, and the measurement ends when a change in velocity, pressure, oscillation, electromagnetic forces, or even color is observed, depending on the particular platform of measurement.[95]

Several clinical variables can affect the ACT (Table 67-3). In addition to physiologic variations, the design of ACT measurement devices (which varies across their many manufacturers) also affects ACT normal and therapeutic values. ACTs also correlate poorly with whole blood and plasma heparin levels, and responses to heparin differ somewhat between adult and pediatric

TABLE 67-3 CLINICAL VARIABLES THAT CAN AFFECT THE ACTIVATED CLOTTING TIME

Hemodilution	Prolongs ACT in heparinized patients
Hypothermia	Prolongs ACT
Thrombocytopenia	Prolongs ACT
Platelet inhibitors	Prolongs ACT
Platelet lysis	Shortens ACT
Aprotinin	Prolongs only celite ACT
Surgical stress	Shortens ACT

ACT, Activated clotting time.

patients.[96] Some authors argue that, because of its poor correlation with heparin concentration, ACT alone is not an adequate monitor of heparin efficacy, and that simultaneous or adjunct monitoring of heparin concentration should also be used during CPB. Prolongation of ACT by non–heparin-related clinical factors, such as hypothermia, hemodilution, or quantitative or qualitative platelet abnormalities, is a well-documented phenomenon, and the anesthesiologist must understand these factors to determine whether it is safe to reduce the heparin dose when the ACT is prolonged. The poor correlation between ACT and measured heparin concentration also makes it possible that a dose reduction will render the heparin concentration inadequate, even when the ACT remains within an acceptable range.

Some point-of-care (POC) monitors, such as the Hepcon HMS system (Medtronic Perfusion Systems, Minneapolis, Minn.), use a protamine titration assay to calculate the heparin concentration. Despotis and associates suggest that monitoring and maintaining heparin concentration—and thus giving larger doses of heparin—actually protect the hemostatic system and may decrease transfusion requirements.[97] However, other investigators have not been able to confirm that higher doses of heparin confer better hemostatic protection; markers of ongoing coagulation are essentially the same whether traditional ACT monitoring or heparin concentration monitoring is used.[98]

The high-dose thrombin time (HiTT) is a modification of the thrombin time that is designed to measure the high levels of heparin that are used during CPB.[99] Unlike ACT, the HiTT correlates well with heparin concentration, both before and during CPB, and it is not affected by hemodilution and hypothermia. As a measure of thrombin inhibition, the HiTT is a more specific test of heparin's effect on thrombin than ACT, and it appears to possess less artifactual variability.[94] Aprotinin and preoperative heparin infusions do not affect HiTT values.[99]

Protamine and Reversal of Anticoagulation. Protamine, which has been in clinical use for as long as heparin has, remains the heparin reversal drug of choice in cardiac surgery. The protamine dose required to reverse heparin is somewhat controversial. In the first published study to examine this question, Bull and associates chose a dose of 1.3 mg protamine for every 100 units of heparin to provide a slight excess of protamine from a projected needed amount of 1.2 mg for every 100 units of heparin.[100] In current practice, dosing usually follows one of the following protocols:

1. Protamine is administered according to the total amount of heparin given (i.e., 1 to 1.3 mg protamine per 100 units of heparin). This method may result in luxuriant protamine doses, which reduce any theoretic or real risks of heparin rebound but may put the patient at higher risk for bleeding events because of the anticoagulant effect of protamine.[95,101]
2. Protamine is administered at a dose calculated from the heparin concentration, which is measured by a protamine titration assay. If the heparin concentration is not measured, the protamine dose can be graphically derived by plotting ACT values throughout the case and creating heparin dose-response curves. The amount of protamine used in this method is based on the circulating concentration of heparin in the patient at the time of reversal. Because, theoretically, no excess protamine exists, these patients may be at risk for heparin rebound and therefore may require additional protamine. In a small study conducted in patients undergoing valve surgery, administering protamine in two divided doses by titration resulted in a larger dose but reduced bleeding, presumably by treating heparin rebound.[102]

Unique Hematologic Considerations in Cardiac Surgery.

Hematologic Effects of Cardiopulmonary Bypass. The hematologic effects of CPB are myriad. Exposure of blood to the surfaces of the extracorporeal circuit is a profound stimulus for inflammatory up-regulation, and activation of the hemostatic system is a component of the normal inflammatory response. According to traditional models of hemostasis, ECC activates both the intrinsic and extrinsic coagulation pathways and directly impairs platelet function. Intrinsic pathway activation can occur by contact activation and the conversion of factor XII to factor XIIa on the various surfaces of the CPB circuit.[103] The tissue factor generated from the wound and the circulating tissue thromboplastin combine to cause the extrinsic activation of coagulation by cell-mediated hemostasis, which involves tissue factor–bearing leukocytes and activated endothelial cells. Tissue factor pathway generation of thrombin has a primary role in CPB-associated hemostasis abnormalities (Fig. 67-5).[103,104]

In addition to activating both extrinsic and intrinsic coagulation pathways, CPB directly impairs platelet function through a variety of mechanisms. Platelets express on their surface numerous glycoproteins that serve as receptors for several circulating ligands, such as fibrinogen, thrombin, and collagen (Fig. 67-6).[103] The components of the bypass circuit adsorb circulating proteins that can serve as foci for platelet attraction and adherence. These surface-bound platelets activate and release the contents of their cytoplasmic granules, which can then serve as localized sources of thrombin generation, or they may embolize to initiate microvascular thrombosis.[103]

Fibrinolytic activity is also increased by CPB. Contact activation leads to the activation of factor XII, prekallikrein, and high-molecular-weight kininogen (HMWK), which causes endothelial cells to produce tissue plasmin activator (t-PA), and lysis of fibrin and fibrinogen ensues (Fig. 67-7).[103]

The vascular endothelium is itself an active substrate that is sensitive to circulating mediators, and it expresses and releases anticoagulant and procoagulant factors. When exposed to hypoxia or inflammatory mediators during CPB, the endothelium responds and can induce a relatively prothrombotic state marked by tissue factor up-regulation, accelerated platelet adhesion, and increased expression of leukocyte adhesion molecules (Fig. 67-8).[103,105]

Heparin Resistance, Altered Heparin Responsiveness, and Antithrombin. Heparin resistance is marked by the inability to raise the ACT to therapeutic levels after administration of the recommended doses of unfractionated heparin. Some investigators have defined heparin resistance as an ACT of less than 480 seconds after 500 units/kg of intravenous heparin are administered.[106,107]

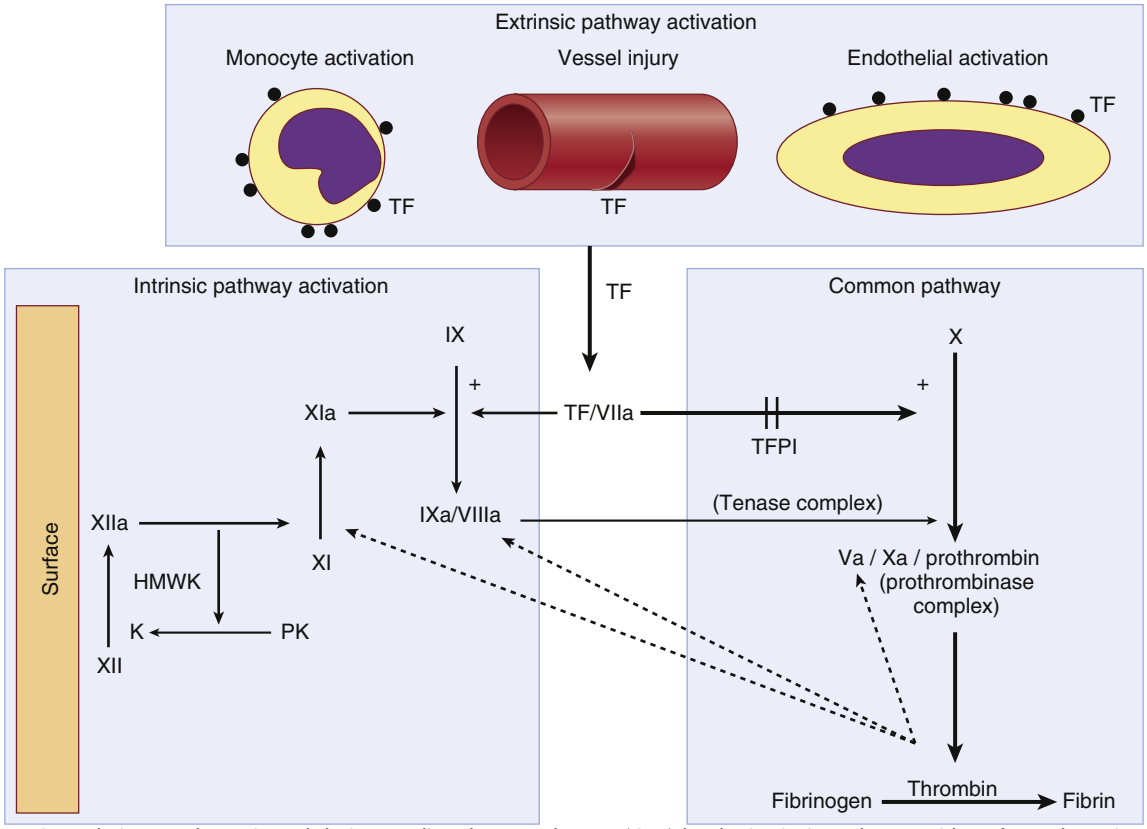

Figure 67-5. Coagulation can be activated during cardiopulmonary bypass (CPB) by the intrinsic pathway, with surface adsorption and activation of factor XII, high-molecular-weight kininogen (HMWK), and prekallikrein (PK). Activation of the extrinsic pathway during CPB occurs with tissue injury, as well as with systemic inflammation, and it leads to monocyte and endothelial expression of tissue factor (TF). TF, in combination with factor VIIa, starts the common pathway with the activation of factor X to factor Xa. Assembly of the prothrombinase complex on phospholipid surfaces leads to the production of thrombin and conversion of fibrinogen to fibrin. Tissue factor pathway inhibitor (TFPI) inhibits TF/VIIa. Thrombin can overcome this TFPI blockade by activating factors XI, VIII, and V and initiating activation of factor X by the tenase complex. *K,* Kallikrein. *(From Kottke-Marchant K, Sapatnekar S: Hemostatic abnormalities in cardiopulmonary bypass: pathophysiologic and transfusion considerations,* Semin Cardiothorac Vasc Anesth *5:187-206, 2001.)*

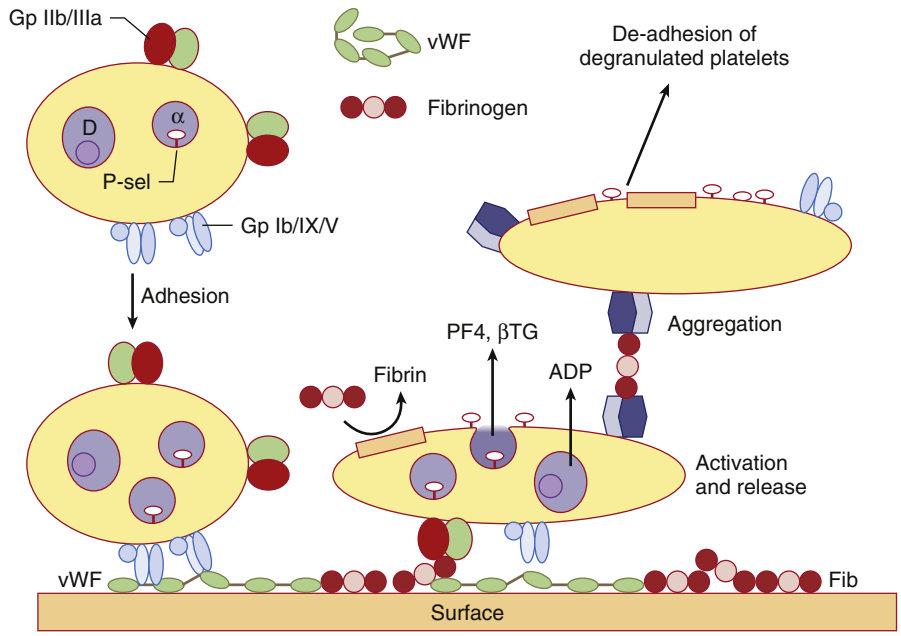

Figure 67-6. Platelet activation by cardiopulmonary bypass materials is facilitated by rapid adhesion and conformational alteration of plasma proteins, including von Willebrand factor (vWF) and fibrinogen (Fib). Platelets adhere to vWF through the glycoprotein (Gp) Ib/IX/V surface glycoprotein and to fibrinogen through the Gp IIb/IIIa receptor. Platelet adhesion stimulates intracellular signaling, which leads to degranulation of α granules (platelet factor 4 [PF4] and β-thromboglobulin [βTG]) and phospholipid reorganization with the formation of coagulation complexes and fibrin formation. Release of adenosine diphosphate (ADP) from dense granules and activation of the Gp IIb/IIIa receptor also occur and lead to the aggregation of platelets to the adherent layer. Because of shear forces, adherent and aggregated platelets can detach from the membrane and circulate in a degranulated state or form small microaggregates that lodge in the distal vasculature. *(From Kottke-Marchant K, Sapatnekar S: Hemostatic abnormalities in cardiopulmonary bypass: pathophysiologic and transfusion considerations,* Semin Cardiothorac Vasc Anesth *5:187-206, 2001.)*

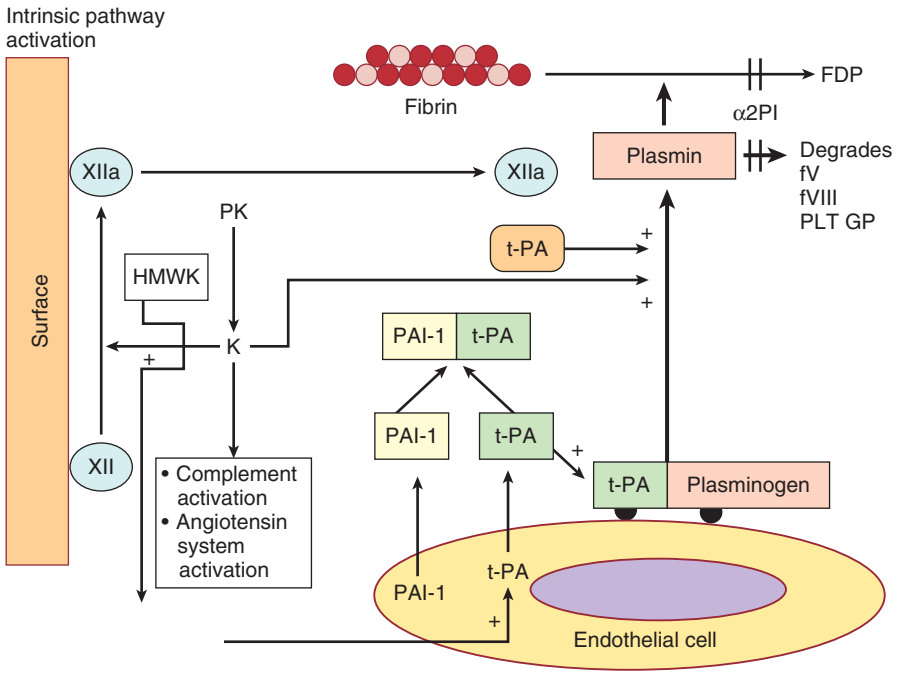

Figure 67-7. The fibrinolytic system results in the degradation of fibrin by plasmin. The intrinsic factors participate in the fibrinolytic system. Adsorption and activation of factor XII, high-molecular-weight kininogen (HMWK), and prekallikrein (PK) occur on the cardiopulmonary bypass material surfaces. Kallikrein (K) and factor XIIa participate in the conversion of plasminogen to plasmin. Plasminogen is also activated by tissue plasminogen activator (t-PA), which is released from endothelial cells, along with its inhibitor, plasminogen activator inhibitor-1 (PAI-1). Plasmin degrades not only fibrin but also coagulation factors V and VIII (fV and fVIII) and platelet surface glycoproteins (PLT GP). Kallikrein plays additional roles in the activation of complement and the angiotensin system, and HMWK accelerates fibrinolysis by stimulating endothelial production of t-PA. *FDP,* Fibrin degradation product; *α2PI*, α2 plasmin inhibitor. *(From Kottke-Marchant K, Sapatnekar S: Hemostatic abnormalities in cardiopulmonary bypass: pathophysiologic and transfusion considerations,* Semin Cardiothorac Vasc Anesth *5:187-206, 2001.)*

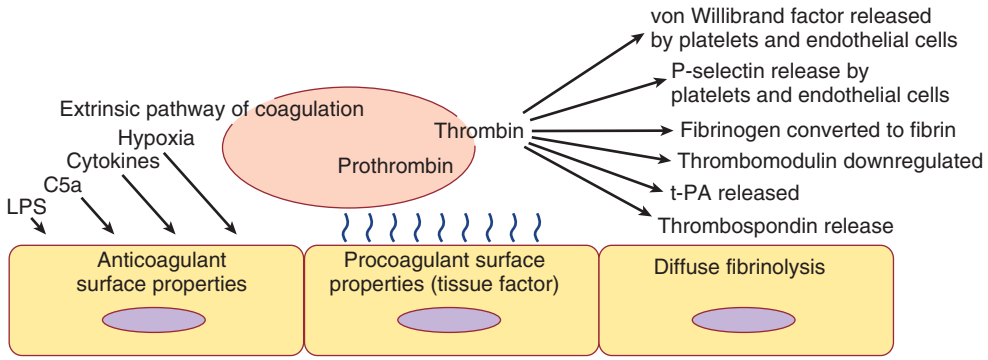

Figure 67-8. Procoagulant endothelial cell activation. When endothelial cells are activated, they express tissue factor, which converts prothrombin to thrombin. Thrombin has multiple biologic actions: (1) stimulation of the release of von Willebrand factor and P-selectin, which cause platelet clumping and platelet, neutrophil, and endothelial cell adhesion; (2) conversion of fibrinogen to fibrin, the solid component of clot; (3) down-regulation of the thrombomodulin/protein C and S systems; (4) release of tissue plasminogen activator (t-PA), which catalyzes the formation of plasmin; and (5) release of thrombospondin, which binds to t-PA, prevents its breakdown by plasminogen activator inhibitor-1 (PAI-1), and accelerates the formation of plasmin. *LPS,* Lipopolysaccharide. *(From Boyle EM Jr, Verrier ED, Spiess BD: Endothelial cell injury in cardiovascular surgery: the procoagulant response,* Ann Thorac Surg *62:1549-1557, 1996.)*

Others have defined heparin resistance as an ACT of less than 400 seconds at any time during the course of CPB and heparin administration.[108] Heparin resistance can result from a congenital deficiency or abnormality of AT, which requires treatment with AT to restore heparin's anticoagulant properties. More often, however, heparin resistance is the result of an acquired condition caused by the patient's disease status and physiologic state. Giving these patients larger doses of heparin may augment the ACT value; therefore, a more accurate term for describing these clinical findings is altered heparin responsiveness.[109] This alteration can result from an acquired AT deficiency, increased levels of heparin-binding proteins, activated platelets, sepsis, or other conditions. In a small study of cardiac surgical patients stratified by their history of preoperative heparin use, altered heparin responsiveness was found in approximately 40% of the patients who had received preoperative heparin therapy.[107]

Reported risk factors for altered heparin responsiveness include AT levels less than 60% of normal, preoperative heparin therapy, and a platelet count greater than 300,000/μL.[108] Ranucci and associates also found that low postoperative AT levels were predictive of a longer length of stay in the intensive care unit (ICU),[110] and others have associated low AT levels with adverse myocardial outcomes.[111] Not all heparin resistance is AT mediated; thus, it is critical to understand the physiologic factors that contribute to the altered heparin responsiveness so that appropriate treatment can be instituted.[112-115]

The most common treatment for altered heparin responsiveness is supplemental heparin. In refractory cases, treatment with AT concentrate, or recombinant AT, in doses that are calculated to produce 80% to 100% AT activity, restores heparin responsiveness. When AT is used for this purpose, careful neutralization with protamine and attention to hemostasis are essential because AT augments the effect of heparin and thereby slightly increases postoperative bleeding.[112]

Heparin Rebound. Heparin rebound is clinical bleeding that occurs within approximately 1 hour of protamine neutralization. It is accompanied by coagulation test results indicating residual heparinization, such as a prolonged partial thromboplastin time (PTT) or thrombin time and increased anti–factor Xa activity. Mechanisms of heparin rebound include slow dissociation of protein-bound heparin after protamine clearance, more rapid clearance of protamine than of heparin, lymphatic return of extracellular sequestered heparin, and the clearance of an unknown heparin antagonist.[109] Heparin rebound is rare, yet it is more likely to occur when the protamine dose is based on the residual heparin concentration at the end of CPB than when protamine is given as a ratio to the total heparin administered, because using this ratio usually results in a slight "overdose." With coagulation monitoring, heparin rebound is easily prevented or treated with supplemental protamine.

Heparin-Induced Thrombocytopenia. HIT is an immune-mediated prothrombotic disorder that occurs in patients exposed to heparin. Antibodies form against the protein platelet factor 4 (PF4) when PF4 has formed a complex with heparin. Although PF4 is found in only trace amounts in human plasma and is stored in platelet α granules, the presence of heparin increases plasma PF4 concentrations 15- to 30-fold by displacing bound PF4 on endothelial cell surfaces. PF4 is also expressed on the surface membrane of activated platelets by membrane fusion with the α-granule membrane; thus, PF4 is exposed and available to bind with heparin.[116] The resulting PF4-heparin complex on the platelet surface is recognized by a specific immunoglobulin G (IgG), which binds to the complex and leads to immunologically mediated platelet activation. Hyperaggregability of these activated platelets is the hallmark of HIT and is responsible for its prothrombotic complications.

A common presentation in patients with HIT is a reduction in the platelet count to less than 100,000/μL or to less than 50% of the baseline count.[117] The incidence of seroconversion after CPB and heparin exposure is quite frequent (20% to 50%).[117,118] However, the reported prevalence of clinical HIT after CPB is only 1% to 3%.[118] Thus, the risk of HIT in cardiac surgical patients with postoperative seroconversion is less than 10%. The strength of the immunologic response, not the mere presence of PF4 or heparin antibodies, may determine which patients are prone to HIT and are at risk for thromboembolic complications.[117,118] The presence of preoperative antibody, in addition to postoperative antibody, has been associated with increased morbidity after cardiac surgery.[119] This morbidity takes the form of gut ischemia, renal dysfunction, limb ischemia, and other prothrombotic events.

Management of the cardiac surgical patient with HIT must include a careful risk-to-benefit analysis. The likelihood that a patient has true disease and is at increased risk for a thrombotic event must be weighed against the risks posed by using an alternative anticoagulant to heparin. The urgency of the surgical procedure is also an important factor that can affect decision making. It is preferable, when possible, to defer the operation until antibody titers have become undetectable or only weakly positive, which may occur after 90 days.[118] If surgical postponement is not practical, then other therapeutic options must be considered (Boxes 67-6 and 67-7). Currently, the direct thrombin inhibitors are used as the anticoagulants of choice. Hirudin and argatroban are approved by the U.S. Food and Drug Administration (FDA) for use in patients with HIT-related thrombosis.[120] The use of these drugs as anticoagulants for CPB is fraught with hemorrhagic complications. Bivalirudin has been approved by the FDA for use in percutaneous interventions and, because of its short half-life, has been favored as an anticoagulant for CPB in patients with HIT.[121-124] However, no drug other than heparin has FDA approval for specific use as an anticoagulant in patients undergoing CPB.[109] Boxes 67-6 and 67-7 summarize therapeutic options and alternative anticoagulant strategies for the patient with HIT whose

BOX 67-6 ***Therapeutic Options for Anticoagulation for Cardiopulmonary Bypass in Patients With Heparin-Induced Thrombocytopenia***

1. Ancrod
2. Low-molecular-weight heparin or heparinoid (test first)
3. Alternative thrombin inhibitor (hirudin, bivalirudin, argatroban)
4. Using a single dose of heparin, promptly neutralizing it with protamine, *and*
   a. Delaying surgery so antibodies can regress *or*
   b. Using plasmapheresis to decrease antibody levels *or*
   c. Inhibiting platelets with iloprost, aspirin and dipyridamole (Persantine), abciximab, or RGD blockers

In all cases:

1. No heparin in flush solutions
2. No heparin-bonded catheters
3. No heparin lock intravenous ports

No agent is currently indicated for anticoagulation in cardiopulmonary bypass.

RGD, Receptor glycoprotein–derived.

operation cannot be deferred until seronegativity is documented. Figure 67-9 delineates how each alternative drug inhibits factor Xa, thrombin, or fibrinogen.

Protamine Reactions. Protamine is associated with several hemodynamic effects that can be categorized by their presentation and mechanism. Adverse reactions to protamine range from moderate hypotension to more profound and hemodynamically significant reactions that can increase in-hospital mortality risk.[125,126] The clinical presentation of these reactions serves as a starting point for understanding their mechanistic relationships. Commonly, these reactions are classified as type I, type II, or type III. A type I protamine reaction involves isolated hypotension, with normal to low filling pressures and normal airway pressures. This reaction is usually mild and responds to volume infusion, slowing of protamine infusion, and the gentle titration of vasoactive medications. Type II reactions include moderate to severe hypotension and include features of anaphylactoid reactions, such as bronchoconstriction. Anaphylactoid reactions include protamine sensitivity reactions that are classically immunologic or allergic in that they are immunoglobulin E (IgE) antibody mediated. Nonimmunologic mechanisms may involve IgG antibodies or complement activation. Type III reactions are thought to be caused by large heparin-protamine complexes that lodge in the pulmonary circulation, cause the release of mediators, and result in severe hypotension and elevated PA pressures that may lead to acute RV failure. This is obviously a profound response, resulting in global cardiovascular collapse or necessitating the reinstitution of CPB because of intractable RV failure. Fortunately, catastrophic hypotension and intractable RV failure are relatively rare events on the spectrum of protamine reactions.[126]

Mechanistic explanations for protamine reactions include endothelial nitric oxide release, mast cell degranulation, and histamine release associated with rapid infusion.[109] A study by Kimmel and colleagues found that neutral protamine Hagedorn insulin use, documented fish allergy, and a history of nonprotamine medical allergies were independent risk factors for protamine hypersensitivity reactions.[127] In this study, 39% of patients who presented for cardiac surgery had one or more of these risk factors. Other possible but unconfirmed risk factors include prior exposure to protamine, a history of vasectomy, decreased LV function, and hemodynamic instability.[127] The site of injection does not influence the incidence of protamine reactions.[128] Pretreatment with histamine blockade is not preventive.[109]

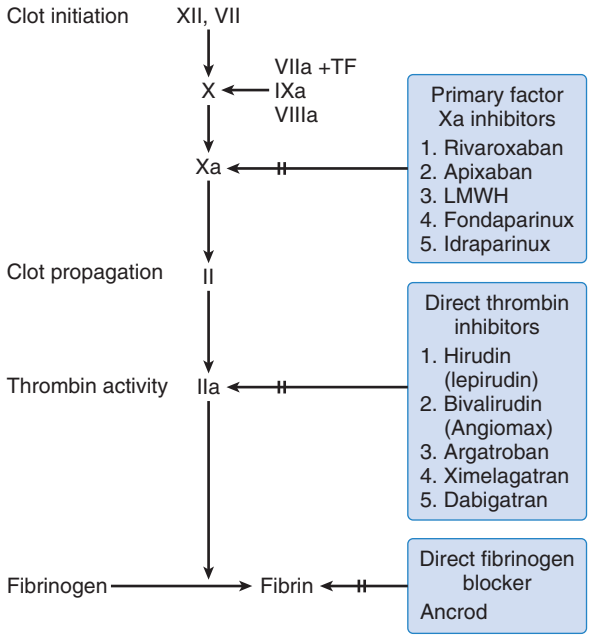

Figure 67-9. Alternatives to heparin. Newer anticoagulants are shown in the boxes on the *right side* of the figure; these drugs inhibit factor Xa, thrombin, or fibrinogen. *LMWH,* Low-molecular-weight heparin. *(From Kaplan JA, Reich DL, Savino JS, editors:* Kaplan's cardiac anesthesia: the echo era, *ed 6, St. Louis, 2011, Saunders, p 968.)*

The following principles summarize the treatment options for all patients and for those at risk for intraoperative protamine reactions:

1. Protamine should be administered slowly (i.e., over ≥5 minutes).
2. In patients with documented adverse events related to protamine, consideration should be given to *not* rechallenging the patient with protamine. Pharmacologic alternatives to protamine can be considered, or a decision can be made not to reverse heparin. Consideration may be given to using non–heparin-based CPB, performing off-pump coronary artery bypass (OPCAB) with an alternative to heparin, or, if heparin is used, administering nonprotamine heparin reversal drugs such as PF4 or heparinase, or simply waiting for heparin's effects to dissipate.
3. Hypotension associated with protamine reversal of heparin often is ameliorated by simply slowing or pausing protamine infusion while volume is infused through intravenous lines or the aortic cannula. Vasoactive medications, such as phenylephrine or ephedrine, or increased inotropic support may be necessary.
4. Severe or intractable hypotension, with or without evidence of pulmonary circulatory involvement, bronchospasm, or overt RV failure, demands immediate aggressive attention, intervention, and planning for a potential return to CPB. Steps to consider include the following:
   a. Reheparinization to prepare the patient for a return to CPB and to reduce heparin-protamine complex size. If hemodynamics permit, a low dose of heparin

(70 units/kg) may be tried first while supportive treatment continues, followed by a full CPB dose of heparin (300 units/kg) if it becomes necessary to return the patient to CPB.

b. Inotropic support, either by infusion or by intermittent bolus administration, is warranted. Epinephrine and norepinephrine are acceptable options, and milrinone may be considered if the patient's hemodynamic status permits.

c. If the patient's hemodynamic status allows, nebulized albuterol is helpful in the management of bronchospasm and elevated airway pressures.

Antifibrinolytic Therapy: Prophylaxis for Bleeding. Prophylactic use of antifibrinolytic drugs before CPB reduces bleeding and transfusion requirements in cardiac surgical patients in randomized trials and in multiple meta-analyses.[129] The most well-known antifibrinolytic drugs include the synthetic lysine analogues ε-aminocaproic acid (EACA) and tranexamic acid (TA) and the serine protease inhibitor aprotinin. Presumably, the blood-sparing effects of the synthetic drugs result from the inhibition of fibrinolysis by their binding to the lysine-binding sites on plasmin. This also has platelet protective properties because plasmin's antiplatelet effects are also inhibited by antagonist binding.

Aprotinin is a direct enzymatic inhibitor of plasmin and has other protease-inhibiting properties that confer its antiinflammatory and antikallikrein effects. However, aprotinin was notably associated with increases in post-CPB creatinine values and other adverse organ system outcomes in large-scale observational trials.[130] When a randomized prospective trial showed an increase in mortality in the aprotinin group, despite a reduction in bleeding, the drug was removed from the global market.[131] Although the causes of death in the aprotinin-treated patients were not found to be related to thrombosis or other drug-related effects, aprotinin was rendered unavailable for commercial use for years after publication of this study. The decision to remove aprotinin from clinical use was revisited on reevaluation of these study data,[131] and aprotinin has been reintroduced in Canada and other countries specifically for use as labeled in CABG surgery.

Hypercoagulable States. The use of antifibrinolytics has become common in cardiac operations that require CPB. The use of antifibrinolytic drugs and prohemostatic drugs and blood products to treat bleeding has brought to light the risk of thrombosis in CPB, during which feedback mechanisms are critical and homeostasis is perturbed. All patients incur this risk of thrombosis as consumptive coagulopathy increases, but the risk is greatly increased in patients with congenital or acquired thrombophilic states.[132] These states may be important in view of current practices that involve pharmacologically inhibiting fibrinolytic pathways in cardiac surgical patients.

The factor V Leiden (FVL) mutation is the most common inherited thrombophilic disorder; its prevalence is 3% to 7% in white populations.[132,133] Mechanistically and clinically, FVL has been implicated in thrombotic complications in cardiac operations, most often those involving a period of circulatory arrest and the use of antifibrinolytics.[134-136] In a review of FVL mutation, Donahue gave the following summation and recommendations[132]:

- Cardiac surgical patients who are heterozygous for the FVL mutation bleed less than do noncarriers.
- The risk of early graft thrombosis may be increased in patients with FVL deficiency.
- The use of antifibrinolytic drugs may increase thrombotic risk in patients with FVL.
- Anecdotal evidence suggests that in patients with FVL mutation who are exposed to deep hypothermic circulatory arrest, antifibrinolytics increase thrombotic risk.

For further information on congenital thrombophilic states, the reader is referred to a review article by Crowther and Kelton.[137]

Cardiac Surgical Patients Taking Anticoagulant or Antithrombotic Drugs. Antithrombotic therapy in cardiac surgical patients has many roles and applications. Patients with ischemic heart disease can be managed short- or long-term with pharmacologic drugs that may include aspirin, AT inhibitors (heparins), direct thrombin inhibitors, or an array of platelet inhibitors (adenosine diphosphate [ADP] receptor inhibitors and glycoprotein IIb/IIIa [Gp IIb/IIIa] receptor inhibitors). Patients with a history of peripheral vascular disease, valvular heart disease, or low ventricular ejection states can similarly be managed with some form of antithrombotic therapy that may also include warfarin. Frequently, patients arrive for surgery while receiving multiple antithrombotic medications. Thus, postoperative bleeding is a common but challenging complication of cardiac surgery, especially when the bleeding risk posed by CPB itself is considered.

The use of percutaneous coronary interventions such as angioplasty and intracoronary stent deployment for ischemic heart disease has led to the use of antithrombotic medications to maintain stent patency and to prevent stent thrombosis. The American College of Cardiology and AHA (ACC/AHA) guidelines for percutaneous coronary intervention recommend (on the basis of class I evidence) the use of both aspirin and clopidogrel for at least 1 year after drug-eluting stent placement.[138] The administration of thienopyridine antiplatelet drugs in addition to aspirin increases the risk of bleeding after cardiac surgery[139]; however, it is unclear whether aspirin alone increases this risk. Abundant evidence (mostly level B evidence from small, retrospective, nonrandomized studies) suggests that the ADP receptor antagonist clopidogrel (Plavix) has been associated with excessive perioperative bleeding in patients who undergo CABG.[140,141] This trend has even been reported in the OPCAB population, although not consistently.[142-144] Some authors have recommended a 5- to 7-day delay after discontinuation of clopidogrel in patients who require CABG. However, two more recent studies suggested that a 3-day delay may be sufficient to lessen bleeding risk and provide safe outcomes.[145] Furthermore, most surgeons do not wait the recommended 5 to 7 days before proceeding with CABG.[146] It is likely that a 5- to 7-day delay is not necessary, but some interval between the discontinuation of clopidogrel and CABG is supported by the available evidence.[139]

Patients with a history of Gp IIb/IIIa receptor blockade as a part of their acute coronary syndrome management are at risk of increased bleeding and blood component use when they are given abciximab, especially within 12 hours of cardiac surgery.[147-149] Shorter-acting Gp IIb/IIIa receptor antagonists do not seem to increase bleeding or adverse outcomes and in fact may improve myocardial outcomes when Gp IIb/IIIa blockers are in use.[150] The interval between the discontinuation of antiplatelet therapy and cardiac or noncardiac surgery is critical to preventing thrombotic events without increasing the risk of bleeding. These decisions regarding the cessation of therapy can be guided by knowledge of drug pharmacology and testing of antiplatelet drug efficacy.

Enoxaparin, a low-molecular-weight heparin, increases transfusion rates and the risk of surgical reexploration when it is used in association with CPB.[151] Low-molecular-weight heparin may also decrease heparin responsiveness.[152,153]

Patients who present for cardiac surgery with residual warfarin effects may benefit by having enhanced anticoagulation during CPB. Postoperatively, if excessive bleeding is noted and is confirmed by hemostasis testing, factor replacement can be performed with blood products or pharmacologic prothrombin complex concentrates.

Patients with atrial fibrillation may be maintained on new antithrombotic therapeutic drugs that include AT drugs (dabigatran) and factor Xa inhibitors (rivaroxaban). These drugs are potent and long-acting, and they have no antidote, so one would expect that treating cardiac surgical patients with these drugs would increase their bleeding risk. These drugs have only relatively recently been prescribed for atrial fibrillation; no recommendations on their use in cardiac surgery currently exist.

In summary, patients who present for cardiac surgery with preexisting, pharmacologically induced inhibition of the hemostatic system may have undesirable post-CPB bleeding. The diagnosis and treatment of this complication should be the same whether the derangement is a function of CPB itself, coexisting pharmacologic inhibition, or both. The management and treatment of persistent postoperative bleeding are discussed in the section on problems in the postoperative period.

INDUCTION OF ANESTHESIA AND THE PREBYPASS PERIOD

Premedication

The anesthesiologist should ensure that appropriate medications are administered with a sip of water on the morning of surgery. With a few exceptions, patients should receive their usual long-term medications, particularly β-adrenergic blocking drugs, on the day of surgery. The clinician should be aware that ACE inhibitors (ACEIs), if administered on the day of surgery, may increase the patient's propensity for hypotension.[154] With respect to aspirin, it is well recognized that aspirin administration in the early postoperative period reduces the risk of ischemic complications after CABG surgery.[155] However, patients who receive aspirin immediately preoperatively may have more mediastinal bleeding and greater transfusion requirements. A consensus statement published by the STS recommends that low-intensity antiplatelet drugs (e.g., aspirin) be discontinued before cardiac surgery to reduce patients' blood transfusion requirements, but this should be done only in purely elective cases in patients without acute coronary syndromes.[82]

However, drugs that inhibit the platelet P2Y12 receptor should be discontinued before operative coronary revascularization (either on-pump or off-pump), if possible.[82] The interval between drug discontinuation and operation is determined from the drug's pharmacodynamics but may be as short as 3 days for irreversible inhibitors of the P2Y12 platelet receptor. POC tests are available to measure platelet ADP responsiveness. These tests are not perfect; they lack sensitivity and specificity.[156-158] Nonetheless, POC tests that show normal platelet ADP responsiveness after administration of an initial dose of clopidogrel indicate P2Y12 resistance with as much as 85% specificity.[156,158] More accurate tests are available but are not POC tests.[156,159] The routine addition of P2Y12 inhibitors to aspirin therapy early after CABG may increase the risk of reexploration and subsequent operation and is not indicated by available evidence except in those patients who satisfy the criteria for ACC/AHA guideline–recommended dual antiplatelet therapy (e.g., patients who present with acute coronary syndromes or who have recently received drug-eluting coronary stents).

The prospect of undergoing cardiac surgery provokes anxiety in most patients. Furthermore, the insertion of intravenous and arterial catheters is painful and must be done before anesthesia is induced. The resultant anxiety and pain can lead to undesirable sympathetic stimulation, with consequent tachycardia and hypertension. The first step in preventing this cycle is thoroughly explaining the anticipated anesthetic techniques and procedures to the patient. Premedication with a narcotic or anxiolytic drug, or both, to mitigate pain and anxiety is usually indicated before the patient is transported to the operating suite. Supplemental intravenous drugs—commonly midazolam and possibly fentanyl—are usually necessary during radial artery cannulation before anesthesia is induced. However, in patients with low CO secondary to congestive HF (CHF), sedation should be performed judiciously to avoid myocardial depression and resultant hypotension. Moreover, in patients with significant pulmonary hypertension, oversedation and respiratory depression leading to hypercapnia or hypoxia must be avoided.

Induction of Anesthesia

In preparing for induction, the clinician should have the following drugs immediately available: vasopressors (e.g., phenylephrine, ephedrine, calcium chloride, readily available vasopressin), one or more inotropes (e.g., ephedrine; epinephrine; readily available norepinephrine, dopamine, or dobutamine), one or more vasodilators (e.g., nitroglycerin, nitroprusside, nicardipine), an anticholinergic drug (atropine), antiarrhythmic drugs (e.g., lidocaine, esmolol, magnesium, amiodarone, adenosine), and heparin.[160] Commonly administered drugs should be drawn up and ready for administration by bolus or infusion, as appropriate; agents that are used less commonly should be readily available in the operating room. Protamine should

be readily available, but many institutions require that protamine be stored in unique packaging or at a separate, nearby location to prevent inadvertent, inappropriate, or premature administration.

Furthermore, the selected antibiotic should be ready to administer according to Surgical Care Improvement Project (SCIP) guidelines. The STS recommends a cephalosporin as the primary prophylactic antibiotic for cardiac surgery; the drug should be administered within 1 hour before incision.[161] In patients who are allergic to penicillin, vancomycin is administered within 2 hours of incision. Finally, antifibrinolytic drugs are commonly used to minimize bleeding and the need for transfusion during cardiac surgery. The only currently available antifibrinolytic drugs are TA and EACA; both reduce total blood loss and decrease the number of patients who require blood transfusion during cardiac procedures.[82]

Anesthetic drugs and techniques for inducing anesthesia should be selected with consideration of the patient's cardiac pathophysiology and other comorbid conditions. No single "recipe" can guarantee hemodynamic stability during anesthetic induction. Hypotension may result from a relatively hypovolemic state and vasodilation secondary to a reduction in sympathetic tone induced by anesthetics. Hypotension is particularly common in patients with poor LV function. Conversely, in patients with good myocardial function, hypertension may occur during induction because of preinduction anxiety or sympathetic stimulation caused by laryngoscopy and endotracheal intubation.

The radial artery or an alternative site should be cannulated before induction of anesthesia to monitor arterial pressure on a beat-to-beat basis. If the radial artery is being harvested as a vascular conduit, the contralateral radial or brachial artery or a femoral artery can be cannulated. Noninvasive blood pressure measurement can be used to check the accuracy of pressure readings if the arterial catheter is "positional" or "dampened." Of course, basic monitors, including the ECG and pulse oximeter, should also be used during the induction of anesthesia. During any cardiac surgical procedure, central venous access is necessary to facilitate volume infusion, possibly including transfusion therapy, and to ensure that vasoactive agents are administered directly into the central circulation. A central venous catheter, a PA catheter, or both can be placed either before or after anesthesia is induced, although an increasing number of anesthesiologists defer central line placement until after anesthetic induction. The urinary bladder catheter, nasogastric tube, TEE probe, and any additional temperature monitors (e.g., a nasopharyngeal probe) are positioned after induction of anesthesia.

When choosing anesthetic drugs and doses during induction and maintenance, one should consider any pharmacodynamic properties that could affect arterial blood pressure, heart rate, or CO, as well as the desirability of "early" extubation of the trachea (i.e., within a few hours after the operation is completed). Anesthesia is most commonly induced with an opioid and a sedative-hypnotic (etomidate, thiopental, propofol, or midazolam). All anesthetics decrease arterial blood pressure by decreasing sympathetic tone, decreasing systemic vascular resistance (SVR), inducing bradycardia, or directly depressing myocardial function. The only exception is ketamine, which has sympathomimetic effects; however, in patients with catecholamine depletion, ketamine's sympathomimetic effects may not counterbalance its direct negative inotropic effects. Because of their pharmacologic complexities, all anesthetic agents should be administered judiciously in patients who are critically ill or who have poor LV function.

Muscle relaxants are usually given early in the sequence of anesthetic induction, particularly if relatively large doses of opioids are administered, to minimize chest wall rigidity (see also Chapter 34). With the routine use of fast track anesthesia techniques, including a trend toward earlier extubation, volatile anesthetics are often chosen as the primary maintenance anesthetic. The predominant effect of isoflurane, desflurane, and sevoflurane is dose-dependent vasodilation with resultant decreases in SVR and arterial blood pressure. These volatile anesthetics may have an advantage in inducing preconditioning, which is particularly important in patients undergoing either CABG with CPB or OPCAB, in which myocardial ischemic insults are likely. The volatile anesthetic agents have several cardioprotective effects, including triggering the preconditioning cascade and mitigating reperfusion injury.[162] However, nitrous oxide probably should be avoided because it can increase gaseous bubble size and adversely affect pulmonary vascular resistance (PVR).

Pre–Cardiopulmonary Bypass Period

After anesthesia is induced, several important details must be remembered, especially positioning (see also Chapter 41). Methods of positioning the arms vary according to institutional practice, but one must avoid causing brachial plexus injury by hyperextending the arms, ulnar nerve injury by improperly padding the olecranon, radial nerve injury by compressing the upper part of the arm against the sternal retractor support posts, or finger injury by entrapping the finger against the metal edge of the surgical table. Proper positioning also ensures that arterial catheters previously placed in the radial, ulnar, or brachial arteries are not "dampened." The head should be padded and occasionally repositioned during the procedure to prevent occipital alopecia, which can occur several days postoperatively. The eyes should be taped, possibly lubricated, and definitely free from pressure. Pressure-related injury to any soft tissue will potentially be exacerbated by hypothermia and decreased perfusion during CPB. All monitors and tubing should be checked after final positioning to ensure that none are kinked, entrapped, tangled, or inaccessible. Additionally, antibiotics must be administered (with documentation) within 1 hour of incision (vancomycin within 2 hours). Arterial blood gases and blood chemistry (electrolytes, glucose, and calcium), as well as baseline ACT, should be measured shortly after anesthesia is induced. If a continuous mixed venous PA catheter has been inserted, mixed venous hemoglobin oxygen saturation should be measured to calibrate the device.

During the prebypass period, the anesthesiologist's main goal is to maintain the hemodynamic and metabolic stability of the patient while making preparations for CPB. The degree of surgical stimulation varies

markedly during this period. Positioning the patient, inserting additional monitors, preparing the skin, and harvesting the saphenous vein or veins cause only minimal sympathetic stimulation. Therefore, hypovolemic patients and those with poor ventricular function may be susceptible to hypotension during these periods. In contrast, chest incision, sternal splitting, and harvesting of the IMA involve more intense surgical stimulation. These events may cause hypertension, tachycardia, and dysrhythmias, even in previously hypotensive patients. However, just before CPB is initiated, during the cannulation of the great vessels, surgical stimulation is again minimal, and manipulation of the heart and great vessels may transiently decrease venous return and cause a precipitous decline in blood pressure. The anesthesiologist must be ready to treat all hemodynamic aberrations with the vasopressor, inotropic, vasodilator, antiarrhythmic, and anticholinergic drugs mentioned earlier.

In preparation for CPB, anticoagulation must be achieved. Heparin is still the standard drug used and is administered through a central venous catheter at an initial dose of 300 to 400 units/kg. The onset of anticoagulation is almost immediate, but generally, the drug is allowed to circulate for 3 to 5 minutes before its effect is measured. The ACT must increase to at least 300 seconds before CPB is initiated, although most institutions use at least 400 seconds as their standard. Additional heparin is administered, if necessary, to increase the ACT to the desired level. Subsequently, it is common to administer an antifibrinolytic drug (EACA or TA) in an attempt to minimize bleeding and the need for transfusion during cardiac surgery.

After heparinization, the next major step in the prebypass phase is vascular cannulation. One or more large veins or the right atrium is cannulated so that all systemic venous blood is diverted to the pump oxygenator. Additionally, a large artery, usually the ascending aorta, is cannulated so that oxygenated blood is delivered back to the arterial circulation. Heparin is always administered before cannulation. Usually, arterial cannulation is established before venous cannulation to allow rapid intravascular volume or blood resuscitation if necessary. Complications of aortic cannulation include arterial dissection, hemorrhage and resultant hypotension, inadvertent cannulation of the aortic arch vessels, and embolic phenomena caused by dislodged atherosclerotic plaque or by air introduced into or entrained around the aortic cannula. Complications of venous cannulation include hypotension from blood loss, dysrhythmias, and surgical mechanical compression of the heart or great vessels. When arterial cannulation is successful and the cannula has been inspected to ensure that no air is present, volume can be administered in 100-mL increments to treat bleeding and hypovolemia. If necessary, dysrhythmias are treated by cardioversion, medications, or rapid initiation of CPB.

Patients undergoing redo cardiac surgery (i.e., those who have previously had a median sternotomy) warrant special concern about the possibility of sudden, massive hemorrhage. At least 2 units of blood should be immediately available for all redo cases. Frequently, the surgeon will elect to use an oscillating saw in these patients, but mediastinal structures adherent to the underside of the sternum may nevertheless be injured. If the right atrium, right ventricle, great vessels, or an existing coronary graft is cut, the surgeon may elect to initiate CPB on an emergency basis. Therefore, the anesthesiologist should have a systemic dose of heparin prepared. As soon as the patient is heparinized, the femoral or aortic arterial cannula is inserted, and the cardiotomy suckers can be used to create venous return (so-called sucker bypass).

Onset of Cardiopulmonary Bypass

With the onset of CPB, to guard against malposition of the aortic or venous cannula, the perfusionist checks the aortic inflow line pressure and for signs of inadequate venous return while the anesthesiologist checks for persistently low arterial pressure, unilateral blanching of the face, or any swelling in the neck veins, face, or conjunctiva. Once full bypass is established and aortic ejection by the heart has ceased, ventilation and inhaled drugs can be discontinued. If a PA catheter is present, it is pulled back 3 to 5 cm to minimize the risk of pulmonary perforation as the pulmonary arteries collapse. Prebypass urine output is recorded and emptied so that urine output during CPB can be monitored separately. The TEE probe may be used to watch for LV distention with the onset of CPB, which may indicate aortic valve regurgitation or other hemodynamic problems. Once CPB is established, the probe is left in the unlocked (neutral) position until the cardiac chambers are de-aired and the patient is weaned from CPB.

To ensure adequate anesthetic depth, supplemental intravenous sedative-hypnotics are administered, or a volatile agent is administered through a vaporizer connected to the oxygenator gas inlet of the CPB circuit. Administration of muscle relaxant is continued to prevent spontaneous ventilation, movement, or shivering during hypothermia and rewarming.

WEANING FROM CARDIOPULMONARY BYPASS

Preparations for Weaning From Cardiopulmonary Bypass: The "CVP" Mnemonic

Fortunately, for most patients, separation from CPB is a relatively uneventful process. A review by Licker and colleagues emphasized that the key to successful weaning from bypass is clear communication among members of the operating room team.[163] In a study conducted at the Mayo Clinic in Rochester, Minnesota,[164] a strong correlation was noted between the frequency of technical errors and poor communication or coordination among the surgeon, anesthesiologist, and perfusionist.

Regarding clinical issues, several criteria should be met in all cardiac surgical cases before weaning from CPB is attempted. Morris, Romanoff, and Royster suggest a mnemonic, "CVP," to help the clinician remember the main tasks necessary for the successful termination of CPB (Table 67-4).[165] Each letter of CVP represents several tasks or important points to remember that begin with that letter.

The first "C" stands for cold and refers to the patient's temperature at the time of weaning from CPB, which should be 36° C to 37° C. Neither the temperature of the

Coagulation		Protamine

From Romanoff ME, Royster RL: The postcardiopulmonary bypass period: weaning to ICU transport. In *Hensley FA, Martin DE, Gravlee GP, editors:* A practical approach to cardiac anesthesia, *ed 4, Philadelphia, 2008, Lippincott Williams & Wilkins, pp 230-260.*

venous blood returning to the CPB circuit nor the nasopharyngeal temperature should ever exceed 37° C because hyperthermia may increase the risk of postoperative neurologic complications (see the section on temperature).

The second "C" stands for conduction and refers to cardiac rate and rhythm. A heart rate of 80 to 100 beats/minute is usually desirable. Bradycardia is treated with epicardial pacing wires and/or with β-adrenergic drugs that have chronotropic and dromotropic, as well as inotropic, properties. Tachycardia (i.e., heart rate >120 beats/minute) is also undesirable. Sinus tachycardia may result from anemia, hypovolemia, "light" anesthesia, or the administration of chronotropic drugs; treatment is tailored to the presumed cause. Rhythm is also an important factor in optimizing CO. Third-degree AV block requires pacing, ideally AV pacing. Sinus rhythm is preferable, particularly in patients with poor LV compliance, who are especially dependent on an "atrial kick" to achieve adequate filling. If supraventricular tachycardia is present, direct synchronized cardioversion is often warranted. In addition, pharmacologic therapy with amiodarone, esmolol, verapamil, or adenosine may be used in the initial treatment of or to prevent the recurrence of supraventricular tachycardia.

The third "C" stands for CO or contractility. Contractility may be estimated from TEE or PA catheter data, if available.

The fourth "C" refers to cells (i.e., red blood cells [RBCs]). The patient's hemoglobin concentration should be 7 to 8 g/dL, or slightly higher, before weaning from CPB. If the hemoglobin concentration is less than 6.5 g/dL when rewarming commences, the perfusionist and anesthesiologist can consider hemoconcentration or transfusion of a unit of packed RBCs (PRBCs).

The fifth "C" is for calcium, which should be immediately available for possible administration to treat hypocalcemia and hyperkalemia. Ionized calcium levels should be measured after rewarming to help direct therapy. Although calcium is not administered routinely, if ionized calcium levels are in the low-normal range, SVR can be beneficially increased by calcium administration.

The sixth "C" stands for coagulation. After protamine is administered, ACT is measured. In patients at risk for coagulation abnormalities, prothrombin time, PTT, and platelet count should also be measured a few minutes later. Examples of patients at risk for coagulation abnormalities include the following: those with long CPB times; those with extreme hypothermia, elective circulatory arrest, or both, during CPB; and those with chronic renal failure. Platelet function tests may be useful in patients taking platelet inhibitors (e.g., clopidogrel or aspirin). (For further discussion of patients having emergency surgery who are taking warfarin or who have been exposed to thrombolytic drugs, antiplatelet Gp IIb/IIIa agents, or direct thrombin inhibitors see the sections on the "hematologic system" and on bleeding and coagulopathy.)

The first "V" is for ventilation of the lungs. As CPB is discontinued, the venous outflow line is gradually occluded, and PA blood flow is gradually restored. Pulmonary ventilation and oxygenation must be reestablished, thus allowing the lungs to become the site of gas exchange again. Ideally, the lungs are initially reinflated manually, with a few sustained inflations to a peak pressure of approximately 30 cm H_2O. If an IMA has been grafted to a coronary artery, the anesthesiologist must examine the surgical field during these inflations to ensure that the grafted artery is not overstretched, which could disrupt the distal anastomosis. Additionally, the compliance of the lungs is judged by these initial inflations, and bronchodilators can be administered if necessary. The surgeon should remove any fluid or blood from the pleural spaces and ensure that any pneumothorax is treated with a chest tube.

The second "V" is for visualization of the heart, both directly in the surgical field (where the right-sided chambers are visible) and on the TEE, to estimate global and regional contractility. Furthermore, the degree of chamber filling (hypovolemic, euvolemic, or distended) can be estimated. In addition, one can do a final check for air within the cardiac chambers with TEE examination.

The third "V" is for vaporizer, meaning that if volatile agents were used to ensure lack of awareness or to control blood pressure during CPB, the clinician usually reinstitutes a low dose immediately after weaning. However, because all the volatile agents decrease contractility and blood pressure, these effects can confuse the differential diagnosis of hypotension and myocardial dysfunction during weaning.

The final "V" is for volume expanders. When all products from the pump have been exhausted and if blood transfusion is not indicated, crystalloid and albumin or hetastarch should be readily available to increase preload rapidly if necessary.

As for the letter "P" in the CVP mnemonic, Morris, Romanoff, and Royster explained that the first "P" represents the need to be aware of predictors of adverse cardiovascular outcome.[165] For example, preoperative low EF and prolonged CPB often predict difficulty in weaning the patient from CPB and the need for inotropic support. In addition, emergency surgery in patients with acute coronary syndrome may lead to myocardial stunning. Furthermore, inadequate surgical repair (e.g., incomplete coronary revascularization) may result in ongoing ischemia.

The second "P" is for pressure. Calibration and rezeroing are accomplished shortly before the patient begins being weaned from CPB. Any discrepancy between the distal (usually radial) arterial pressure and the central aortic pressure should be recognized. Occasionally, the surgeon may need to insert a temporary aortic root cannula or a longer-lasting femoral arterial cannula to

monitor systemic blood pressure accurately during and after the termination of CPB.

The third "P" is for pressors, meaning vasopressors and inotropic agents that should be immediately available. A vasodilator, such as nitroglycerin, nicardipine, or nitroprusside, also should be immediately available.

The fourth "P" is for pacer because an external pacemaker should be readily available for all patients. Pacing is often needed to treat bradycardia. In patients with heart block, ideally, an AV sequential pacemaker is used to maintain the atrial kick.

The fifth "P" is for potassium because hypokalemia may contribute to dysrhythmias, and hyperkalemia may result in conduction abnormalities. In addition, the patient's ionized calcium level is usually checked; most clinicians have a low threshold for administering additional calcium chloride. Furthermore, magnesium (2 to 4 g) is usually administered before CPB is terminated. Although magnesium's efficacy in preventing postoperative atrial or ventricular dysrhythmias has not been clearly demonstrated, hypomagnesemia is common after CPB. The risk-to-benefit ratio for administering a 2- to 4-g dose is low.

The final "P" is for protamine. Many institutions require that protamine be uniquely packaged or kept in a nearby but separate area to ensure that the drug is not prematurely administered. (Administration during ongoing CPB is a disastrous error.) Nevertheless, it should take but a few moments to retrieve protamine when the surgeon, anesthesiologist, and perfusionist agree that it is time to reverse anticoagulation.

Termination of Cardiopulmonary Bypass

After all the preparations described previously have been made and the patient's ventilation has been reestablished, the venous return to the pump is reduced by gradually clamping the venous line. The patient's intravascular volume is carefully increased by continued inflow through the aortic or other arterial cannula. Ventricular distention should be avoided because it increases wall tension and myocardial oxygen consumption. The pump flow into the aorta is lowered, in effect moving into a "partial bypass" phase, in which some of the venous blood still goes into the pump and some passes through the right ventricle and lungs to be ejected into the aorta by the left ventricle. Some clinicians reduce the pump flow to half flow rather than gradually reducing venous return to the pump. Once loading conditions are optimal and contractility appears adequate, the aortic inflow line may be clamped to separate the patient from CPB.

If CPB has been successfully terminated but cardiac performance is not optimal, preload can be increased by infusing additional blood from the pump into the aortic cannula, usually in 100-mL increments in adult patients. Monitoring the left intraventricular volume in a qualitative fashion by TEE, observing the right ventricle directly, and monitoring the filling pressures give a good estimate of the adequacy of preload. At this point, the anesthesiologist and surgeon jointly determine whether myocardial filling and performance are adequate. This determination can best be accomplished by using TEE to observe the global and regional function of both ventricles. Supplemental information can be obtained by measuring CO, if possible. Afterload can also be optimized at this point. Usually, 95 to 125 mm Hg is a desirable systolic pressure in adult patients in the immediate postbypass period, whereas increased systolic blood pressure should be avoided to prevent excessive stress on suture lines in the heart and aorta. If the patient is hemodynamically unstable and additional time is needed to administer initial or additional inotropes or vasoconstrictors, CPB can be reinstituted by unclamping the venous outflow line and directing all flow to the oxygenator again (Fig. 67-10).

Once protamine is administered, the reinstitution of CPB becomes a more complicated process because the patient must first be reheparinized. Therefore, final checks of cardiac function, heart rate and rhythm, preload, afterload, and perfusion should be made jointly by the anesthesiologist and the surgeon. The venous cannula or cannulas are usually removed after the initial test dose of protamine is given. Many surgeons remove the aortic cannula only after at least half of the protamine dose has been administered. The rate and mode of protamine administration (incremental small boluses versus continuous infusion) vary according to institutional and individual clinicians' practices, but a large dose of protamine should never be administered as a rapid bolus.

Table 67-5 shows the characteristics and treatment modalities of specific TEE-diagnosed difficulties that may be encountered during weaning and termination from CPB.[163]

POSTBYPASS PERIOD

Common Problems After Cardiopulmonary Bypass

Awareness. The potential for the patient's awareness must be assessed during and after CPB (see also Chapter 50). The incidence of this distressing complication is more frequent in cardiac operations than in other cases.[64,166] Although patients may sweat during the rewarming period, usually because of perfusion of the thermoregulatory site in the hypothalamus with warm blood, sweating may also result from awareness if anesthetic concentrations are low during the period when the brain becomes normothermic. Awareness may be more likely if considerable time has elapsed since any sedative-hypnotic or narcotic has been administered, if small doses of anesthetic drugs were administered during CPB, or if the patient is young. Consideration should be given to continuing to administer a volatile anesthetic agent once pulmonary ventilation is reestablished and to administering additional sedative-hypnotic doses, an opioid, or both. Some clinicians begin infusing an anesthetic agent such as propofol or dexmedetomidine shortly after weaning the patient from CPB and continue it during and after transport to the ICU or cardiac recovery area.

Published studies support the hypothesis that the use of depth-of-anesthesia monitors such as the BIS can decrease the incidence of intraoperative awareness in patients at high risk for this problem[63,64] (see also Chapter 50). However, falsely high BIS values during cardiac surgery have been attributed to interference from pump head rotation, pacemakers, and hypothermia itself.[167]

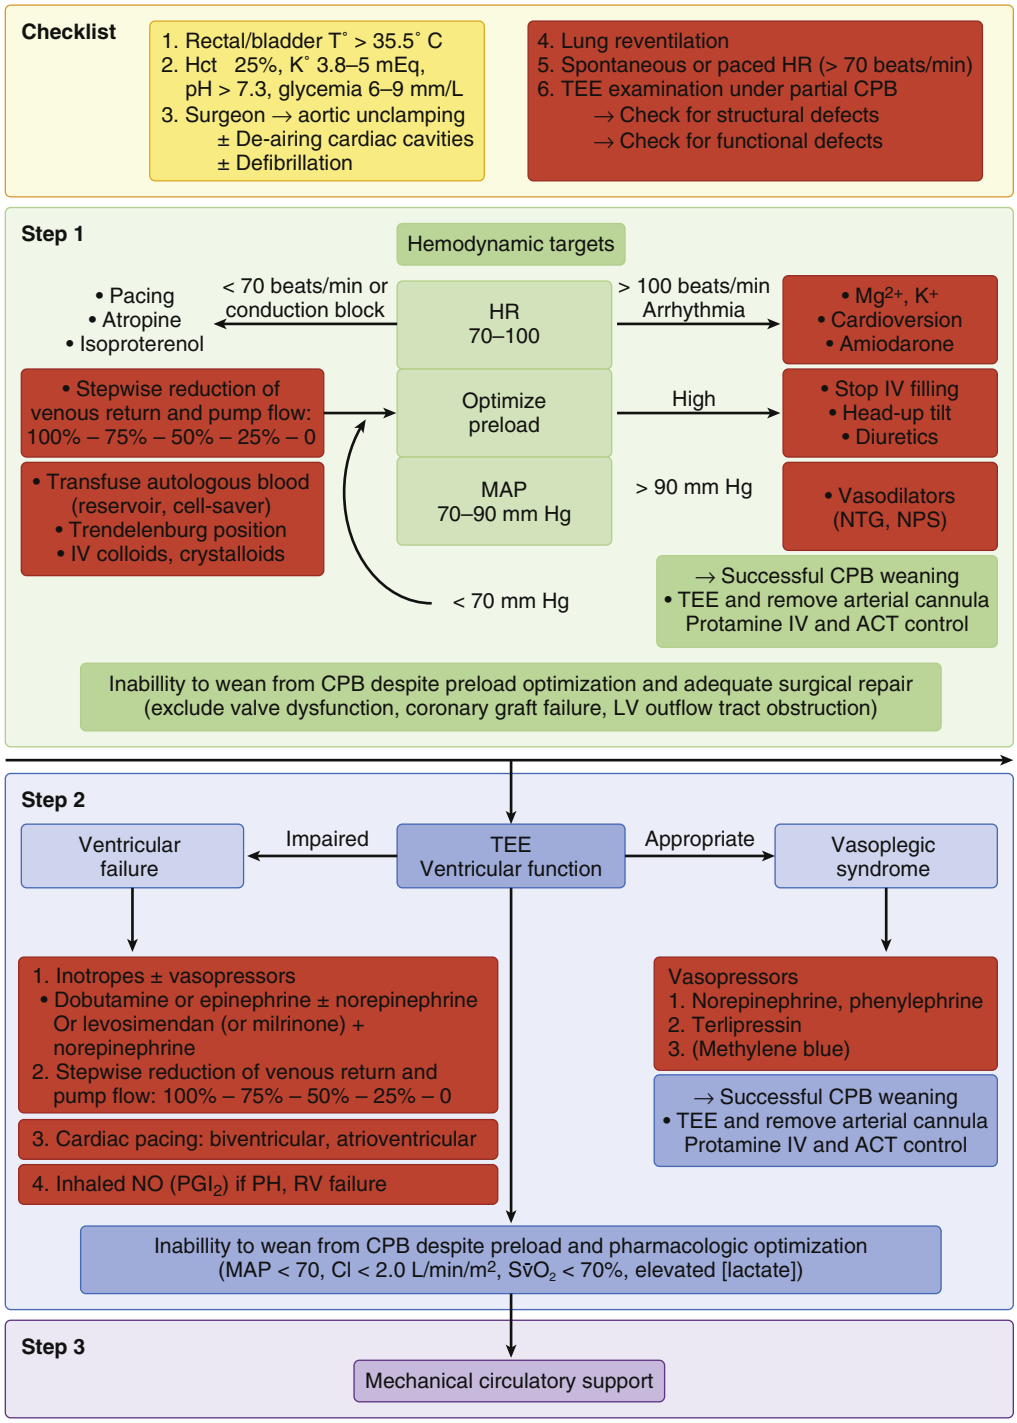

Figure 67-10. Algorithm for weaning from cardiopulmonary bypass (CPB). *ACT,* Activated clotting time; *Hct,* hematocrit; *HR,* heart rate; *IV,* intravenous; K^+, potassium; *LV,* left ventricular; *MAP,* mean arterial pressure; Mg^{2+}, magnesium; *NO,* nitric oxide; *NPS,* sodium nitroprusside; *NTG,* nitroglycerin; PGI_2, prostacyclin; *PH,* pulmonary hypertension; *RV,* right ventricular; $S\bar{v}O_2$, mixed venous oxygen saturation; *TEE,* transesophageal echocardiography. *(From Licker M, Diaper J, Cartier V, Ellenberger C, et al: Clinical review: management of weaning from cardiopulmonary bypass,* Ann Card Anaesth *15:206-223, 2012.)*

Furthermore, because processing of the raw EEG and data smoothing to generate the BIS number occur over 15 to 30 seconds, the BIS number lags slightly behind clinical events.

Another important decision to be made is whether additional neuromuscular blocking drugs are needed during and after weaning from CPB. Use of a peripheral nerve stimulator may facilitate this decision (see also Chapter 53). Although movement of the patient may serve as an indication of the patient's awareness, such movement can be extremely dangerous if it results in dislodgment of the aortic or venous cannulas. Furthermore, shivering can occur because of the "afterdrop" in temperature after a period of hypothermic CPB (see also Chapter 54). Because shivering can increase oxygen demand by 300% to 600%, it should be prevented by administering a neuromuscular blocking drug.

Cardiovascular Decompensation. Failure of the left or right ventricle is one of the common causes of cardiovascular decompensation during or shortly after weaning from CPB. Such failure may result in part from preexisting

chronic ventricular dysfunction exacerbated by the ischemia-reperfusion injury that occurs during CPB with cardioplegia-induced cardiac arrest. In operations involving revascularization for CAD, myocardial injury resulting in postbypass ischemia or infarction is particularly likely. Causes include thrombosis, particulate or air emboli in a coronary graft or a native coronary artery, kinking of the graft, a distal suture causing constriction, coronary spasm, incomplete myocardial preservation during CPB, and incomplete revascularization secondary to distal disease or inoperable vessels. Another possibility is acute mitral regurgitation (MR) of the native valve resulting from papillary muscle ischemia or rupture. In the case of valvular surgery, a prosthetic valve may be malpositioned with a perivalvular leak, the valve may be malfunctioning, or ventricular dysfunction may be unmasked after mitral valve replacement or repair for MR.

Usually, LV dysfunction is amenable to inotropic therapy or combination therapy with positive inotropic and vasodilator drugs to optimize CO. Sympathomimetic amines (i.e., catecholamines such as epinephrine, norepinephrine, dopamine, and dobutamine) and phosphodiesterase inhibitors (e.g., milrinone) are commonly used as first-line therapy (see Chapters 20 and 28 for specific drug pharmacology and doses). Small boluses of ephedrine (5 to 20 mg) or diluted epinephrine (2 to 10 μg) may be administered initially to treat ventricular dysfunction and hypotension temporarily while infusions are being prepared. Milrinone, an inodilator, improves CO but significantly reduces SVR; concomitant use of an arterial vasoconstrictor is often necessary. Nitroglycerin is usually administered if ischemia is suspected. Occasionally, a mechanical assist device, such as an intraaortic balloon pump (IABP) or VAD, is necessary.

RV dysfunction or failure may also occur after CPB, usually because of inadequate myocardial protection, inadequate revascularization with resultant RV ischemia or infarction, preexisting pulmonary hypertension, intracoronary or pulmonary air embolism, chronic mitral valve disease, or tricuspid regurgitation (TR). Such RV failure may be evidenced by RV distention and hypokinesis on TEE, as well as by elevations in CVP and PA pressure (PAP). Therapy for RV failure includes increasing preload and inotropic support; milrinone, dobutamine, and isoproterenol are the usual first-line drugs. Other pharmacologic drugs occasionally used to induce pulmonary vasodilation include nitroglycerin and nitroprusside. One potential problem with the use of intravenous inodilator and vasodilator agents is that their effects are not limited to the pulmonary circulation. SVR must be adequate to maintain RV perfusion pressure. Inhaled drugs such as nitric oxide (see also Chapter 104), epoprostenol (Flolan), and inhaled iloprost are considered in refractory cases. Adjuncts to decrease PVR include hyperventilation (higher respiratory rate) to induce mild hypocapnia and preventing hypoxemia and acidosis. Rarely, patients may require support with an RVAD.

Inappropriate vasodilation with a low SVR is another common cause of immediate post-CPB cardiovascular decompensation that may result in unacceptable hypotension. Predisposing factors include long-term administration of medications such as ACEIs or angiotensin receptor blockers (ARBs), prolonged duration of CPB, severe anemia with decreased viscosity, acid-base disturbances, and sepsis. Treatment with infusion of a vasoconstrictor drug such as phenylephrine, norepinephrine, vasopressin, or, rarely, methylene blue is usually successful.

Dysrhythmias. Normal sinus rhythm is ideal because it provides an atrial contribution to ventricular filling and a normal synchronized contraction of the ventricles (see also Chapter 47). However, either supraventricular or ventricular arrhythmias can occur in the immediate postbypass period. Ventricular flutter or fibrillation must be treated immediately with defibrillation. Internal paddles are applied directly to the heart to deliver 10 to 20 J of electricity. If ventricular arrhythmias persist or recur, an antiarrhythmic drug, usually lidocaine or amiodarone, is infused. Persistent or recurrent ventricular fibrillation should prompt concern regarding the adequacy of coronary blood flow.

Atrial fibrillation is the most common dysrhythmia after cardiac surgery, although it usually develops 2 to 5 days postoperatively. Atrial fibrillation or atrial flutter that occurs in the immediate postbypass period can often be converted to normal sinus rhythm with synchronized cardioversion, especially if sinus rhythm was present before CPB. Hypokalemia should be corrected. Magnesium is thought to have a low risk-to-benefit ratio and may modify the ventricular response rate and promote conversion to sinus rhythm. The primary drug used to treat atrial fibrillation is amiodarone, administered as a bolus followed by a continuous infusion. Other drugs sometimes used for rate control and initial treatment include esmolol, diltiazem, and digoxin.[168] Initiation of a long-acting β-adrenergic blocker (e.g., atenolol or metoprolol) is common on the first postoperative day. Prophylactic strategies to decrease the incidence of postoperative atrial fibrillation are being investigated because prevention may decrease the number of days spent in the ICU and the total length of stay in the hospital.[169,170]

When bradycardia, complete heart block, or asystole develops after CPB, temporary epicardial pacing wires are used to provide electrical pacing. Sinus bradycardia may respond well to atrial pacing. If asystole or complete heart block is present, AV sequential pacing is preferable because, as with normal sinus rhythm, it provides an atrial kick to promote adequate filling of the LV chamber and synchronized ventricular contraction. However, if no organized atrial rhythm is present (as in patients with atrial fibrillation) and the ventricular response rate is slow, ventricular pacing is the only option. With this mode of pacing, synchronization of ventricular contraction is less efficient, without atrial augmentation to ventricular filling, which is particularly detrimental in patients with poor LV compliance.

Bleeding and Coagulopathy. Although inadequate surgical hemostasis is a common reason for blood loss after CPB, coagulopathy resulting from excessive contact activation, platelet dysfunction, and fibrinolysis can occur and must be excluded. Historically, the most common causes of excessive bleeding in cardiac surgical patients have been related to platelet activation, platelet consumption, and hyperfibrinolysis induced by the extracorporeal circuit, and these conditions are especially pronounced in older patients.[171] Despite the use of high-dose heparin, thrombin generation remains ongoing during CPB. This results in microvascular coagulation and fibrinolysis and has deleterious effects on platelet function.

Patients who are taking antithrombotic medication before cardiac operations constitute yet another subset of patients at risk for post-CPB bleeding, and information obtained preoperatively about the degree of platelet inhibition should be used to assess its contribution to bleeding. Chen and colleagues found that preoperative testing of platelet function can identify patients at highest risk for perioperative bleeding and transfusions and may further reduce perioperative transfusion requirements.[172]

An evidence-based approach to the diagnosis and treatment of residual post-CPB microvascular bleeding entails the timely detection and treatment of specific causes of coagulopathy.[173] (Diagnosis and treatment of this complication are further discussed in the section on postoperative bleeding and coagulopathy.) Patients with postoperative bleeding benefit from POC testing incorporated into a transfusion algorithm that uses pharmacologic and transfusion therapies. Algorithms are designed to minimize unnecessary and indiscriminate blood product transfusion.[172,174]

Metabolic Disturbances. Hypokalemia is relatively common after CPB and may contribute to the development of dysrhythmias. Causes include diuresis secondary to preoperative diuretics, mannitol administration during CPB, and aggressive treatment of hyperglycemia with insulin administration. Hypokalemia contributes to increased automaticity and may lead to atrial or ventricular arrhythmias. Therefore, hypokalemia should be corrected by the carefully monitored administration of potassium through

an infusion pump at a rate of 10 to 20 mEq/hour, with frequent measurement of potassium, as well as glucose and arterial blood gases.

Hyperkalemia also occurs occasionally after CPB and is usually caused by large doses of cardioplegia or by extracellular shifts associated with respiratory or metabolic acidosis. Hyperkalemia is more likely to occur if renal function is impaired. Occasionally, hyperkalemia is severe enough to interfere with conduction. It can be treated with moderate hyperventilation or the administration of calcium, a combination of glucose and insulin, or both.

Hypocalcemia can occur after CPB, particularly in bleeding patients who are receiving multiple blood transfusions with large amounts of citrate. This phenomenon is exacerbated by hypothermia and low-output states. Hypocalcemia should be corrected because it may reduce cardiac contractility. Intermittent boluses of 10% calcium chloride or calcium gluconate (250 to 1000 mg) are administered.

Hypomagnesemia is common in the postbypass period and is associated with postoperative dysrhythmias, myocardial ischemia, and ventricular dysfunction.[175] Causes include hemodilution with magnesium-free fluids during CPB and diuresis. If hypomagnesemia is suspected, magnesium can be administered in amounts of 1 to 2 g intravenously over 15 minutes. Many centers routinely administer 2 to 4 g of magnesium during weaning or after CPB in an attempt to minimize the incidence of ventricular and atrial arrhythmias.

Hyperglycemia is extremely common after CPB (see the earlier section on the endocrine system). Poor perioperative glycemic control in patients undergoing CABG is associated with increased morbidity and mortality.[71,73] In patients with diabetes, maintaining serum glucose less than or equal to 180 mg/dL during CABG reduces morbidity and mortality, lowers the incidence of wound infections, reduces hospital length of stay, and enhances long-term survival.[71,73] In nondiabetic patients undergoing CABG surgery, maintaining serum glucose at less than 180 mg/dL has also improved perioperative outcomes. Current STS guidelines recommend that blood glucose should be kept at less than 180 mg/dL for the duration of ICU care and at less than 150 mg/dL in patients who require more than 3 days of ICU care as a result of ventilator dependency, the need for inotropes, mechanical device support, antiarrhythmic drugs, or renal replacement therapy.[76]

Pulmonary Complications. Respiratory failure is a very common complication of cardiac surgery (see the section on respiratory insufficiency in problems in the postoperative period). Pulmonary complications that arise immediately after CPB vary from mild to severe and include atelectasis, bronchospasm, hemothorax, pneumothorax, endobronchial intubation, mucus plugs or blood clots in the endotracheal tube, pulmonary edema, and pulmonary dysfunction that varies from a mild increase in the alveolar-arterial oxygen gradient to a form of adult respiratory distress syndrome (ARDS) known as postperfusion lung syndrome.

Atelectasis is a common cause of decreased arterial oxygenation in the postbypass period because during CPB either the lungs are not ventilated or very small tidal volumes are used. Ideally, the lungs are fully reinflated manually before machine ventilation is reestablished during weaning from CPB. During controlled ventilation, it is common to apply positive end-expiratory pressure after CPB and in the immediate postoperative period. Chronic obstructive pulmonary disease (COPD) or any preexisting tendency toward bronchospasm may be exacerbated during CPB. Treatment includes inhaled β_2-agonists (e.g., albuterol), inhaled anticholinergic drugs (e.g., ipratropium), epinephrine, and corticosteroids.

Hemothorax is caused by the accumulation in the pleural cavity of blood and clot, which should be surgically removed before chest closure. Pneumothorax may result from entry of the pleural cavity during dissection of the IMA or from excessive positive-pressure ventilation of the lungs. Pneumothorax may not manifest until after chest closure; it is treated by inserting a chest tube.

Endobronchial intubation may occur when the patient's head is partially hidden from the anesthesiologist's view. The expansion of both lungs should be confirmed during initial full ventilation before weaning from CPB, when the chest is open, so that a good view of both lungs may be obtained. If any blood or mucus is present in the endotracheal tube, it should be suctioned during and after weaning from CPB.

Pulmonary edema may be cardiogenic because of preexisting HF exacerbated by the additional fluid load in the pump prime. Ultrafiltration during CPB and diuresis during and after CPB may minimize such pulmonary edema. Noncardiogenic pulmonary edema may occur after prolonged CPB with sequestration of neutrophils in the pulmonary capillaries and elevation of lysosomal enzyme activity, resulting in a localized "inflammatory response" and increased capillary permeability. Other causes of ARDS include multiple pulmonary emboli and transfusion reactions (transfusion-related acute lung injury).

Chest Closure

Hemodynamic deterioration may occur during chest closure because of cardiac tamponade in patients with ongoing bleeding. Other reasons for severe hypotension during chest closure include hypovolemia, ischemia secondary to kinking of an arterial or venous coronary graft, and impairment of RV contractility and venous return in patients with significant myocardial edema. TEE can be particularly useful in determining the cause of hypotension during chest closure because it can quickly reveal tamponade, hypovolemia, RV or LV global dysfunction, and severe new wall motion abnormalities. Reopening the chest may be necessary while treatment is instituted. Occasionally, the patient's sternum cannot be closed because of hemodynamic instability; in such cases, only skin closure is attempted, and plans are made to return to the operating room for sternal wiring after a period of myocardial recovery in the ICU.

Transport to the Intensive Care Unit

After all incisions are closed and dressings are applied, provided the patient is hemodynamically stable, the next step is transport to the ICU. Monitoring should not be

completely interrupted even for a few moments—the ideal transport monitoring system has a "brick" that can be ejected from the operating room monitor and is compatible with the transport monitor. If such equipment is not available, sequential disconnection of monitoring devices is advised so that an online monitor is always visible.

On arrival in the ICU or cardiac recovery area, a transfer of the patient and the patient's information from one team to another, termed handoff or handover, occurs. Handoff failures have been identified as a significant source of medical errors, both between and within teams.[176-178] Implementing a handoff protocol reduces information omission and reduces errors. The process is intended to be strictly sequential: monitoring should be transferred before ventilator transfer, and all phase 1 items should be completed before information transfer.[179,180] Using formal, sequential handoff procedures does not increase the duration of the process.[181] The following sequence is suggested[181] (Wahr J, personal communication, November 17, 2012):

Phase 1: Equipment and Technology Handover

1. Monitoring transferred to ICU equipment
2. Ventilator function initiated
3. Infusions and fluids checked
4. Chest drains secured and on suction
5. Vital signs confirmed to be stable, ventilator functioning well, infusions running appropriately
6. Anesthesiologist, nurse, and surgeon confirm that they are ready for information transfer

Phase 2: Information Handover

1. Anesthesiologist presents
   a. Patient-specific information (age, weight, medical and surgical history, allergy status, baseline vital signs, pertinent laboratory results, diagnosis, current condition and vital signs)
   b. Anesthetic information (intraoperative course and any complications, lines present, blood transfusion or fluid totals, paralytics or opioids, antibiotics, current infusions, vital sign parameters or limits, pain relief plan, laboratory values)
2. Surgeon presents: surgical course (diagnosis, operation performed, surgical findings, complications, blood loss, drains, antibiotic plan, deep vein thrombosis prophylaxis, medication plan, tests to be done, nutrition, key goals for the next 6 to 12 hours)

Phase 3: Questions and Discussion

In all cases, the anesthesiologist should remain with the patient until hemodynamic stability and overall stability are ensured.

CARDIOPULMONARY BYPASS

CPB is a form of extracorporeal (*extra* = "outside of," *corporeal* = "the body") circulation (ECC) in which the patient's blood is rerouted outside the vascular system, and the function of the heart, the lungs, and, to a lesser extent, the kidneys is temporarily assumed by surrogate technology. The circuitry and equipment used to facilitate this substitution are topics of the next section of this chapter.

CIRCUITRY AND EQUIPMENT

The most common and most complicated ECC procedure is CPB. The goal of CPB is to provide a motionless and bloodless field for the surgeon by rerouting the patient's entire CO around both the heart and the lungs. Other ECC techniques include left heart bypass (LHB), cardiopulmonary support (CPS), and extracorporeal membrane oxygenation (ECMO).

The pumps, tubing, artificial organs, and monitoring systems used in CPB are diagrammed in Figure 67-11. Simply stated, venous blood is intercepted as it returns to the right atrium and is diverted through the *venous line* of the CPB circuit to a *venous reservoir*. The *arterial pump* functions as an artificial heart by withdrawing blood from the reservoir and propelling it through a *heat exchanger*, an artificial lung (the *oxygenator*), and an *arterial line filter* before returning it through the *arterial line* to the patient's arterial system. Additional pumps and components are used to assist in the operation to manage shed blood (the *pump sucker*), decompress the heart (*vent*), and deliver the *cardioplegia solution*.

Blood Tubing

The tubing used to connect the various components and conduct blood into and out of the patient's vascular system is medical-grade polyvinyl chloride. For decades, the blood-tubing interface was untreated polyvinyl chloride. However, the newer generation of polyvinyl chloride tubing has surface coatings and other modifications that significantly alter the bioreactivity of the surface. Collectively, these coatings have been shown to reduce plasma levels of markers of subclinical coagulation, attenuate the increase of cytokines and other inflammatory markers, and shorten intubation times.[182-184]

Venous Reservoirs

Blood reservoirs perform an important function in the conduct of CPB by facilitating the displacement of a large volume of blood out of the circulation at strategic times during the operation. Positioned between the venous line and the arterial pump, blood reservoirs may be collapsible plastic bags or clear plastic hard-shelled containers. Hard-shelled reservoirs include an integral filtration mechanism with a screen and depth filters through which blood must pass before leaving the outlet of the vessel. Almost universally, hard-shelled reservoirs have integrated positive- and negative-pressure release valves, which are necessary for the application of vacuum to the reservoir to augment venous drainage. If vacuum-assisted venous drainage is employed, the vacuum pressure in the reservoir should be maintained at the minimum necessary, and entrainment of air from the surgical field into the venous line should not be permitted. Reservoir pressures in excess of 60 mm Hg have been shown to increase microbubble counts measured in the circuit's arterial infusion line dramatically.[185]

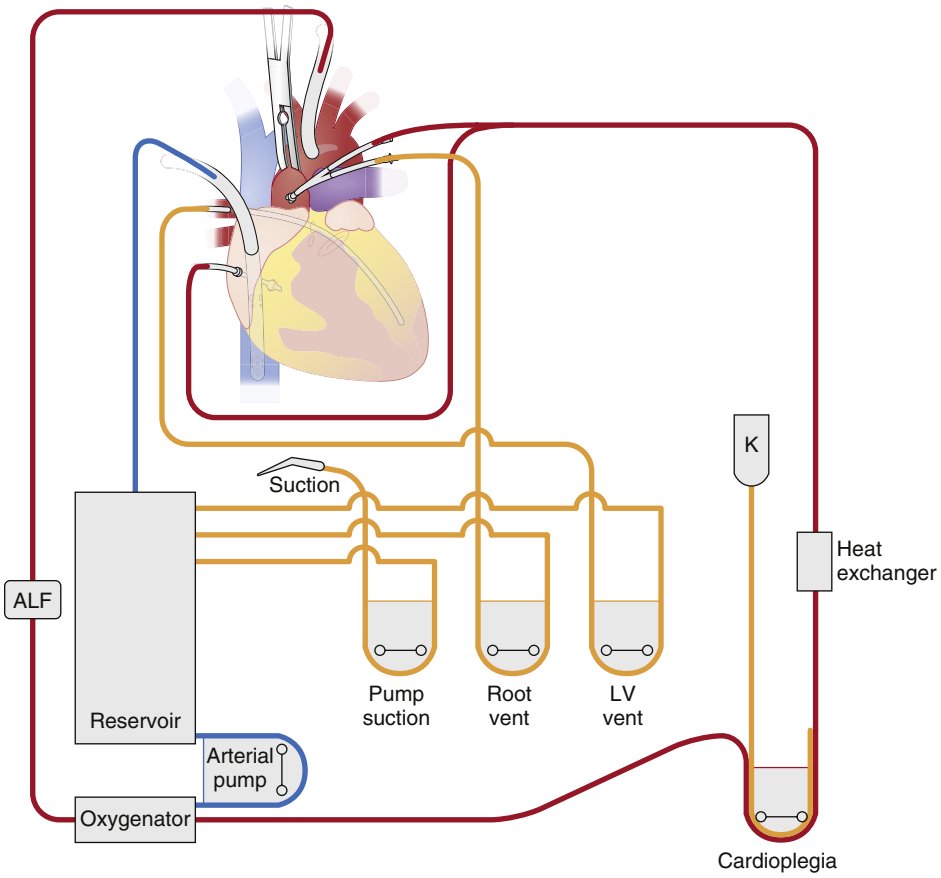

Figure 67-11. A typical cardiopulmonary bypass circuit interfaced with a patient. *ALF,* Arterial line filter; *K,* potassium; *LV,* left ventricular.

Arterial Pumps

The pumping device used to replace the function of the heart generally uses one of two primary technologies: a roller pump or a centrifugal pump. Roller pumps are positive-displacement pumps that function by occluding a point in a piece of tubing and then rolling the occlusive point of contact along a length of the tubing. This process forces the fluid in the tubing to move forward in front of the occlusive point while simultaneously drawing in fluid behind the occlusive point. Centrifugal pumps, in contrast, are nonocclusive kinetic pumps that generate flow by magnetically coupling the high-speed revolution of a reusable motor to the plastic plates, fins, or channels inside a disposable cone. This process produces a constrained vortex that propels fluid through the opening on the side of the cone while drawing fluid into the point of the cone. Both pump technologies are traumatic to the formed elements in blood; however, centrifugal pumps are thought to be less traumatic than roller pumps.[186]

Each type of pump poses unique risks that must be appreciated. Roller pumps, by virtue of their occlusive nature, are capable of generating extremely high positive and negative pressure and are also able to pump massive quantities of air. Consequently, the national standard of care requires that these pumps be servoregulated to reduce their speed automatically when either high pressure or air is detected in the path of the blood. In contrast, centrifugal pumps, being nonocclusive, are unable to generate extremely high or low pressure. Additionally, if a large bolus of air is introduced into the disposable cone, the air will remain in the cone, thus displacing the blood, and the pump will be unable to generate forward flow. This feature prevents centrifugal pumps from pumping large volumes of air. However, the lack of a point of tubing occlusion inside the pump allows retrograde flow from the patient's high-pressure arterial system backward through the arterial line, filter, and oxygenator and ultimately into the low-pressure venous reservoir. This situation may occur whenever the pump's revolutions per minute are reduced below a critical threshold. A large-bore one-way valve or a computer-activated electronic clamp can be positioned in the arterial line to eliminate the possibility of retrograde arterial flow and inadvertent exsanguination of the patient.

Heat Exchanger

Heat exchangers are essential to CPB because they facilitate the management of the patient's blood temperature. Throughout the period of CPB, 20% to 35% of the patient's circulating blood volume is outside the body and is exposed to the ambient temperature of the operating suite, which can cause hypothermia. Therefore, in all CPB procedures, an inherent need exists to warm the blood before CPB is terminated. Additionally, for many surgical procedures, some amount of hypothermia, from mild (35° C) to profound (18° C), is desirable to reduce the patient's metabolic rate. In these cases, the heat exchangers may be used to reduce the temperature of the blood when CPB is initiated and then to warm the blood before CPB is terminated.

Oxygenator

The oxygenator substitutes for the patient's native lungs and performs the essential function of gas exchange. Several similarities exist between the native lung and the oxygenator: Both have a gas space and a blood space, both are driven by passive diffusion gradients, and both use a membrane to separate the blood from the gas. In the oxygenator, the membrane is usually made from microporous polypropylene. This material is extruded into thin straws with an outer diameter of 200 to 400 μm, a wall thickness of 20 to 50 μm, and a total surface area of 2 to 4 m^2. Typically, oxygenators have a static priming volume of 135 to 340 mL and are capable of arterializing up to 7 L/minute of typical venous blood.[187]

The native lung uses the conductive airways for both inspiration and expiration and depends on a certain tidal volume and respiratory rate to refresh the gas in the alveolar space regularly. The oxygenator, however, has separate gas inlet and outlet ports and can refresh the gas inside its gas space (the internal lumen of the straws) with a continuous flow or "sweep" of gas through the oxygenator. The blood space of an oxygenator is the space around the outside of the straws. Venous blood entering the oxygenator is directed across the outside of the fibers while gas is concurrently circulated through the inside of the fibers. Pressure gradients between the blood space and the gas space drive oxygen across the membrane and into the blood, whereas carbon dioxide is driven out of the blood and into the gas phase. Similarly, volatile anesthetic agents can be delivered to the patient through the oxygenator's sweep gas. Unlike the membrane in the native lung, however, the oxygenator's membrane is not a true membrane. The microscopic (0.5- to 1.0-μm) pores on the sides of the fibers are small enough to prevent plasma and the formed elements of blood from leaking through but are still large enough to allow gas to pass through. Therefore, care must be taken to ensure that the pressure in the gas space never exceeds the pressure in the blood space, or gaseous emboli will form in the blood. In appreciation of the risks inherent in using a pressurized gas space, most oxygenators are designed with multiple gas outlet ports. In any case, caution should be exercised to ensure that the outlet of the gas phase cannot become occluded.

Arterial Line Filter

In the United States, arterial line filters are used in more than 95% of CPB procedures in adults. These filters are placed in the arterial line as the last component through which blood passes before it returns to the patient. With pore sizes of 20 to 40 μm, arterial line filters increase the patient's safety by removing particulate and gaseous microemboli. To remove bubbles from the blood path effectively, arterial line filters must be continuously "purged" by allowing a small amount of blood to recirculate from the top of the filter back into the venous reservoir. Many ECCs are designed to capitalize on this continuous arterial shunt with the incorporation of a flow-through blood gas sensor that continually monitors the blood gas concentrations in the postoxygenator blood. These in-line blood gas measurements are generally reliable and can be used for the early identification of trends and precise management of oxygenator performance.

SEQUENCE OF EVENTS

Although the approach to surgical procedures that require CPB varies among institutions, all procedures loosely follow a predictable sequence of events. At any institution, CPB requires circuit selection and priming, anticoagulation, cannulation, initiation and maintenance of CPB, myocardial protection, and finally, weaning and termination from CPB.

Circuit Selection and Priming

When selecting the components for an extracorporeal circuit, the perfusionist first calculates the highest blood flow that may be necessary during the procedure. Typically, the highest blood flow is approximately 2.4 to 3.0 L/minute/m^2 or 60 to 70 mL/kg/minute. The calculated flow is then compared with the rated flow for the components of the ECC circuit. This flow rating represents the highest blood flow rate at which the component can perform its function within the acceptable range of hydraulic forces (pressure and shear stress) without causing an unacceptable amount of blood trauma.

The combination of components included in the ECC determines the prime volume of the circuit, or the volume of balanced electrolyte solution necessary to de-air the circuit completely. This prime volume is the main cause of the hemodilution associated with CPB. Therefore, the perfusionist must calculate the patient's resultant hematocrit (HCTr), which is the patient's predicted hematocrit after the patient's preoperative blood volume is mixed with the asanguineous prime volume of the ECC. The HCTr is computed by dividing the patient's calculated volume of RBCs into the calculated total volume of distribution represented by the addition of the ECC prime volume to the patient's blood volume (Box 67-8). An adult patient's intravascular volume of distribution will increase by 20% to 35% when CPB is initiated. This increased volume of distribution dilutes not only all the proteins and formed elements of the blood but also plasma levels of drugs. If this dilution is not anticipated, the patient's depth of anesthesia and circulating concentrations of many pharmacologic drugs may be reduced when CPB is initiated.

BOX 67-8 *Resultant Hematocrit Formula*

HCTr = Patient's preoperative red blood cell volume / Total volume of distribution at the start of CPB

$$\mathbf{HCTr} = (\mathbf{BVp} \times \mathbf{HCT}) / (\mathbf{BVp} + \mathbf{PVc})$$

$$\mathbf{HCTr} = (\mathbf{kg} \times \mathbf{75} \times \mathbf{HCT}) / (\mathbf{kg} \times \mathbf{75}) + \mathbf{PVc}$$

where

HCTr = resultant hematocrit
BVp = patient's blood volume
kg = patient's weight in kg
PVc = prime volume of the extracorporeal circuit

CPB, Cardiopulmonary bypass.

The solution used to prime the CPB circuit is generally a balanced electrolyte solution containing normal plasma concentrations of many of the standard blood ions. Various drugs may be added to the solution to attenuate the dilutional effect of CPB on those ions (e.g., albumin, heparin, bicarbonate) or to discourage edema formation or encourage diuresis of the prime fluid by the patient (e.g., mannitol).

Anticoagulation

With the circuit primed and the vessels exposed, standard procedure requires that the patient be fully anticoagulated before cannulation. Dosing of heparin and monitoring of the ACT are discussed earlier in this chapter. Many commercial devices are designed to monitor the ACT, and although the ACT is used as if it were a standardized test, the results produced by different instruments are far from standardized. We have shown that these devices, when used on the same pool of heparinized blood, can produce ACT results that vary by as much as 40% (see Fig. 67-6).

The ACT test is not used to monitor heparin levels but to monitor the anticoagulant effects of heparin and other anticoagulants. Thus, elevated ACT measurements taken before, during, or after CPB may be influenced by variables other than heparin (e.g., hypothermia, hemodilution, coagulopathy, and anticoagulants).

Although controversial, some studies suggest that subclinical coagulation may progress despite acceptable ACT times during CPB and that maintaining higher circulating heparin levels may reduce this process.[98,188] POC heparin level tests are commercially available and may be used to monitor circulating heparin levels in CPB-supported patients. Indeed, some centers monitor both the circulating level of heparin and its anticoagulant effects and administer heparin intermittently throughout the procedure to maintain a predetermined therapeutic heparin level, as well as a minimally acceptable ACT.

Heparin dosing may be based on the patient's weight (300 to 400 units/kg) or determined by a dose-response curve. Heparin dose-response curves are determined in vitro by measuring the ACT of the patient's blood at baseline (without heparin) and after a known concentration of heparin (2.5 units/mL) is added. By graphing the ACT in seconds against the blood concentration of heparin, one can extrapolate the blood concentration of heparin needed to achieve a target ACT acceptable for CPB. Most patients need circulating blood heparin concentrations between 1.5 and 3.0 units/mL to achieve an ACT of 480 seconds. A commercial device designed to automate this process is available; from the patient's height, weight, sex, and heparin dose-response test results, the machine calculates the appropriate patient-specific heparin dose to administer during CPB.

Cannulation

Every CPB procedure requires a high-flow cannula in a large vein and another such cannula in a large artery for withdrawing blood from and returning blood to the patient (Table 67-6). Most procedures include additional cannulas for administering cardioplegia solutions to the heart and removing (venting) blood and air from

TABLE 67-6 COMMON APPROACHES TO VENOUS AND ARTERIAL CANNULATION FOR CARDIOPULMONARY BYPASS

Procedure	Venous	Arterial	Cardioplegia	Vent	Comments
CABG	2-stage approach in the RA	Ascending aorta	Root and/or CS	Aortic root	Patients with low EF or failure to wean from CPB may benefit from LV venting
AVR	2-stage approach in the RA	Ascending aorta	Root and/or CS, plus handheld selective once the root is open	LV and aortic root	None
MVR	Bicaval	Ascending aorta	Root and/or CS	LV and aortic root	None
Aortic root replacement, not including the arch	2-stage approach in the RA	Ascending aorta	Root and/or CS	LV and aortic root	The closer the repair is to the head vessels, the more difficult aortic cannulation becomes
Aortic arch	2-stage approach in the RA	Axillary or femoral artery	Root and/or CS	LV and aortic root	CS cardioplegia unlikely if the coronaries are unobstructed
Redo procedures	Femoral vein	Femoral artery	Root and/or CS	Aortic root and/or LV	Only in extreme cases (i.e., when the heart is tightly adhered to the back of the sternum, or any time that the heart is lacerated during sternotomy)
Other intracardiac procedures	Bicaval	Ascending aorta	Root and/or CS	LV and aortic root	Any procedure that requires opening the RA or excessive surgical retraction

AVR, Aortic valve repair or replacement; *CABG,* coronary artery bypass grafting; CPB, cardiopulmonary bypass; *CS,* coronary sinus; *EF,* ejection fraction; *LV,* left ventricle; *MVR,* mitral valve repair or replacement; *RA,* right atrium.

the chambers of the heart (Fig. 67-12). Different surgical procedures require different cannulation techniques, the most common of which are described here.

The target for venous cannulation is generally the right atrium. The right atrium is the central repository for all venous blood, and the RA appendage is conveniently accessible through a sternotomy. Although RA cannulation is optimal for most cardiac surgical cases, the cannula may not perform well when the heart is being retracted. Significant retraction of the heart is necessary to access some posterior coronary arteries for bypass or to access the mitral valve through a left atriotomy. Because of surgical retraction involving the right atrium, the venous cannulation site for mitral valve repair or replacement procedures is generally moved away from the right atrium to the SVC and inferior vena cava (IVC). If a single cannula is placed in each vena cava, venous blood can be intercepted just before it enters the right atrium so that the cannula can provide acceptable drainage throughout the procedure. The right atrium may also be approached through the femoral vein. A femoral venous cannula extends the entire length of the IVC and rests with its openings in the right atrium.

An improperly sized or positioned venous cannula obstructs the flow of blood into the ECC circuit. This may elevate CVP and encourage extravasation of blood volume from the vascular compartment into the extracellular compartment (third spacing). Therefore, it is important to evaluate the performance of the venous cannula or cannulas when CPB is initiated. Properly placed venous cannulas allow complete decompression of the right side of the heart, as indicated by a CVP and PAP of zero and a nonpulsatile arterial blood pressure.

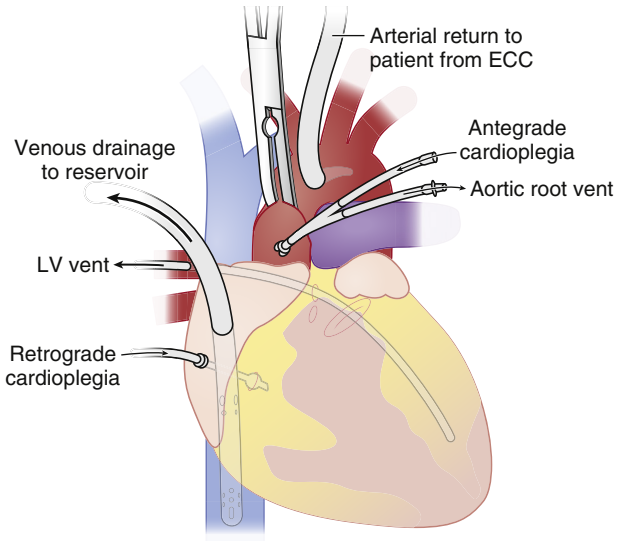

Figure 67-12. A common cannulation approach for cardiopulmonary bypass (CPB) procedures. Two cannulas are necessary to provide CPB. A cannula in the right atrium provides venous drainage to the extracorporeal circuit (ECC), and an arterial cannula placed in the ascending aorta allows arterial return to the patient from the ECC. Additional cannulas are necessary to protect the heart after cross-clamping. Cardioplegia can be administered in antegrade fashion through a special needle placed in the ascending aorta between the aortic valve and the aortic cross-clamp. Retrograde cardioplegia can be delivered directly into the coronary sinus through a special balloon-tipped cannula. Vent cannulas are used to decompress the heart while the aorta is clamped and to remove bubbles before cross-clamp removal. The aortic root vent is integrated into the antegrade cardioplegia needle, and the left ventricular (LV) vent cannula is inserted through the right superior pulmonary vein.

The ECC returns oxygenated blood to the patient through the arterial cannula. For CABG and valve procedures, the standard target for the arterial cannula is the portion of the ascending aorta below the aortic arch but 3 to 4 cm above the aortic valve. The alternative approaches of axillary or femoral artery cannulation are used in procedures that require the manipulation of much of the aortic root, arch, or both. Axillary artery cannulation is generally facilitated by the anastomosis of a tube graft to the side of the axillary artery to provide access for the arterial cannula without interrupting blood flow to the right arm. An added benefit of axillary cannulation for aortic arch procedures is that clamping the innominate artery allows antegrade cerebral perfusion to be performed during a period of circulatory arrest. Femoral arterial cannulation involves inserting the cannula through the femoral artery and into the abdominal aorta. Blood flow to the thorax is directed in retrograde fashion upward into the aorta. Ischemia of the cannulated limb is a risk commonly associated with femoral arterial cannulation, and dissection of the cannulated artery is a risk associated with the cannulation of any arterial site. Iatrogenic aortic dissection at the cannulation site occurs in approximately 200 procedures annually in the United States, with a resultant mortality of 48%.[189] Proper cannula placement and patency should be confirmed before CBP is initiated.

With venous and arterial cannulas in place, the heart and the lungs can be bypassed. However, additional cannulas are needed to facilitate aortic cross-clamping and cardiac arrest. For example, cardioplegia cannulas can be placed in the ascending aorta, and then the aorta can be occluded by placing a large vascular clamp (i.e., a cross-clamp) across it. Occluding the aorta between the arterial cannula and the antegrade cardioplegia cannula interrupts blood flow from the arterial line of the ECC to the coronary arteries, thereby initiating a period of global myocardial ischemia. Intermittent or continuous administration of cardioplegia through the antegrade and retrograde cardioplegia cannulas (see Fig. 67-12) serves to attenuate the ischemic insult (by a mechanism discussed later).

Bronchial pulmonary vascular connections deliver approximately 1% of the CO to the lungs, from where it is subsequently returned to the left side of the heart. In patients with chronic pulmonary disease, this recirculation may increase to more than 10% of CO. During the period when the aorta is cross-clamped, this blood volume will distend the left side of the heart and the pulmonary vasculature if the blood is not actively removed. Additionally, intracardiac procedures inherently introduce air into the left-sided chambers, and this air must be removed before the patient is weaned from CPB.

Vent cannulas facilitate decompression and de-airing of the heart. The heart is most commonly vented at the aortic root or directly from the left ventricle. Aortic

root vents use the same cannula that is used to deliver antegrade cardioplegia (see Fig. 67-12) and draw blood and air from the left ventricle across the aortic valve and into the reservoir of the ECC circuit. Because the antegrade cardioplegia needle has a small gauge and is positioned above the aortic valve, root vents have several significant limitations: they cannot be used when antegrade cardioplegia is being administered, and they are ineffective in decompressing the left ventricle when the cross-clamp has been removed. These limitations are not generally significant during an uncomplicated CABG procedure, but for CABG in patients with severely compromised ventricular function and for all intracardiac procedures, direct LV venting becomes essential. Typically, LV vents are introduced through the right superior pulmonary vein and are advanced through the left atrium, across the mitral valve, and into the left ventricle (see Fig. 67-12). The 10- to 14-Fr cannula used for this purpose offers significantly better venting capacity than does the root vent. Flows in the range of several liters per minute can be drawn through these cannulas when necessary, and because these cannulas are inserted directly inside the left ventricle, they are very effective in removing air bubbles that remain after an intracardiac procedure has been completed. Additionally, because the LV vent is separate from the cardioplegia cannula, it can be used to decompress the heart during antegrade cardioplegia administration, which may be necessary for patients with aortic insufficiency. Unfortunately, numerous case reports exist of injuries to patients that resulted from air being pumped into the heart through malfunctioning vent lines. The proper function of the vent pump should be confirmed at the field before the pump is connected to the patient.

Initiation and Maintenance of Cardiopulmonary Bypass

Once the patient is anticoagulated and cannulated, CPB may be initiated. Before initiating CPB, it is good practice to verify the patency of the arterial cannula. After the proper position of this cannula is confirmed, CPB may be initiated by removing the clamps on the venous line between the venous cannula and the reservoir. The patient's blood then passively drains into the ECC. Simultaneously, the arterial pump on the CPB machine begins to infuse the mixture of prime solution and autologous blood into the patient through the arterial cannula. Evaluating the performance of the venous and arterial cannulas is very important during the initial seconds of CPB. The pressure in the arterial line of the ECC should be maintained at less than 300 mm Hg to prevent excessive trauma to the formed elements of the blood. Venous cannula position is evaluated mainly by examining the patient's hemodynamics. Provided the venous cannula is adequately draining the venous return to the heart, right-sided heart pressure (CVP and PAP) should decrease to 0 mm Hg, and the arterial blood pressure should reach a normal mean pressure (50 to 90 mm Hg) while also becoming nonpulsatile.

The arterial trace usually becomes nonpulsatile as the heart is emptied and the pumping force is changed from the ventricle to the nonpulsatile arterial pump of the heart and lung machine. However, patients with aortic insufficiency continue to have a pulsatile arterial trace despite complete venous drainage (CVP and PAP = 0 mm Hg) because of regurgitation of blood from the arterial cannula across the incompetent aortic valve and back into the left ventricle. If right-sided heart pressure does not reduce to 0 mm Hg, the arterial trace remains pulsatile, and arterial pump flow cannot be increased to full flow; in that case, the position of the venous cannula must be reevaluated. Once full flow has been achieved, the function of the heart and lungs will have been completely transferred to the CPB machine; the anesthesiologist then can turn off the ventilator, and hypothermia of the patient can be initiated.

The initiation of CPB is often associated with a period of hypotension, which can be managed with the administration of an α-agonist (e.g., phenylephrine) into the venous reservoir of the ECC circuit (Fig. 67-13). Although it is common for cerebral oximetry values to reduce transiently at this point, acutely reduced cerebral oximetry values on CPB initiation may provide the first indication of poor SVC drainage or selective perfusion of a single aortic head vessel.[190-192] Markedly changed cerebral oximetry values warrant additional confirmation of cannula position and function. While CPB is maintained, the adequacy of perfusion is continuously evaluated by monitoring hemodynamic variables. Blood flow from the arterial pump can be manipulated across a range of 1.6 to 3.0 L/minute/m^2 to deliver an arterial blood pressure of 50 to 90 mm Hg and $S\bar{v}O_2$ greater than 65%. Any hypotension or hypertension that occurs despite adequate flow and $S\bar{v}O_2$ can be treated by adjusting the patient's SVR with vasoconstrictors or vasodilators.

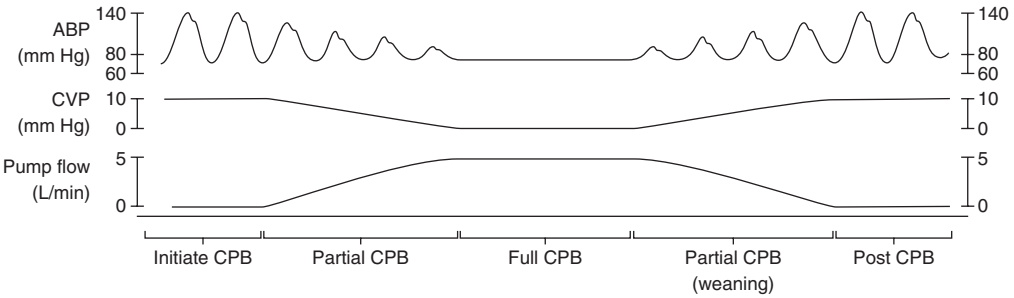

Figure 67-13. Illustration of a patient's hemodynamics before cardiopulmonary bypass (CPB), during the initiation of CPB, during full CPB, while weaning from CPB, and after CPB. *ABP,* Arterial blood pressure; *CVP,* central venous pressure.

Arterial blood gas samples should be taken at least every 30 minutes to assess the performance of the oxygenator and to monitor the patient for the development of acidosis and proper anticoagulation status. Base deficit values of −5 or less can be corrected with sodium bicarbonate, but the underlying cause of the acid production should ultimately be addressed. Increased perfusion flow and pressure may be indicated. ACTs shorter than the institutional parameter acceptable for CPB (usually ≥400 seconds) should be treated with a heparin bolus administered into the ECC.

Urine output is also monitored during CPB as an indicator of perfusion flow and pressure. However, poor urine production during CPB has not been shown to predict postoperative renal insufficiency. Rather, age, preoperative renal function, the duration of CPB, and EF have been correlated with postoperative renal dysfunction.[193]

Myocardial Protection

To provide a motionless field for the surgeon, the heart is arrested in diastole by the administration of a potassium-enriched cardioplegia solution to the heart. Interrupting myocardial electromechanical activity is the single most important step in reducing the heart's metabolism. Potassium-induced arrest alone reduces the heart's myocardial oxygen consumption by 90%. It is common to augment this reduction with hypothermia by administering cold cardioplegia solution. The combined influence of potassium arrest and myocardial temperatures lower than 22° C reduces myocardial oxygen consumption by 97% and enables the tissue to withstand a complete interruption of blood flow for periods of 20 to 40 minutes. Once the surgical procedure is completed, myocardial arrest can be reversed by reperfusing the heart with warm normokalemic blood.

The ingredients of cardioplegia solutions vary considerably from institution to institution, save that potassium is always used as the arrest agent. Whereas some centers may use a very simple solution of potassium-enriched whole blood, others may choose a more complex solution with a variety of chemical additives. The trend in clinical practice has been not to use purely crystalloid cardioplegia solutions; instead, most centers now use some form of blood cardioplegia. The ratio of blood to crystalloid is generally 4:1 or 8:1. The crystalloid solution is often mixed with arterialized whole blood from the ECC circuit in an exact ratio by placing two different-sized tubes (the larger drawing from the arterial line of the ECC and the smaller drawing from the bag of cardioplegia solution) through a single roller pump and splicing the two tubes together downstream from the outlet of the pump. Generically, the chemicals added to the cardioplegia solutions are designed to make the solution slightly hypertonic to reduce edema, and these chemicals include a buffer to counter the heart's production of acidic metabolites and a substrate for energy or catalysts to assist the heart in the production of adenosine triphosphate. Typically, solutions with two different potassium concentrations are used during the procedure. For inducing cardioplegic arrest, a "high-K" solution with a potassium concentration of approximately 20 to 30 mEq is used. After isoelectric arrest is induced, the solution is changed to a "low-K" mixture with a potassium concentration of approximately 10 mEq.

These solutions can be administered in *antegrade* fashion into the coronary arteries via the aortic root, through a needle placed between the aortic cannula and the aortic valve, or in *retrograde* fashion into the coronary veins, via a balloon-tipped cannula placed in the coronary sinus. Antegrade cardioplegic delivery is the most physiologic approach. However, when the patient has pronounced CAD or aortic valve insufficiency, antegrade administration may not uniformly deliver cardioplegia to the myocardium. Retrograde cardioplegia administration also has limitations. For example, the free wall of the right ventricle and the posterior third of the septum (the distribution territory of the right coronary artery [RCA]) are poorly perfused by retrograde delivery.[194] Additionally, the microvascular areas of the heart that are perfused by retrograde cardioplegia are less able to sustain normal myocardial energy metabolism.[195] Thus, the most complete technique for myocardial protection involves both antegrade and retrograde delivery. In fact, it is not uncommon for cardioplegia to be delivered simultaneously in both antegrade and retrograde fashion.

Cardioplegia is commonly administered intermittently in a volume-dosing regimen. After an initial arrest dose of approximately 1000 to 1500 mL of "high-K" solution is administered, perfusion of the heart is suspended for a period of 10 to 40 minutes while the surgeon works on the heart. Then, periodically throughout the procedure, 200- to 500-mL doses of "low-K" solution are administered to deliver nutrients to the cells and maintain the potassium concentration. Intraoperative evaluation of the adequacy of myocardial protection is empirical and based on the quiescence of the ECG, the time since the last dose was administered, and the temperature of the heart. The filling state of the ventricular chambers should also be evaluated. If the vent lines are not keeping the heart empty, it will warm more quickly and the heart muscle will be under tension. This state increases myocardial oxygen consumption and compromises myocardial protection. To reinstitute the electromechanical activity of the heart, warm, normokalemic blood is infused into the coronary arteries. This may be done by administering a "hot shot" through the cardioplegia cannulas or by simply removing the cross-clamp.

Weaning and Termination of Cardiopulmonary Bypass

The process of weaning the patient from the heart and lung machine requires an increased level of communication and awareness among the anesthesiologist, perfusionist, and surgeon. Before weaning and termination, the patient should be rewarmed and the heart de-aired. Regular cardiac electrical activity should be confirmed and supported with a pacemaker if necessary. Ventilation of the lungs must be resumed and laboratory values confirmed and corrected if needed. By slowly reducing venous drainage to the ECC and transfusing volume from the reservoir to the patient, normal filling volume can be returned to the heart. As the CO is returned to normal, flow from the arterial pump of the heart and lung machine is decreased and eventually terminated. Immediately after the termination of CPB,

the patient is often hemodynamically supported by volume replacement with the blood remaining in the ECC, frequently supplemented with vasopressors or inotropic agents (see the earlier section on weaning from CPB).

When the patient is hemodynamically stable, protamine can be administered to reverse the anticoagulatory effect of heparin. The administration of protamine to the patient is a sentinel event that must be communicated clearly by the anesthesiologist to the perfusionist and surgeon. In the event of inadvertent return of blood containing protamine to the ECC through the pump sucker, the blood remaining in the circuit may coagulate and render the circuit unusable for urgently reinstituting CPB. Therefore, all cannulas should be removed before the action of heparin is fully reversed, and the blood remaining in the ECC should be salvaged by centrifugation or hemofiltration for return to the patient by the anesthesiologist.

Protamine inactivates heparin by irreversibly binding with the strongly acidic heparin molecule to form a stable salt with no anticoagulant effects. POC tests are available for several ACT machines to calculate a patient-specific protamine dose.[196] If an automatically generated protamine dose-response curve is not available, many institutions calculate the protamine dose needed from the total dose of heparin delivered to the patient. This calculation usually results in the administration of 1 to 1.3 mg of protamine for every 100 units of heparin given. Protamine should be administered slowly over a period of 5 to 10 minutes to reduce the risk of hypotension. After protamine administration, ACTs should return to baseline. An increased ACT may indicate residual heparin or may be the result of a coagulation deficiency that necessitates additional laboratory tests, such as coagulation panel tests, heparin assays, platelet function analysis, thromboelastography, or any combination of these investigations.

OTHER ISSUES

Temperature

Deliberate hypothermia is a reliable method of neuroprotection and is often used during routine CPB. Deep hypothermia unquestionably confers cerebral protection when the circulation must be arrested during cardiac surgery. Even mild hypothermia (as little as 1° C to 2° C) minimizes the severity of cerebral ischemia in animal models. Various suggested mechanisms for the neuroprotective effects of hypothermia have been tested in animal models (Table 67-7).[197] Hypothermia may attenuate the effects of cerebral ischemia by creating a favorable balance between oxygen supply and demand and by decreasing the cerebral metabolic rate of oxygen. Hypothermia not only reduces the metabolic rate but also delays the release of excitatory amino acids, neurotransmitters that play an important role in the process of neuronal death. Additionally, hypothermia reduces the permeability of brain arterioles and prevents blood-brain barrier dysfunction. Hypothermia may also interfere with the inflammatory response by suppressing the adhesion of polymorphonuclear leukocytes in the damaged region.

However, after performing a meta-analysis, Rees and colleagues concluded that no definitive evidence for a neuroprotective effect of hypothermia during routine CPB exists,[198] although the studies examined in that analysis had some important limitations. For example, the timing of hypothermia may have limited its protective value. Hypothermia is always initiated after aortic cannulation and the onset of bypass, but macroembolization to the brain is unlikely during this period because the heart is excluded from the circulation by the aortic cross-clamp. Instead, the periods of highest risk for microembolization and macroembolization are during and shortly after aortic manipulation, cross-clamping, and unclamping because aortic cannulation and cross-clamping are performed near the start of CPB, when the brain is not yet cold. Similarly, the aortic cross-clamp is removed near the end of CPB, usually after the patient has been rewarmed.

In contrast, hyperthermia is known to be deleterious. Elevation of body temperature by as little as 2° C decreases cerebral tolerance to ischemia. Hyperthermia delays neuronal metabolic recovery and increases excitotoxic neurotransmitter release, oxygen free radical production, intracellular acidosis, and blood-brain barrier permeability, with subsequent multifocal breakdown at sites in the thalamus, hippocampus, and striatum (see Table 67-7). Hyperthermia also affects protein kinase activity and destabilizes the cytoskeleton. Clinically, fever and hyperthermia worsen the prognosis of hospitalized patients with stroke.[199]

In the 1990s, some centers began using normothermic cardioplegia to improve cardiac outcomes while avoiding deliberate hypothermia. This practice of "warm heart surgery" was debated because of concern that the neuroprotective effects of hypothermia would be lost. Subsequent studies produced inconsistent results with respect to the incidence of stroke and postoperative neurocognitive decline. Such differences in neurologic outcome may have resulted from variations in the temperature management strategies used in different "warm heart surgery" studies; these variations ranged from allowing a downward "drift" that resulted in actual mild hypothermia to active rewarming that may have led to inadvertent cerebral hyperthermia.[200]

TABLE 67-7 PROTECTIVE EFFECTS OF HYPOTHERMIA AND DELETERIOUS EFFECTS OF HYPERTHERMIA DURING CEREBRAL ISCHEMIA

Hypothermia	Hyperthermia
Favorable balance between oxygen supply and demand	Imbalance between oxygen supply and demand

↓ Blood-brain barrier permeability	↑ Blood-brain barrier permeability
↓ Inflammatory response	↑ Inflammatory response
	↑ Free radical production
	↑ Intracellular acidosis
	Destabilized cytoskeleton

From Hindler K, Nussmeier NA: Central nervous system risk assessment. In *Newman M, Fleisher L, Fink M, editors:* Perioperative medicine: managing for outcome, *Philadelphia, 2008, Saunders, pp 69-88.*

In patients undergoing CPB, cerebral hyperthermia during the rewarming period may aggravate any cerebral injury that has occurred. Aggressive rewarming was once commonly practiced to prevent the "afterdrop" in temperature that usually occurs after CPB is discontinued, but this practice can cause cerebral hyperthermia at the exact moment when cerebral embolization is most likely. Therefore, rewarming should be gradual and should start early enough to achieve stability of the desired temperature before CPB is terminated.[201]

The surgeon should also be aware of the limitations of any temperature-monitoring site used during CPB. Brain parenchymal temperature cannot be measured directly during cardiac surgery; rather, it must be estimated from tympanic, nasopharyngeal, esophageal, rectal, bladder, skin surface, pulmonary arterial, or jugular venous bulb temperature. However, concordance between cerebral temperature and temperatures measured at most of these sites is poor.[202,203] Jugular bulb temperature is generally considered to be the gold standard because the proximity of the jugular bulb to the carotid artery origins and the aortic cannula makes jugular bulb temperature more similar to brain temperature than are temperatures measured at other commonly used sites.[203,204] Temperatures measured at the nasopharyngeal, esophageal, bladder, rectal, or skin surface sites underestimate jugular bulb temperature during rewarming.[202,203] Because monitoring jugular bulb temperature is not usually feasible, monitoring the temperature of the blood in the arterial line that exits the oxygenator [203] or in the PA[202] may be the best way to estimate global brain temperature.

Hyperthermia that develops postoperatively may be just as hazardous as intraoperative hyperthermia. Temperatures exceeding 38.5° C are common during the first 48 hours after cardiac surgery and occur in nearly 40% of patients.[205] This postoperative hyperthermia is known to be correlated with increased cognitive dysfunction 6 weeks after cardiac surgery.[206] Therefore, hyperthermia in the postoperative period should be treated with antipyretics and, if necessary, active body surface cooling.

In summary, patients maintained on CPB should be rewarmed early and slowly. No monitored temperature should be allowed to exceed 36.5° C to 37.0° C. This practice prevents cerebral overheating.

Blood Gas Management

Temperature has a significant effect on the solubility of gases in solution. Specifically, in blood gas analysis, the carbon dioxide concentration (and consequently the pH) is profoundly altered by changes in temperature. As temperature decreases, the partial pressure of arterial carbon dioxide ($Paco_2$) decreases as carbon dioxide becomes more soluble in plasma. Therefore, inducing hypothermia during CPB poses a dilemma in terms of how best to approach acid-base management at lower temperatures (i.e., whether *temperature-corrected* or *temperature-uncorrected* blood gas values should be used to manage the patient's care). This question has been the basis for a decades-old debate: alpha-stat versus pH-stat blood gas management (Table 67-8).

Alpha-Stat Hypothesis. In aqueous systems, neutrality (pN) is said to occur when $[H^+] = [OH^-]$. The dissociation of water depends on temperature; therefore, the pH value at which pN occurs varies with the temperature. Acid-base comparative physiologic studies of animals whose blood temperature varies (i.e., ectotherms and poikilotherms) suggest that blood and intracellular pH values parallel the temperature-related changes seen in the neutrality of water.[207] From these findings emerged the alpha-stat strategy, which endeavors to maintain intracellular electrochemical neutrality across all temperatures.

Maintaining this neutrality requires an appropriate buffering system. It is thought that protein buffering is largely responsible for maintaining this temperature-pH relationship. Specifically, the imidazole group of the amino acid histidine has a dissociation constant (p*Ka*) value similar to that of blood. Therefore, if carbon dioxide stores are held constant during cooling, the ionization state (termed alpha) will remain constant. This may be important because the ionization state affects both the structure and the function of proteins. Keeping the charge state constant (alpha-stat) by allowing blood pH to change with the neutrality of water is thought to be essential for maintaining the most physiologically beneficial

TABLE 67-8 SUMMARY OF BLOOD GAS MANAGEMENT STRATEGIES

Strategy	Goal	Implementation	Total CO_2 Content	Theoretic Benefits
Alpha-stat	Achieve electrochemical neutrality by maintaining a constant OH^-/H^+ ratio	Use normal *temperature-uncorrected* blood gas values	Constant	Preserves enzyme function and cerebral autoregulation
pH-stat	Maintain constant pH	Use normal *temperature-corrected* blood gas values	Increases	Produces more homogeneous brain cooling; decreases brain O_2 consumption
Combination	Maintain constant pH during cooling, then restore electrochemical neutrality before circulatory arrest	During the cooling phase, use *temperature-corrected* values, then switch to *temperature-uncorrected* values before interrupting flow; use *temperature-corrected* values during the rewarming period	Initially increases during cooling, then returns to baseline	Produces homogeneous brain cooling, then restores neutrality; improves $CMRO_2$

$CMRO_2$, Cerebral metabolic rate of oxygen; *CO_2*, carbon dioxide; *O_2*, oxygen; *OH^-/H^+*, ratio of hydroxyl ion to hydrogen ion.

structure and function of enzymes during hypothermia. Research suggests that when the alpha-stat strategy is used, cerebral autoregulation remains largely intact until deep hypothermic temperatures are reached.[208]

To manage acid-base balance during hypothermic CPB by using the alpha-stat approach, one must maintain temperature-*un*corrected blood gas values. The term *un*corrected is often confusing because it refers to the values that the blood gas machine typically reports without being programmed to correct the values to the actual temperature of the patient. For example, blood drawn from a patient undergoing CPB at 18° C is measured in a blood gas machine, which anaerobically warms the sample to 37° C and reports values at normothermia. With alpha-stat management, one would strive for normal temperature-uncorrected results, which would theoretically maintain intracellular electrochemical neutrality.

pH-Stat Hypothesis. An alternative strategy is the pH-stat approach to acid-base management. The pH-stat strategy endeavors to maintain a constant pH despite changes in temperature. Hibernating animals tend to follow this strategy. To counter the tendency of cooling blood to follow the neutrality of the water curve and become more alkalotic as temperature decreases, these animals increase their blood carbon dioxide content and maintain normal pH at hypothermic body temperatures.

Carbon dioxide is a potent cerebral vasodilator; therefore, the increase in carbon dioxide content during pH-stat management uncouples cerebral autoregulation; cerebral blood flow increases independent of cerebral metabolic demand. These effects are thought to be neuroprotective for infants maintained on CPB who may have aortopulmonary collateral vessels and also to promote deep homogeneous cooling of the brain before circulatory arrest.[209] However, during rewarming, the higher cerebral blood flow that results from using pH-stat management may increase the embolic load sent to the brain.

Using the pH-stat strategy with CPB involves managing blood gas parameters with temperature-*corrected* values by programming the blood gas machine to correct the values to the patient's body temperature. During bypass, decreasing blood temperature increases the solubility of carbon dioxide and, consequently, results in decreased $Paco_2$ values. Therefore, the perfusionist must either decrease the "sweep speed" of the air-oxygen mixture or, less commonly, add carbon dioxide to the oxygenator ventilation system to increase the carbon dioxide content and maintain a $Paco_2$ of 40 mm Hg (and normal pH) as the temperature of the blood decreases. The extracorporeal circuitry must be equipped with an in-line blood gas analyzer so that $Paco_2$ levels can be continually monitored during CPB.

Which Strategy Is Best? In adult patients, several independent, prospective randomized trials have shown that using alpha-stat management during moderate hypothermia produces better neurologic outcomes than observed with pH-stat management. These and other data have led to an evidence-based recommendation (ACC/AHA class I, level A) that alpha-stat management be used in adults undergoing moderate hypothermic CPB.[200,210] It is unclear which strategy is superior in adults when deep hypothermia is used with or without circulatory arrest.

In pediatric CPB, however, several human and animal studies suggest that pH-stat management may be more beneficial than alpha-stat management for infants. These studies showed that pH-stat management produced more homogeneous cooling, less oxygen consumption, and better cerebral metabolic recovery than did alpha-stat management. The clear trend in pediatric CPB is to use pH-stat alone or in combination with alpha-stat (i.e., to use pH-stat during cooling and alpha-stat during rewarming) when deep hypothermia is used.[211]

Inflammatory Response to Cardiopulmonary Bypass

Since the 1980s, much has been written about the rapid and profound inflammatory response that CPB elicits. Surgical stress itself causes an inflammatory response, which CPB aggravates by subjecting the patient's blood to contact with foreign surfaces, ischemia and reperfusion, and gaseous and particulate microembolization, which initiate and amplify multiple redundant and interconnected immune cascades. With the onset of CPB, the increased expression of *initiator* substances (including endotoxin, tumor necrosis factor [TNF], and nuclear factor κB, as well as anaphylatoxins and cytokines) stimulates *effector* cells (including polymorphonuclear neutrophils, platelets, and endothelial cells) to up-regulate adhesion molecules and release cytotoxic oxygen radicals and proteases. This response can produce tissue injury of varying degree in a variety of organ systems.

Numerous clinical approaches have been shown to reduce the inflammatory response measurably in cardiac surgical patients (Fig. 67-14). These approaches can be loosely grouped into three primary categories: modification of surgical and perfusion techniques, modification of circuit components, and pharmacologic strategies.

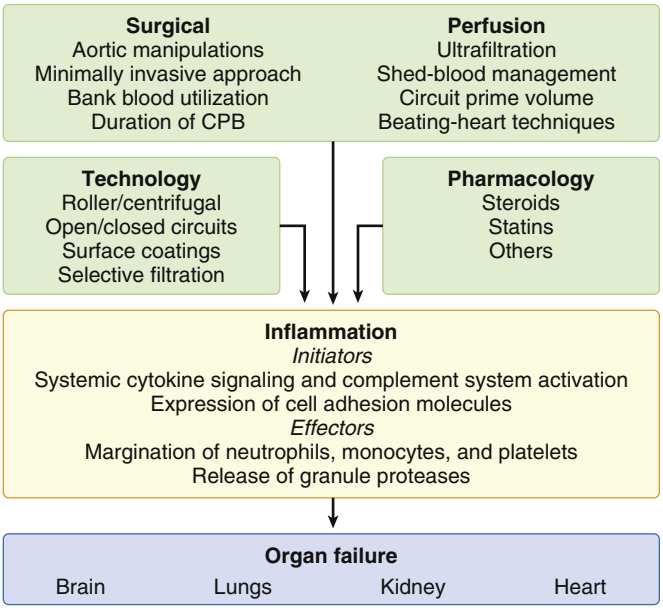

Figure 67-14. Brief review of the current understanding of the many variables that influence the inflammatory response in patients undergoing cardiopulmonary bypass (CPB).

Modification of Surgical Techniques or Perfusion Techniques

Modification of Surgical Technique. The movement toward minimally invasive cardiac surgery is at least partly motivated by the goal of reducing inflammation in the patient. The term *minimally invasive* may refer to procedures that use modified surgical techniques, including miniature incisions with or without robotic assistance, and to procedures that use classic surgical approaches but that minimize or eliminate the use of CPB and thus exposure to the ECC (e.g., OPCAB). Although OPCAB does not eliminate the patient's inflammatory response, it may produce less expression of inflammatory cytokines than does CABG with CPB.[212] However, it may be that the OPCAB-related reduction in inflammation is minimal in the days after the surgical procedure.[213] Moreover, any improvements in outcomes that may be attributable to the use of OPCAB instead of standard CABG are probably not exclusively caused by elimination of the ECC. Rather, minimizing or eliminating aortic manipulation, particularly in patients with severe atherosclerosis, may independently reduce the incidence of stroke.[45]

Modification of Perfusion Techniques. Reasons for the lack of consensus on the exact contribution of CPB to the inflammatory process include the issue that perfusion practice is far from standardized.[210] Various perfusion techniques and technologies have been shown to reduce inflammation, including shed-blood management,[214] ultrafiltration,[215,216] temperature management,[197] circuit miniaturization,[217,218] and on-pump beating-heart techniques.[219]

Perfusion Technology

In addition to the ways in which perfusion technology is used, the type of technology used may moderate the inflammatory response to CPB. No consensus exists regarding which arterial pump technology, roller pumps or centrifugal pumps, is less hemolytic. Some investigators have shown that using modified surface materials in the CPB circuit, such as heparin coatings, may reduce inflammation.[220-222] Additionally, selective filtration of leukocytes with an in-line leukocyte filter has been proposed as a method for reducing the concentration of activated leukocytes and inflammation. Warren and associates,[223] in a review of 63 studies, concluded that leukocyte filtration may have some modest benefits, but definitive evidence of any improvement in inflammatory-mediated complications is insufficient. Additionally, hemoconcentrators may be able to remove inflammatory mediators from circulation through large-volume zero-balance ultrafiltration techniques,[216] but little evidence exists of significant clinical improvements in the adult CPB population.

Pharmacologic Strategies

After decades of laboratory studies and clinical trials, a rigorously vetted pharmacologic approach to reducing inflammation in CPB-supported patients is still lacking. The best-established drug, aprotinin, was removed from the market in 2007 because of concerns about an increased risk of acute kidney failure after administration.[130] Thus, the clinician is left to select from a short list of drugs whose use is supported only by mixed mechanistic results and insipid evidence of improved clinical outcomes.

Corticosteroids have been used in cardiac surgery for decades for their immunosuppressive and antiinflammatory effects. The results of meta-analyses of small randomized clinical trials of methylprednisolone or dexamethasone have yielded conflicting results.[224,225] These drugs may reduce the incidence of atrial fibrillation, but they may also increase gastrointestinal bleeding, and they did not influence postoperative mortality or cardiac or pulmonary complications.[224,225] The first large (4494 patients) randomized controlled clinical trial of the use of routine corticosteroids during cardiac surgery in adults showed that high-dose (1 mg/kg) dexamethasone did not reduce the 30-day incidence of major adverse events (death, MI, stroke, renal failure, or respiratory failure).[226]

One meta-analysis of randomized controlled studies of the use of prophylactic preoperative statins to reduce inflammatory mediators concluded that evidence indicates that statins reduce plasma concentrations of IL-6, IL-8, TNF-α, and CRP when doses of 20 to 80 mg/day are administered for 1 day to 3 weeks preoperatively.[227] In a Cochrane Database review of 11 randomized controlled trials performed in patients undergoing on- or off-pump cardiac surgical procedures, pooled analysis showed that statin pretreatment before surgery reduced the incidence of postoperative atrial fibrillation and was associated with a shorter length of stay in the ICU but failed to influence mortality.[228] Finally, a meta-analysis of 14 studies of ketamine, which may also have antiinflammatory effects, suggests that ketamine administration significantly reduces the IL-6 response to surgery.[229]

DEEP HYPOTHERMIC CIRCULATORY ARREST

DHCA involves reducing the patient's core temperature to profoundly hypothermic levels (15° C to 22° C) before globally interrupting blood flow to the body, draining all the blood out of the patient, and collecting it in the ECC reservoir. In adults, this procedure is primarily used during surgical repair of the aorta, especially in cases of dissection or aneurysm involving the transverse arch.

Deliberate hypothermia with systemic cooling is the only reliable method of neuroprotection during complete global ischemia. Some clinicians also put ice bags on the patient's head to augment or maintain cerebral cooling. Pharmacologic approaches to neuroprotection, such as administering steroids to reduce inflammation or barbiturates or propofol to induce burst suppression, are used in some centers, although evidence to support their efficacy in the setting of complete global ischemia is scant. Furthermore, if the EEG is monitored, it is important to induce EEG isoelectricity with hypothermia before commencing the period of circulatory arrest rather than relying on supplemental barbiturates or propofol to provide neuroprotection.[230]

The equipment and circuitry of the heart and lung machine used for DHCA procedures are not generally different from those used for standard CPB procedures. Blood gas management during cooling and rewarming for DHCA procedures typically follows the alpha-stat

management scheme in adult patients and the pH-stat management scheme in pediatric patients (see the earlier section on blood gas management). Systemic cooling is begun when CPB is initiated and is continued until the temperature of the patient is low enough to provide adequate protection for the anticipated duration of circulatory arrest. When deciding what temperature is "adequate," one must give top priority to protecting the brain. Because no clinically feasible method for measuring brain temperature is available, surrogate temperatures must be used to estimate core temperature (see the earlier section on temperature). A time lag exists between the time that arterial blood reaches a target temperature and the time that the brain's parenchymal tissue equilibrates with the blood temperature. Consequently, when aggressive cooling is used, arterial blood temperature underestimates brain temperature. For an average-sized adult, cold arterial perfusion at full CO flow should be continued for 20 to 30 minutes after the "goal" arterial blood temperature is reached to ensure that the brain has had sufficient time to cool. For an anticipated circulatory arrest period of 30 to 40 minutes, a temperature of 18° C to 20° C is probably adequate; however, slightly warmer temperatures may be acceptable if a shorter period of arrest is used or if cerebral perfusion is maintained.[231] It is also good practice to monitor temperatures at multiple sites on the patient, in addition to blood temperature, to observe the relative change over time during cooling and rewarming. Furthermore, the EEG provides a good pharmacodynamic endpoint for the cerebral effects of cooling; hypothermia-induced EEG isoelectricity should be present before elective circulatory arrest commences.[231]

As the patient cools, the viscosity of blood will increase. At a temperature of 18° C, the viscosity of blood with a hematocrit of 30% to 35% increases to three to four times its normal level. Cardiac surgical textbooks suggest that hemodilution is important in minimizing any microcirculatory disturbances that may occur because of increased blood viscosity. Consequently, some clinicians may target a hematocrit value that is appropriate to the patient's temperature during DHCA, approximately 18% to 20%. However, the results of a study performed in piglets by Duebener and colleagues suggested that a hematocrit of 30% is preferable if DHCA is used.[232]

When the patient has reached an appropriate core temperature as determined by temperatures measured at multiple sites and after adequate time for equilibration, the arterial blood flow from the pump is stopped, and the patient's blood is drained into the ECC reservoir. During the period of circulatory arrest, the blood in the ECC reservoir should be recirculated to prevent stasis and maintain the desired temperature. Gas flow to the oxygenator should be discontinued to prevent profound hypocapnia. Reperfusion should be initiated with cold blood. An initial period (5 to 10 minutes) of cold reperfusion may enhance cerebral protection by removing accumulated metabolic products from the cerebral capillary beds while maintaining a low cerebral metabolic rate of oxygen.

The risk of neurologic injury after cardiac surgery involving DHCA extends into the postoperative period because cerebral vascular resistance is increased and cerebral blood flow is decreased for several hours after the procedure. In addition, hyperthermia, possibly secondary to a systemic inflammatory response, is common in the postoperative period and should be treated aggressively.

In an effort to reduce the period of cerebral ischemia during circulatory arrest, selective cerebral perfusion techniques have been developed. Selective antegrade cerebral perfusion can be accomplished by directly cannulating the left common carotid artery,[233] or perfusion can easily be delivered through the right common carotid artery when the aortic cannulation approach for CPB involves cannulating the axillary or innominate artery.[234] Axillary cannulation facilitates the delivery of arterial blood from the ECC to the entire circulatory system during cooling and rewarming or, with the addition of a clamp to the proximal innominate artery, selectively into the right common carotid and radial arteries. Because of the proximity of the arterial cannula to the right radial artery, arterial blood pressure monitored in the right radial artery may be significantly higher than pressure monitored in the left radial or femoral artery. Consequently, right radial arterial pressure should not be used to control perfusion during cooling and rewarming. During delivery of selective antegrade cerebral perfusion, cold arterial blood from the extracorporeal circuit should be delivered to maintain the cerebral blood pressure between 30 and 60 mm Hg. The perfusion flow rates necessary to achieve this pressure vary depending on the site or sites of arterial cannulation. Direct cannulation of only the left common carotid artery requires the least flow, whereas cannulation of multiple head vessels or of the axillary artery (which perfuses the right common carotid, right internal thoracic artery, and right arm) requires higher flow rates. Subsequently, flow rates of 150 to 1500 mL/minute have been reported. Selective retrograde cerebral perfusion is delivered through a snared cannula introduced into the right atrium and advanced into the SVC; this type of perfusion can be initiated after the patient's systemic perfusion is discontinued. Cold oxygenated blood from the ECC can be administered at a flow rate (≈5 mL/kg/minute) high enough to maintain SVC pressure between 35 and 40 mm Hg.[235] Although some debate remains about whether selective cerebral perfusion of any kind is necessary to achieve optimal neurologic outcome after DHCA procedures,[236] investigators generally agree that antegrade cerebral perfusion, when used properly, is superior to retrograde perfusion.[237,238]

LEFT HEART BYPASS

If a descending aortic aneurysm or aortic dissection is to be surgically replaced with a tube graft, blood flow through the patient's thoracic aorta must be interrupted. The application of vascular clamps to this major vessel acutely increases the afterload of the heart and produces global ischemia in all parts of the body distal to the clamp. Patients with compromised cardiac function or those undergoing a surgical procedure in which the duration of ischemia will be unacceptably long require some method of circulatory support. Temporary interposition of a shunt (e.g., a Gott shunt) around the area of repair is the simplest approach, but it does not offer the level of support that can be achieved with LHB or CPB.

For these procedures, the approach is usually through a left thoracotomy incision, which provides excellent access to the left atrium. The simplest approach to LHB is to withdraw blood from the left atrium with a centrifugal pump and return the blood to the patient's femoral artery. This *simple* LHB circuit gives the clinician excellent control of blood flow distal to the clamps and therefore the ability to manipulate the afterload against which the heart must work. However, the complexity of some surgical procedures requires that full CPB be used.

Surgical complications are not uncommon in these patients and include hypoxia, hypothermia, and exsanguination. A double-lumen endotracheal tube or bronchial blocker is often used to isolate the left lung from the right. After left thoracotomy and exposure of the aneurysm, ventilation of the left lung is discontinued. Patients with preexisting lung dysfunction or traumatic lung injury associated with aortic dissection may have difficulty maintaining oxygenation with a single lung. Because of the large surgical exposure required and the sometimes extended duration of the procedure, it is not unusual for the patient to become hypothermic. Furthermore, these procedures carry an elevated risk of blood loss and the consequent need for rapid replacement of fluids and blood products. It is often advisable to use *complete* LHB to reduce these risks.

Figure 67-15 illustrates the simple-circuit and complete-circuit approaches to LHB. The major difference between a complete LHB circuit and the standard CPB circuit is the position of the reservoir in the circuit and the position of the venous cannula in the patient. In a complete LHB circuit, the reservoir does not receive the blood returning from the patient as in the CPB circuit. With the reservoir out of the pathway of the blood, the effective surface area of the ECC is reduced; this reduction attenuates contact activation of the blood and minimizes the need for high-dose heparinization.

In both circuits, the management goal is the same—to keep arterial blood pressure higher than 60 mm Hg both proximal and distal to the aortic cross-clamp throughout the procedure. However, the complete LHB circuit gives the clinician the ability to manage hypoxia, hypothermia, and blood loss. The addition of an oxygenator to the circuit makes it possible to augment the patient's ventilation and oxygenation. The heat exchanger is used to maintain normothermia. The reservoir facilitates the addition of large volumes of fluid or blood products in the event of hemorrhage, hypovolemia, or both.

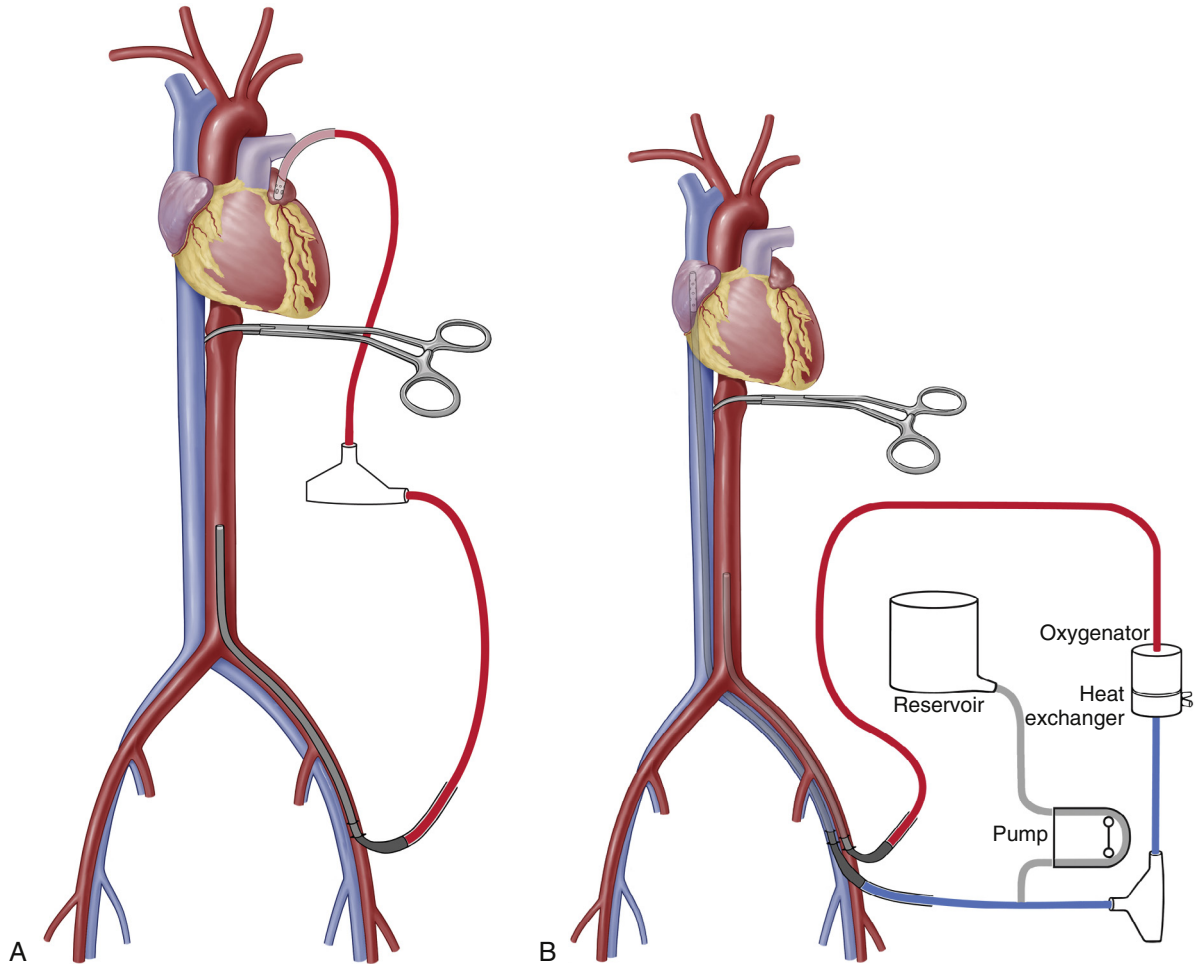

Figure 67-15. Left heart bypass (LHB) diagram. **A**, Simple LHB (left atrium, cone, and femoral artery). **B**, Complex LHB (including an oxygenator, heat exchanger, and reservoir for fluid administration).

CARDIOPULMONARY SUPPORT AND EXTRACORPOREAL MEMBRANE OXYGENATION CIRCUITS

For all practical purposes, no difference exists between a CPS circuit and an ECMO circuit. Both consist of a CPB circuit without a reservoir, an arterial line filter, or any of the ancillary pumps that are used during cardiac surgery (i.e., pump suction, vent, and cardioplegia). Because the reservoir is removed from the circuit, these systems are considered closed. Closed circuits have a static internal volume and cannot unload the patient's vascular system.

The removal of the reservoir and filters from the circuit has advantages and disadvantages. The chief advantage is that the surface area of the circuit is significantly reduced, which facilitates a reduced anticoagulation regimen with an initial heparin dose of 75 to 150 units/kg and a continuous infusion of heparin at 25 to 75 units/kg/hour to maintain ACTs of 180 to 250 seconds. The chief disadvantage is that the closed circuits are less able to trap emboli. Special precautions should be taken when connecting a closed ECC to the patient's cannulas, injecting fluids and medications into the circuit, or sampling from the venous line. Additionally, because of the reduced anticoagulation regimen, blood stasis in the circuit should be avoided, and periods of low flow should be minimized.

In intensive care settings, ECMO or CPS is used to support the heart, lungs, or both for days or weeks. The newer generation of centrifugal pumps and hollow-fiber oxygenators perform acceptably well during these long-term applications and are becoming more commonly used in desperate situations (Fig. 67-16).

CORONARY ARTERY DISEASE

Pathophysiology of Coronary Disease

Coronary Anatomy. Understanding the coronary anatomy is important to understand the pathophysiology of CAD and the anesthetic care of patients undergoing myocardial revascularization. Two main coronary arteries take off from the aorta and supply the myocardium: the left main coronary artery (LMCA) and the RCA. The LMCA subsequently divides into the left anterior descending (LAD) coronary artery and the left circumflex artery (LCx). The LAD courses down the interventricular

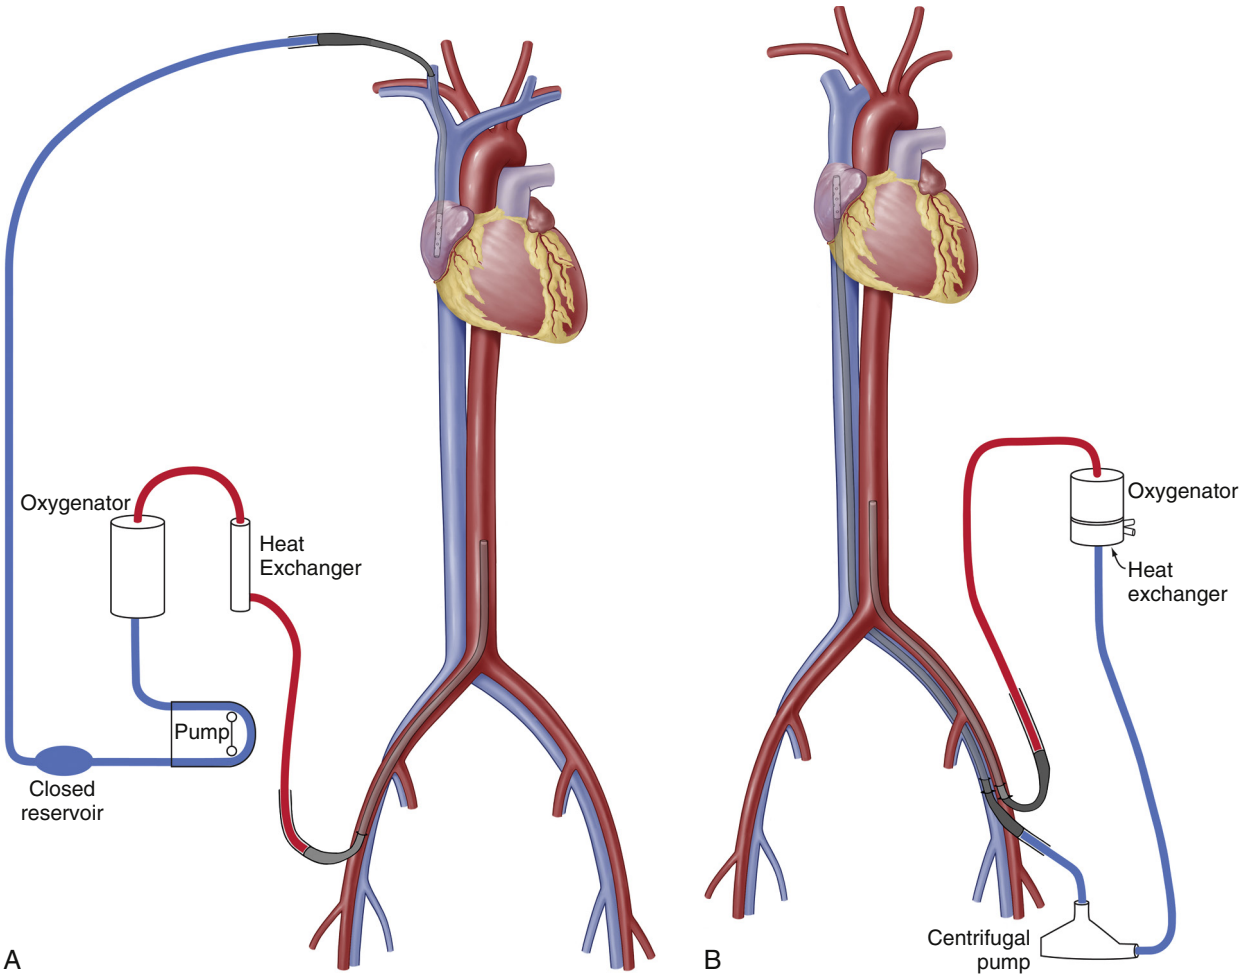

Figure 67-16. A, Patient cannulated through the internal jugular vein and femoral artery, with a traditional extracorporeal membrane oxygenation circuit. **B,** Patient cannulated through the femoral vein and femoral artery, with a simple cardiopulmonary support circuit.

groove and gives rise to the diagonal and septal branches. The diagonal branches of the LAD supply the anterolateral aspect of the heart. The septal branches supply the interventricular septum, as well as the bundle branches and the Purkinje system. The LAD itself terminates at the apex of the left ventricle. The other branch of the LMCA, the LCx, courses along the left AV groove and gives rise to one to three obtuse marginal branches that supply the lateral wall of the left ventricle. In 45% of patients, the sinus node arterial supply arises from the LCx. In 15% of patients, the LCx gives rise to the posterior descending artery, which supplies the posterior inferior aspect of the left ventricle ("left-dominant" system).

The RCA traverses the right AV groove and supplies the right anterior wall of the right ventricle through its acute marginal branches. In 85% of the population, the RCA gives rise to the posterior descending artery supplying the posterior inferior aspect of the left ventricle ("right-dominant" system). The AV node arterial branch arises from the dominant artery to supply the node, the bundle of His, and the proximal part of the bundle branches. In addition, in 55% of the population, the sinus node arterial supply arises from the RCA.

Determinants of Myocardial Oxygen Supply and Demand. The balance of oxygen supply versus demand is somewhat complex (Figs. 67-17 and 67-18). Oxygen supply is determined by the oxygen content of arterial blood and by coronary blood flow. Extraction of oxygen from arterial blood is maximal at rest. As demand increases (with exercise or hemodynamic stress), the oxygen supply to the myocardium must also increase.

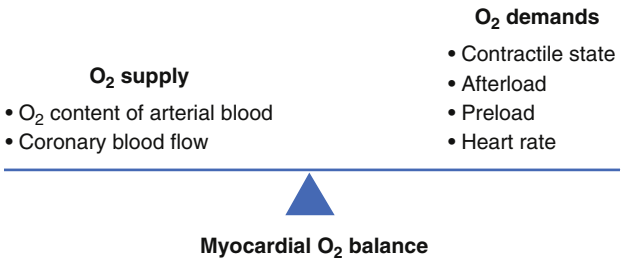

Figure 67-17. Factors determining myocardial oxygen (O_2) supply and demand. *(From Mittnacht AJC, Weiner M, London MJ, Kaplan JA: Anesthesia for myocardial revascularization. In Kaplan JA, Reich DL, Savino JS, editors:* Kaplan's cardiac anesthesia: the echo era, *ed 6, St. Louis, 2011, Saunders, p 524.)*

Determinants of blood flow in normal coronary arteries include the pressure differential across the coronary bed (i.e., the coronary perfusion pressure) and coronary vascular resistance. The coronary perfusion pressure for the left ventricle is the aortic blood pressure during diastole minus the LV end-diastolic pressure (LVEDP); thus, elevations in LVEDP impede subendocardial blood flow. Because coronary stenosis causes vessels to dilate maximally distal to the stenosis, manipulating coronary perfusion pressure is an important means of controlling coronary blood flow (and preventing or treating myocardial ischemia). However, because the determinants of myocardial oxygen balance interact in a complex manner, altering any one of them can have multiple effects. For example, a rise in blood pressure increases coronary blood flow but also increases afterload, thereby elevating wall tension and oxygen demand.

The duration of diastole is another important factor affecting oxygen supply to the myocardium because 70% to 80% of coronary arterial blood flow occurs during the diastolic phase of the cardiac cycle. During the systolic phase, cardiac contraction increases intraventricular cavitary pressure and coronary vascular resistance, thus impeding myocardial perfusion. The total time per minute spent in diastole is a function of the heart rate, but a nonlinear relationship exists between heart rate and the duration of diastole (Fig. 67-19). This is a major reason for the use of β-blockers as antiischemic drugs, both for long-term therapy and for preventing even small increases in heart rate during the perioperative period.

The oxygen content of blood depends on hemoglobin-bound oxygen and, to a lesser extent, dissolved oxygen. Although a high hemoglobin level gives the blood high oxygen-carrying capacity, the minimum level of hemoglobin necessary to avoid ischemia has not been well defined in clinical studies. Factors that affect this limit include the severity of CAD, the heart rate, perfusion pressure, and myocardial wall thickness and tension.

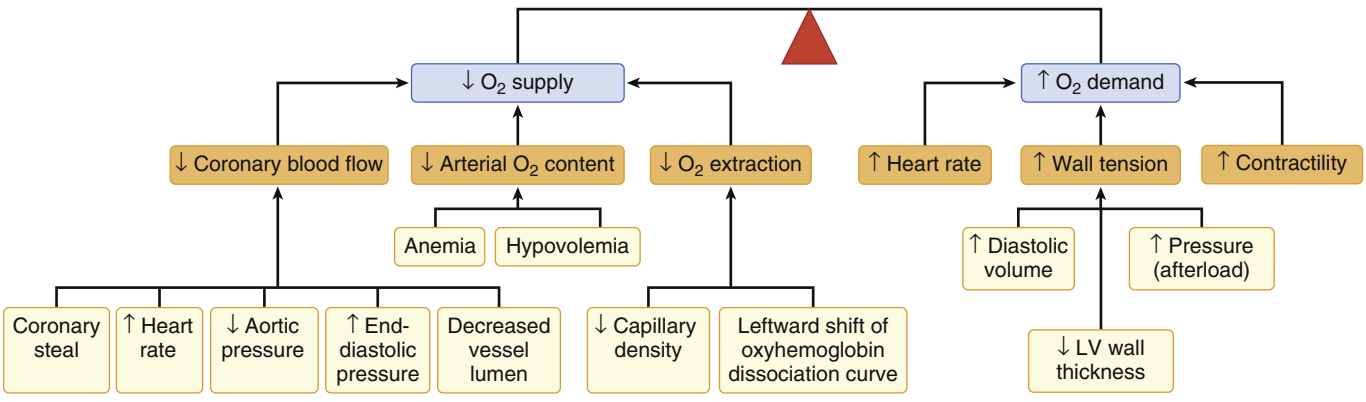

Figure 67-18. Summary of factors that affect myocardial oxygen supply and demand. *LV,* Left ventricular. *(From Green MS, Okum GS, Horrow JC: Anesthetic management of myocardial revascularization. In Hensley FA, Martin DE, Gravlee GP, editors:* A practical approach to cardiac anesthesia, *ed 5, Philadelphia, 2013, Lippincott Williams & Wilkins, pp. 319-358; modified from Crystal GJ: Cardiovascular physiology. In Miller RD, editor:* Atlas of anesthesia, *vol 8,* Cardiothoracic anesthesia, *Philadelphia, 1999, Churchill Livingstone, p 1:1.)*

Furthermore, delivery of oxygen to myocardial tissue also depends on a high partial pressure of oxygen (PO_2), and actual release of oxygen from hemoglobin occurs according to the oxyhemoglobin dissociation curve. A leftward shift of this curve caused by alkalosis, hypothermia, or low levels of 2,3-diphosphoglycerate decreases the release of oxygen.

In patients undergoing myocardial revascularization, reductions in myocardial oxygen supply may occur because of hypotension, tachycardia, anemia, or coronary vasoconstriction, as well as increases in demand secondary to tachycardia or increased afterload. Although myocardial ischemia is certainly possible without any changes in systemic hemodynamics, vigilant monitoring for imbalances in myocardial oxygen supply versus demand, as well as monitoring for the development of ischemia, is necessary throughout the perioperative period. Myocardial ischemia may be detected by ECG monitoring and ST-segment analysis, as well as by TEE monitoring for the development of regional wall motion abnormalities.

On-Pump Coronary Artery Bypass Grafting Surgery

Preoperative Evaluation. Typically, patients undergoing CABG have had extensive preoperative assessment of their cardiac disease (see Chapter 38). Coronary artery anatomy should be noted, particularly a high-grade lesion in the LMCA or proximal LAD coronary artery or triple-vessel disease. Ventricular function, assessed by angiography or echocardiography, is usually recorded as an estimated EF. Other cardiac disease discovered in the preoperative workup should be noted and understood, including valvular abnormalities such as concurrent MR, aortic stenosis (AS), aortic insufficiency, atrial septal defect (ASD) or ventricular septal defect (VSD), or ventricular aneurysm. The anesthesiologist should be aware of any abnormal cardiac rhythm on the ECG or noted in the history, such as atrial fibrillation or other supraventricular tachycardia (which may lead to hemodynamic instability or increase the patient's risk of an embolic neurologic complication), left bundle branch block or a prolonged PR interval (which may progress to a more advanced heart block), or complete heart block, which may be underlying a paced rhythm. Antiarrhythmic therapy, with either pharmacologic drugs or devices such as a pacemaker or automated implantable cardioverter-defibrillator (ICD), should be noted.

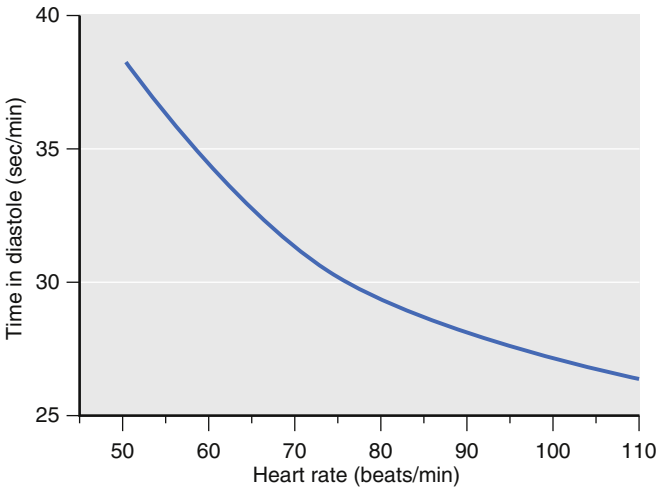

Figure 67-19. Total time spent in diastole each minute plotted as a function of heart rate in beats per minute. The reduction in diastolic interval leads to diminished left ventricular blood flow as heart rate increases. *(From Green MS, Okum GS, Horrow JC: Anesthetic management of myocardial revascularization. In Hensley FA, Martin DE, Gravlee GP, editors:* A practical approach to cardiac anesthesia, *ed 5, Philadelphia, 2013, Lippincott Williams & Wilkins, pp 298.)*

Various models for assessing overall risk have been developed that include certain factors associated with increased risk: poor LV function (history of CHF or LVEF <30%), advanced age, obesity, emergency surgery, combined procedures (e.g., valve repair or replacement combined with CABG), prior cardiac surgery, and history of diabetes or renal failure (Table 67-9).[239,240] The ACC/AHA 2004 Guideline Update for Coronary Artery Bypass Graft Surgery recommends using a published model to assess patients' risk for mortality, morbidity, and length of hospital stay, but only as a level IIa recommendation (level of evidence C).[241]

Premedication. In the current era, cardiac surgical patients often have same-day admissions. Frequently, the only premedication they receive is midazolam on the morning of the surgical procedure, to allay anxiety. However, small additional doses of midazolam, fentanyl, or both may be administered during line placement (please see the section on induction of anesthesia and the prebypass period); this may be particularly important in patients with CAD, to minimize undesirable sympathetic stimulation that could cause tachycardia and hypertension. However, administration of these drugs should be incremental and judicious in patients with low CO or significant pulmonary hypertension.

No single anesthetic agent or combination of anesthetic drugs is suitable for anesthetic induction and maintenance in every patient undergoing CABG surgery. Induction of anesthesia for coronary revascularization is often achieved by administering a benzodiazepine (typically midazolam) in combination with a narcotic, usually fentanyl, and a muscle relaxant.[240] However, either etomidate or propofol in combination with a narcotic has frequently been used. The goal is to avoid wide swings in hemodynamics with induction and with subsequent intubation. Typically, volatile agents are used throughout the prebypass, bypass, and postbypass periods to limit the total fentanyl dose to 10 to 15 μg/kg. In addition, the volatile anesthetics have several cardioprotective effects, including triggering the preconditioning cascade and mitigating reperfusion injury.[162] Additional midazolam may be given to ensure that intraoperative awareness is avoided.

One factor in the choice of specific anesthetic agents and doses is the patient's preexisting LV function. Patients with normal LV function can have a significant sympathetic response to surgical stimulation that results in hypertension and tachycardia. Use of β-blockers, additional propofol, higher doses of a volatile anesthetic agent, or vasodilators may be warranted if this situation develops. Conversely, in patients with poor LV function, hypotension may develop with the administration of

LV, Left ventricular.

anesthetic agents because of a reduction in CO or vasodilation, or both. Such patients may require vasopressor or inotropic pharmacologic support, or both.

Another factor in the choice of anesthetic agent is the possibility of early extubation within 4 to 6 hours of arrival in the ICU (so-called fast tracking). Patients who have good preexisting cardiac function and who will be undergoing CABG as an isolated procedure are usually candidates for fast tracking. This strategy necessitates the use of agents in dosages that would not keep the patient sedated or render the patient unable to ventilate adequately for a prolonged period. Early extubation may not be appropriate in patients with poor cardiac function, severe pulmonary disease, or obesity or in those undergoing emergency procedures, CABG combined with other procedures, or redo operations.

Monitoring. Monitoring for patients scheduled to undergo coronary revascularization surgery has evolved since the 1960s, in an effort to detect intraoperative ischemia. The standard American Society of Anesthesiologists (ASA) monitors and invasive arterial blood pressure monitoring (with noninvasive blood pressure backup) are always used. Typically, both leads II and V_5 are used for continuous monitoring, as well as automated ST-segment analysis to improve the chances of detecting ischemia.[242]

PA catheters are used less commonly now than in the past because several studies have shown that using such catheters does not improve outcome.[243] In fact, the risks inherent in the use of these catheters may actually exceed the benefits.[26] Certainly, the absolute PAP is not diagnostic of ischemia, although waveform changes may be more predictive. For example, the appearance of a new V wave on the PCWP tracing indicates ischemic papillary muscle dysfunction. In addition, specialized PA catheters allow derivation of several indices of cardiac function, including CO, cardiac index, and $S\bar{v}O_2$. Furthermore, some clinicians believe that the PA catheter is useful in the postoperative period when TEE is not available for continuous monitoring of the patient.

Regional wall motion abnormalities detected by TEE are more sensitive to ischemia than ECG changes or PA catheter waveform and pressure changes.[242] TEE can be used to interrogate regions of the heart representative of all three major coronary arteries simultaneously. This technology is commonly used throughout revascularization procedures to assess regional wall motion by qualitative inspection of radial shortening and wall thickening, and it is particularly useful after revascularization. In addition, TEE is used to assess ventricular preload and contractility, diagnose any valvular abnormalities, evaluate calcific and atherosclerotic lesions at the aortic cannulation sites, and detect LV thrombus and uncommon congenital abnormalities (e.g., ASD or VSD, persistent left SVC). See Chapter 46 for details on the perioperative use of TEE.

Surgical Considerations. Conventional (on-pump) CABG is the most commonly performed procedure in cardiac surgery. A full median sternotomy performed with a sternal saw is standard. Ventilation of the lungs is halted briefly during sawing of the sternum to avoid a pleural tear. An oscillating saw may be used in patients with a previous sternotomy (redo). The risks posed by redo sternotomy include perforation of the right ventricle, damage to existing vein grafts, and ventricular fibrillation from the transmission of electrocautery energy through preexisting sternal wires. Therefore, PRBCs (2 units) should be immediately available, and external defibrillation pads should be positioned before preparation and draping. Furthermore, surgical manipulation of previous vein grafts may result in embolization of atheroma and resultant ischemia. If a complication does occur during sternotomy or exposure of the heart and cannulation sites, emergency bypass may be established by cannulating a femoral artery and vein.

If an IMA is to be used, the surgical table is elevated and often rotated somewhat to the left to facilitate surgical comfort in performing the dissection. Tidal volumes are also reduced to facilitate exposure. Heparin administration usually occurs before the IMA pedicle is clamped, and papaverine may be injected into this vessel. The prebypass period for on-pump CABG may be relatively short (<1 hour) or may require several hours for dissection of the left IMA, right IMA, radial arteries, or any combination of these vessels. In addition, for most CABG procedures, adequate venous conduits must be harvested, and endoscopic saphenectomy is now common.

Before aortic cannulation, TEE or epiaortic echocardiography, or both, provides critical information regarding the presence and precise location of calcification or mobile atheromas in the aortic arch. The surgeon may

request TEE guidance for placement of the retrograde catheter into the coronary sinus; furthermore, if a persistent left SVC is diagnosed, this abnormality may render retrograde cardioplegia problematic.[240] After CPB is initiated, TEE may also be used to ensure correct placement of the LV vent, as well as to verify the absence of LV thrombus in patients with a recent anterior wall MI or aneurysm.

Surgical and technical complications of CABG surgery that manifest as ischemia include (1) poor-quality proximal or distal anastomoses of the grafts, (2) inadvertent incision of the coronary back wall leading to coronary dissection, (3) suturing of the coronary artery closed, (4) inadequate vein graft length resulting in stretching of the vein when the heart is filled, (5) excessive vein graft length leading to kinking of the vein, and (6) vein graft thrombosis.[239] CPB may need to be reinstituted to correct surgical causes of ischemia after revascularization. Heparin should be immediately available if emergency reinstitution of CPB becomes necessary.

After bypass, other causes of ischemia include (1) incomplete revascularization resulting from ungraftable vessels or diffuse distal disease, (2) coronary embolization of air or atheromatous debris, (3) coronary spasm, (4) mechanical factors such as vein graft stretching or occlusion of IMA flow secondary to overinflation of the lungs, and (5) thrombus formation.[239] The treatment of ischemia includes administering various drugs: nitroglycerin or vasopressors when SVR is either high or low; nitroglycerin, a calcium channel blocker (diltiazem, nifedipine, or nicardipine), or both to treat coronary spasm; a vasoconstrictor (usually phenylephrine) to "push" intracoronary air through the vasculature when air embolism is suspected; a β-blocker (usually esmolol) to treat tachycardia; and one or more inotropic agents to increase CO if necessary. In addition, AV sequential pacing may be used to improve rate, rhythm, and hemodynamic stability when appropriate. At times, mechanical support with intraaortic balloon counterpulsation or an LV and/or RV assist device (LAVD or RVAD) may become necessary. Residual effects of cardioplegia, a ventricular aneurysm, or pericarditis may cause ST-segment elevation without actual ischemia.

Off-Pump Coronary Artery Bypass Surgery, Minimally Invasive Coronary Artery Bypass Surgery, and Hybrid Coronary Revascularization

Off-Pump Coronary Artery Bypass Surgery. Awareness of the deleterious effects of CPB has driven advocacy for alternative myocardial revascularization techniques, particularly OPCAB surgery. Proponents of OPCAB cite the low morbidity and mortality of patients who undergo this procedure, as well as faster recovery and reduced procedural costs. Data from the STS suggest that approximately 22% of coronary revascularization procedures are being performed off pump.[244]

The midline sternotomy is the traditional approach used for OPCAB procedures. Potential sources of bypass grafts include the right and left mammary arteries, the saphenous veins, and the radial arteries. The pericardium

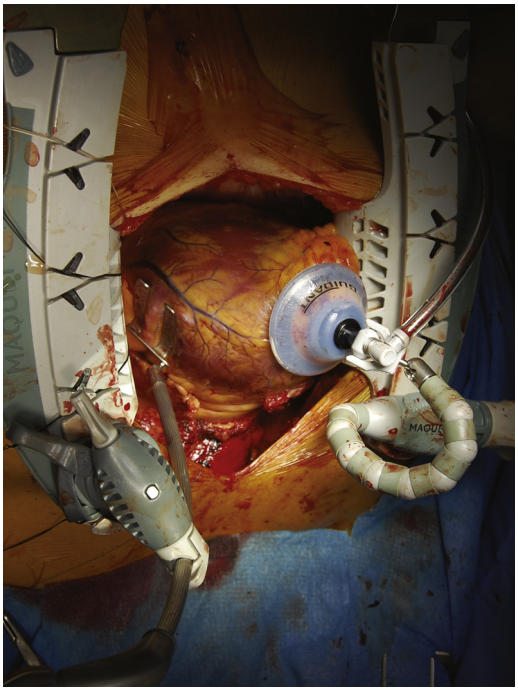

Figure 67-20. Image depicting the first obtuse marginal (OM1) anastomosis during off-pump coronary artery bypass grafting with a saphenous vein graft. The view is from the head of the patient. The previously completed left internal mammary artery–to–left anterior descending coronary artery anastomosis is seen. The Maquet access device (MAQUET, Wayne, NJ) uses suction to position the heart (verticalization) for easy access to the circumflex coronary artery system. *(Courtesy Alexander Mittnacht, MD, Mount Sinai School of Medicine, New York; From Mittnacht AJC, Weiner M, London MJ, Kaplan JA: Anesthesia for myocardial revascularization. In Kaplan JA, Reich DL, Savino JS, editors:* Kaplan's cardiac anesthesia: the echo era, *ed 6, St. Louis, 2011, Saunders, p 524.)*

is incised, reflected, and secured to the edges of the mediastinum. Special sternal retractors allow the placement of adjustable and flexible fixation devices that work by direct surface pressure on the myocardium, by suction, or by both methods. These devices stabilize the target vessel and allow the surgeon to "verticalize" the cardiac apex out of the pericardial well to access the posteriorly and laterally located vessels (Fig. 67-20). Dosing of heparin for OPCAB cases is institution specific; both full-dose and low-dose regimens are currently in use.

When the target vessel and surrounding myocardium are stabilized, an elastic ligature is placed circumferentially around the coronary artery to minimize bleeding as an arteriotomy is performed. Surgical visualization is also optimized by the application of a blower or mister, held by a surgical assistant, that releases sterile irrigation fluid aerosolized in carbon dioxide gas. Under these conditions, one or more distal coronary anastomoses are performed. The proximal connections of saphenous vein grafts or free arterial conduits are anastomosed directly to the aorta with a side-biting clamp. Alternatively, an indirect proximal connection is made by creating a T-graft (end-to-side anastomosis) to a mammary artery that is still connected to a vascular pedicle on the subclavian artery.

Surgical considerations include (1) obtaining adequate exposure of the anastomosis site, (2) restraining cardiac

motion during anastomosis, and (3) preserving myocardium during coronary flow interruption.[245] To achieve the first two goals, the surgeon must use maneuvers that may significantly compromise hemodynamics by several mechanisms, including impairment of biventricular filling, particularly in the thin-walled, easily compressed right ventricle. In addition, altered ventricular filling can result from verticalization of the cardiac ventricular apex (which may kink or partially obstruct venous return) (see Fig. 67-20). Furthermore, myocardial ischemia occurs in native coronary arteries and is exacerbated by temporary elastic suture ligation of a target vessel.[246] Ischemia of distal myocardial segments can occur during anastomosis of bypass grafts, and the degree of functional deterioration depends on the severity of the stenosis and the extent of collateralization.[245]

Therefore, the anesthesiologist must take measures to prevent severe hypotension to minimize the reduction in coronary perfusion caused by these hemodynamic changes and intraoperative myocardial ischemia. Typically, intravascular volume loading (either crystalloid or colloid) and a head-down position of the patient are used, and it is also common to administer a vasoconstrictor drug (either phenylephrine or norepinephrine). When increased mitral insufficiency further exacerbates the hemodynamic changes, repositioning the heart is a simple maneuver that may increase ventricular filling and normalize ventriculoannular geometry.

Monitoring of the patient includes a five-lead ECG and an invasive arterial pressure catheter. PAP and CO measurements or continuous pulse contour CO can be considered.[245] TEE is beneficial, but views are limited during certain portions of the surgical procedure; verticalization of the heart and the application of external compression footplates cause suboptimal imaging. The midesophageal imaging view, rather than the transgastric view, may be best for continuous TEE monitoring while distal coronary anastomoses are performed.

Persistent or worsening ECG change or impending cardiovascular collapse warrants quick action on the part of the anesthesiologist and surgeon. One option is to have a low threshold for the insertion of small, flexible intracoronary stents into the open coronary anastomosis to allow some distal segment flow. Instituting full or partial CPB and placing an IABP are other therapeutic options. Emergency conversion from OPCAB to CABG with CPB, which occurs in approximately 3% of these cases,[247,248] is not an innocuous event. Such unplanned conversions are reportedly associated with an elevated risk of death, stroke, renal failure, wound infections, and respiratory failure.

The short-term outcomes and long-term efficacy of OPCAB surgery continue to be investigated and debated in the literature. Meta-analyses have noted no significant differences in 30-day mortality.[249,250] In the largest multicenter randomized trial to compare on-pump CABG with OPCAB, no difference was seen in 30-day mortality or the composite outcome of death and complications.[251] In contrast, very large observational analyses do suggest a mortality benefit. Hannan and associates found a mortality benefit in 49,830 patients from the New York State registry by using a risk-adjusted analysis (i.e., Cox proportional hazard models and propensity analysis).[252] However, the need for repeat revascularization was greater among OPCAB patients (93.6%) than CABG patients (89.9%).[252] Several large retrospective reviews of traditional CABG versus OPCAB procedures have found a gender-specific survival benefit for women who undergo OPCAB surgery, compared with those who undergo on-pump CABG.[253-255]

Minimally Invasive Coronary Artery Bypass Surgery. The most popular alternative approach to sternotomy is the minimally invasive coronary artery bypass (MIDCAB) through a left anterior thoracotomy, which allows direct-access IMA harvesting and grafting to the LAD artery. Some surgeons harvest the left IMA (LIMA) by using robot-assisted endoscopic technology before making the small incision to complete the LIMA-to-LAD anastomosis through the left anterior thoracotomy incision. In these cases, deflation of the left lung is required for visualization of the anastomosis, accomplished with a double-lumen endotracheal tube or a bronchial blocker. In addition, carbon dioxide is insufflated into the left hemithorax during the period while the lung is deflated.

Usually, the MIDCAB technique involves grafting of only a single vessel, and exposure for this anastomosis may be suboptimal.[245] Challenges for the anesthesiologist in MIDCAB cases include the need for single-lung ventilation while the LIMA is dissected and the anastomosis is performed. Because the graft is only to the LAD in these cases, no extreme positioning of the heart occurs that could significantly compromise hemodynamic status. However, external defibrillator or pacing pads should be attached to the patient before preparing and draping because surgical access to the heart is limited during these procedures.[246]

Hybrid Coronary Revascularization. Hybrid coronary revascularization combines MIDCAB techniques with catheter-based interventions.[256] Ideally, a hybrid operating room is used. The surgical component of the hybrid procedure may be offered in a completely endoscopic fashion, using robotic technology. The goal of such procedures is a very short recovery time.[256] Although the perioperative results and intermediate-term outcomes of hybrid procedures appear to meet the standards of CABG performed with CPB, no data on long-term outcomes are available.

Patients undergoing OPCAB, MIDCAB, or hybrid coronary revascularization do not have a period on CPB. Therefore, rewarming from hypothermia with the pump is not an option. Surface convective warming is somewhat limited because of the need for intrathoracic surgical exposure and access to the patient. Therefore, heating blankets for patients and a warm operating room environment are essential to prevent unacceptable reductions in body temperature.

CARDIAC VALVE LESIONS

Mitral Valve Disease

In the United States and other industrialized nations, mitral valve disease is usually caused by primary

degenerative (i.e., age-associated) or inherited mitral valvular abnormalities or, increasingly, by ischemic heart disease resulting in functional mitral incompetence. In developing countries, conversely, rheumatic heart disease is relatively more prevalent and therefore a more common cause of mitral valve disease.[257] Primary or "organic" mitral valve disease involves abnormalities in the valve itself or in its subvalvular structural components.[258] Mitral valve prolapse, myxomatous degeneration of the mitral valve, rheumatic mitral insufficiency, cleft mitral valve associated with an AV septal defect, and any infiltrative or fibrotic processes caused by systemic diseases are all associated with inherent structural abnormalities of the mitral valve.

Anatomy of the Mitral Valve. The mitral valve leaflets are composed of segments, more easily discernible in the posterior leaflet, that are sometimes referred to as scallops. In the Carpentier classification scheme, the segments of the posterior leaflet are labeled P1, P2, and P3, with P1 laterally oriented and P3 medial (Fig. 67-21). The segments of the anterior leaflet are labeled A1, A2, and A3 and have the same medial and lateral orientation as the segments of the posterior leaflet (see Fig. 67-21). This terminology is used to ensure accurate communication between the surgeon and the echocardiographer, who is often an anesthesiologist, as they attempt to localize valve abnormalities.

Mitral Stenosis.

Pathophysiology. The disease process of rheumatic mitral stenosis (MS) includes thickening, commissural fusion, and increased rigidity of the mitral valve leaflets, as well as thickening, fusion, and contracture of the chordae and papillary heads. Furthermore, with long-standing rheumatic disease, some degree of calcification of the valve apparatus inevitably occurs. Physiologically, these changes result in obstruction at the level of the mitral valve.

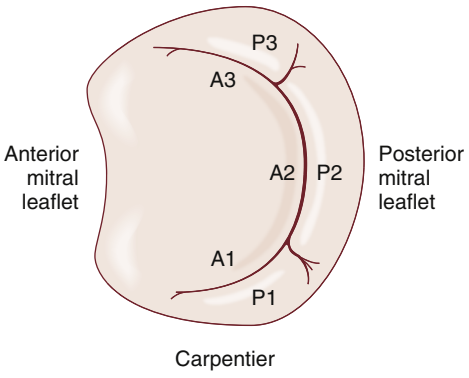

Figure 67-21. Standard terminology as applied to the mitral valve leaflets is illustrated in this image. The anterior and posterior mitral valve leaflets are each divided into three segmental regions. *(From Savage RM, Aronson S, Thomas JD, et al, editors: Comprehensive textbook of intraoperative transesophageal echocardiography, Baltimore, 2005, Lippincott Williams & Wilkins.)*

The normal mitral valve orifice area is approximately 4 to 5 cm^2.[259] Symptoms can occur if the valve area is less than 2.5 cm^2 and can be precipitated by clinical events associated with increased CO and consequent increased flow across the valve; these events include stress, exercise, anemia, pregnancy, and febrile illness (Fig. 67-22). Symptoms do not usually occur at rest unless the mitral valve area (MVA) is less than 1.5 cm^2. Obstructed flow across the mitral valve is associated with a pressure differential or gradient across the valve. The more severe the MS, the greater is the gradient, as long as flow across the valve is held constant.

Transmitral pressure gradients through the mitral valve depend on the volume flow rate. Severe MS may be present with a low measured or calculated gradient across the valve, as in patients with right HF and pulmonary hypertension. An MVA estimate is a more independent measure of the severity of MS. Currently, MS is primarily diagnosed

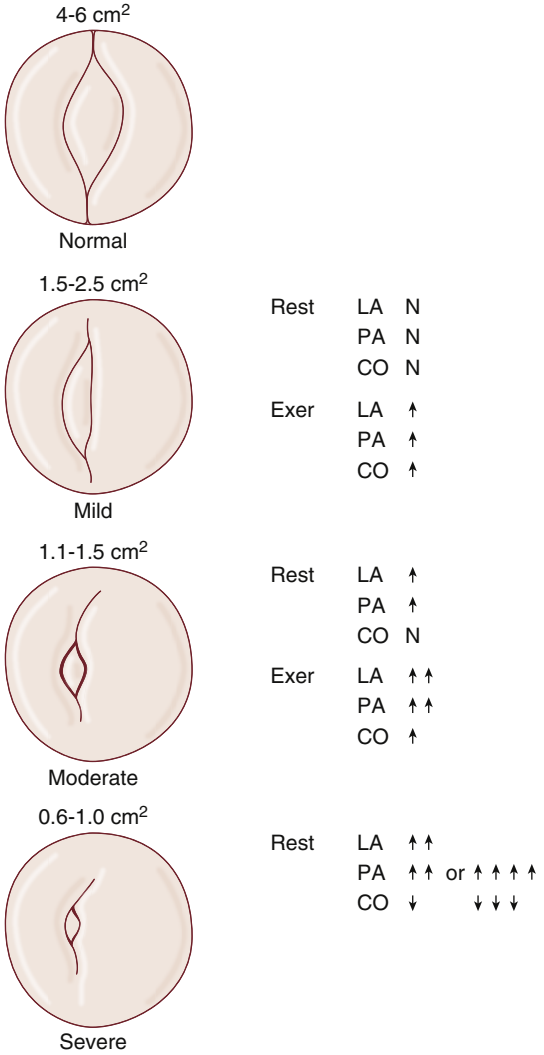

Figure 67-22. Diagrammatic representation of the hemodynamic changes that occur at various stages of severity of mitral stenosis. The valve area is listed above each stage. ↑, increased; ↓, decreased; *CO,* cardiac output; *Exer,* exercise; *LA,* left atrial pressure; *N,* normal; *PA,* pulmonary arterial pressure. *(From Rappaport E: Natural history of aortic and mitral valve disease, Am J Cardiol 35:221-227, 1975.)*

and monitored with echocardiography, although MVA can be calculated during catheterization by using the Gorlin equation.[260] Assessing MS severity by echocardiography involves two-dimensional planimetry of the valve orifice and Doppler-derived measurements of gradient, pressure half-time, and deceleration time. The advent of three-dimensional technology has enabled clinicians to visualize the mitral valve anatomy more accurately (Fig. 67-23).

Management considerations in MS emphasize the pathophysiologic changes that occur in the left atrium, the pulmonary vasculature, the right heart, and the left ventricle. Obstructed mitral inflow with secondary increases in LA pressure (LAP) gradually causes enlargement of the left atrium, which can lead to the onset of atrial fibrillation, thromboembolic complications, or both if low blood flow velocity causes clot formation in the atrium or appendage.

Patients with MS and chronic atrial fibrillation are at increased risk of embolic stroke, at a rate of 7% to 15% per year.[260] Treatment may include anticoagulation with intravenous heparin or oral warfarin, pharmacologic rate control, and pharmacologic or electrical cardioversion for hemodynamically significant or acute-onset atrial fibrillation. In patients scheduled for cardioversion, TEE may need to be performed first to rule out the presence of LA thrombus.[259]

Elevated LAP leads to passive increases in pulmonary venous and arterial pressures. Most patients with MS have a greater PAP than would be expected if PAP were estimated solely from elevations in LAP. These exaggerated pressures are secondary to reactive pulmonary vasoconstriction or histologic changes in the medial and intimal layers of pulmonary arteries and arterioles. PAP sometimes correlates with the severity of MS, but pressures can range widely because of factors such as transmitral pressure gradient, LVEDP, the actual MVA, and a history of chronic pulmonary disease.

The chronic elevation in PAP caused by MS leads to compensatory and decompensatory changes in the right ventricle. Exposure to elevated pressure leads to compensatory RV hypertrophy; however, the response in the right ventricle is less efficient than in the left ventricle because of the shape, wall thickness, and smaller muscle mass of the right ventricle. Because of the right ventricle's relative vulnerability, chronic pulmonary hypertension invariably leads to progressive RV dilation and eventual RV failure.

The effect of MS on the left ventricle is primarily the result of obstruction of diastolic inflow. The narrowed mitral valve orifice leads to prolonged early diastolic mitral inflow and delayed filling of the left ventricle. Late diastolic filling, which occurs during atrial systole, is obviously compromised in patients who have atrial fibrillation secondary to MS. In cases of MS, pressure-volume loops are shifted to the left, so LVEDP and LV end-diastolic volume (LVEDV) are lower. Stroke volume is diminished, especially in clinical situations that result in elevated heart rate and shortened diastolic filling intervals (Fig. 67-24).

LV function or contractility is assumed to be normal in most patients with MS. However, in a review of the literature, Klein and Carroll showed that the assumption of preserved LV contractility in patients with MS is debatable.[261] Instead, the prevalence of LV dysfunction in patients with MS may be as high as 30%. Proposed mechanisms include reduced filling of the left ventricle, muscle atrophy, inflammatory myocardial fibrosis leading to wall-motion abnormalities, scarring of the subvalvular apparatus, abnormal patterns of LV contraction, reduced LV compliance with diastolic dysfunction, increased LV afterload leading to ventricular remodeling, right-to-left septal shift secondary to the effect of pulmonary hypertension on the right ventricle, and coexistent diseases such as systemic hypertension and CAD.[261] The hemodynamic changes associated with MS are summarized in Figure 67-22.

Figure 67-23. Three-dimensional image of a stenotic mitral valve from the left atrial perspective. *(From Lang RM, Tsang W, Weinert L, et al: Valvular heart disease: the value of 3-dimensional echocardiography,* J Am Coll Cardiol *58:1933-1944, 2011).*

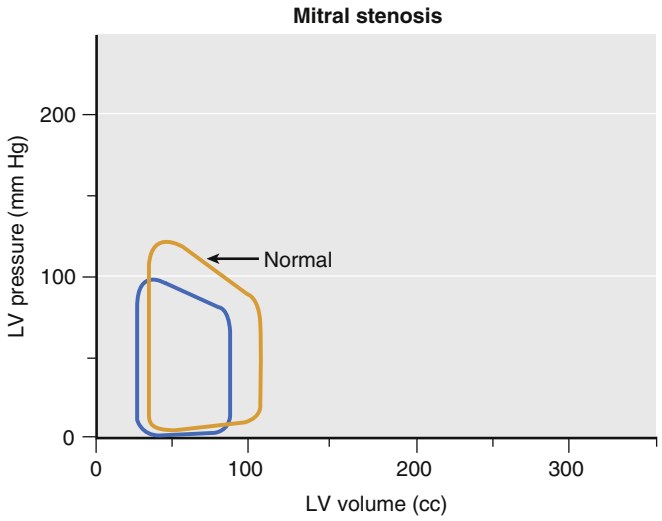

Figure 67-24. Pressure-volume loop in mitral stenosis. *LV,* Left ventricular. *(From Jackson JM, Thomas SJ, Lowenstein E: Anesthetic management of patients with valvular heart disease,* Semin Anesth *1:239, 1982.)*

Anesthetic Management. An understanding and appreciation of the pathophysiologic changes associated with MS form the foundation of anesthetic management in these patients (Table 67-10). Primary concerns in patients with MS include managing ventricular preload, heart rate, and coexisting pulmonary hypertension, as well as potentially diminished RV and LV contractile function. Most patients with valvular heart disease have increased dependency on and sensitivity to ventricular preload. Flow through a stenotic mitral valve requires a higher-than-normal pressure gradient between the left atrium and the left ventricle. Thus, reduction in preload, either from blood loss or from the venodilatory effects of anesthesia, can markedly affect stroke volume, CO, and tissue perfusion. However, in higher grades of MS, LAP may be very high, and the difference between adequate filling pressure and an LAP that leads to congestive failure may be small. Thus, judicious fluid management is required.

In patients with MS, the heart rate should be kept within its normal range. Tachycardia may be poorly tolerated because of the decreased time for diastolic filling. Moreover, pressure gradients are somewhat flow dependent in MS. Elevated flow states, such as pregnancy and increased sympathetic activity from any source, can dramatically increase the pressure gradient across the valve and are reflected in elevated LAP or pulmonary venous pressure. From data obtained by continuous wave Doppler interrogation of the inflow velocities across the mitral valve, the pressure gradient is derived through the use of a modified form of Bernoulli's equation, $\Delta P = 4v^2$, where v is the measured velocity of blood flow through the valve. Thus, any increase in transvalvular flow rate caused by an increase in heart rate has a significant impact on transvalvular flow dynamics and on LAP.

Atrial contributions to stroke volume may be elevated in patients with MS who are in the early stages of the disease and are not in atrial fibrillation. When atrial fibrillation has occurred, the atrial kick is lost. However, the most important factor in the deterioration of the patient's clinical condition is tachycardia itself, rather than loss of the atrial kick.

Contractility and SVR are usually preserved in MS. If anything, the left ventricle is chronically underloaded, but wall motion abnormalities or global systolic dysfunction develop in a small percentage of MS patients. Usually, SVR is not a factor in augmenting forward flow because stroke volume is determined by the mitral valve orifice area and the diastolic filling interval. It may be appropriate to lower SVR for a left ventricle that has marked systolic dysfunction, but care must be exercised because a reduction in afterload is inevitably accompanied by a reduction in preload, which may not be desirable in patients with significant MS.

RV dysfunction probably poses a greater challenge in treating patients with MS than does LV dysfunction. The chronic elevations in LAP can be persistent in patients with long-standing pulmonary hypertension. In the patient with residual pulmonary vascular disease and irreversible pulmonary hypertension, supporting a failing or marginally functional right ventricle becomes the top clinical priority.

Monitoring includes standard noninvasive modalities and invasive monitoring of blood pressure, CVP, and intraoperative echocardiography. Monitoring PAP and using a PA catheter to monitor CO may be very helpful, but care and judgment must be exercised, given the propensity for PA rupture in patients with long-standing pulmonary hypertension. Inotropic support may be needed for patients with secondary RV dysfunction or failure. Epinephrine and milrinone are good therapeutic options. Management of RV dysfunction includes optimizing acid-base balance and using hypocapnia, hyperoxia, and possibly vasodilators to decrease PVR.

Mitral Regurgitation. The complex anatomic structure of the mitral valve is especially pertinent in any consideration of the pathophysiology and management of patients who present for operative intervention for MR. The mitral apparatus consists of six primary components: the LA wall, the annulus of the mitral valve, the mitral valve leaflets, the chordae tendineae, the papillary muscles, and the wall of the left ventricle. Abnormalities or dysfunction in any component can result in mitral valve incompetence.

MR can be classified as either organic (intrinsic valvular disease) or functional (i.e., related to nonvalvular components of the mitral apparatus).[262] It is common for MR to have a functional and an organic component, as in rheumatic valve disease resulting in annular or LV dilation with superimposed abnormalities of leaflet coaptation. In developed countries, the most common causes of MR are as follows: (1) myxomatous degeneration of the mitral valve resulting in annular dilation, chordal elongation and rupture, and redundant, prolapsing, or flail mitral valve leaflets; and (2) mitral insufficiency caused by ischemic heart disease. The most common indication for surgical repair or replacement of the regurgitant mitral valve is myxomatous degeneration, which includes mitral valve prolapse syndromes.[263] Chronic ischemic or functional MR is present in 10% to 20% of patients with CAD and, unlike MR with primary valvular causes, it does not involve abnormalities in the morphology of the mitral valve.[264] Nonetheless, the long-term morbidity and mortality associated with this type of MR are significant.[258]

The severity of MR is assessed in the context of whether the MR is acute or chronic. Symptom presentation,

LV, Left ventricular.

physical examination, hemodynamics, and echocardiography all provide useful information for ascribing a severity grade (Table 67-11). Echocardiographic assessment is particularly important for guiding intraoperative decisions about the need for intervention and the adequacy of repair or replacement of the mitral valve. As with MS, several echocardiographic parameters, both two-dimensional and Doppler-derived, can be used to grade the severity of MR (Table 67-12). The advent of three-dimensional technology and current calculation software greatly improved clinicians' ability to assess the severity and identify the precise cause of MR (Fig. 67-25).

Pathophysiology. The incompetent mitral valve allows retrograde passage of blood from the left ventricle into the left atrium during systole. The magnitude of the regurgitant volume is a function of the size of the regurgitant orifice, the pressure differential between the left atrium and the left ventricle, and the duration of the regurgitant cycle.[262] Thus, higher systolic driving pressures, as in hypertension, can increase the regurgitant volume. Loading conditions are important as well, especially whenever functional changes in annular and LV geometry are important components of the mechanism of MR. These conditions should be considered during the intraoperative evaluation of MR because anesthetic effects on afterload and preload can drastically alter the severity of MR from its baseline level, as seen in preoperative echocardiographic or catheterization assessments.

LV function and pressure tend to be normal in patients with chronic MR. EF is often normal or supranormal unless the ventricle has decompensated with chronic MR or is acutely ischemic. A normal EF can be misleading, and masked ventricular dysfunction may be revealed after valve repair or replacement. The left atrium serves as a low-pressure pathway during systolic ejection, so that EF overestimates ventricular function.

When MR has an acute onset, LAP is elevated, because LA compensatory changes have had no time to occur. A v wave may be present on the LAP, PAP, or PCWP recordings. In contrast, in chronic MR, the LAP increases are less dramatic because of compliance changes in the left atrium as a function of chamber dilation.

The long-term sequelae of MR are related to chronic pressure and volume effects on the left atrium and the left ventricle. The left ventricle is exposed to a chronic, isolated volume-overload state. Eccentric hypertrophy of the left ventricle develops, causing chamber enlargement without significant increases in wall thickness. Forward CO is preserved because of eccentric hypertrophy and the low impedance of the left atrium—a physiologic equivalent of afterload reduction. The larger stroke volume ejected by the left ventricle is composed of the normal venous return into the left atrium in addition to the regurgitant volume from the previous cardiac cycle. In the early stages of MR, LVEDP is relatively normal because of

MR, Mitral regurgitation.

compliance changes of the left ventricle. With time, however, compensatory eccentric hypertrophy fails to preserve LV systolic function, and gradual systolic failure ensues, as noted on pressure-volume loops (Fig. 67-26). In patients with MR, deciding on the timing of surgical intervention is an important duty of the referring cardiologist because LV systolic performance can deteriorate to a point that full functional recovery after valve surgery may not be possible.

The LA is exposed to increases in volume and pressure. The LA dilates to compensate for the regurgitant volume

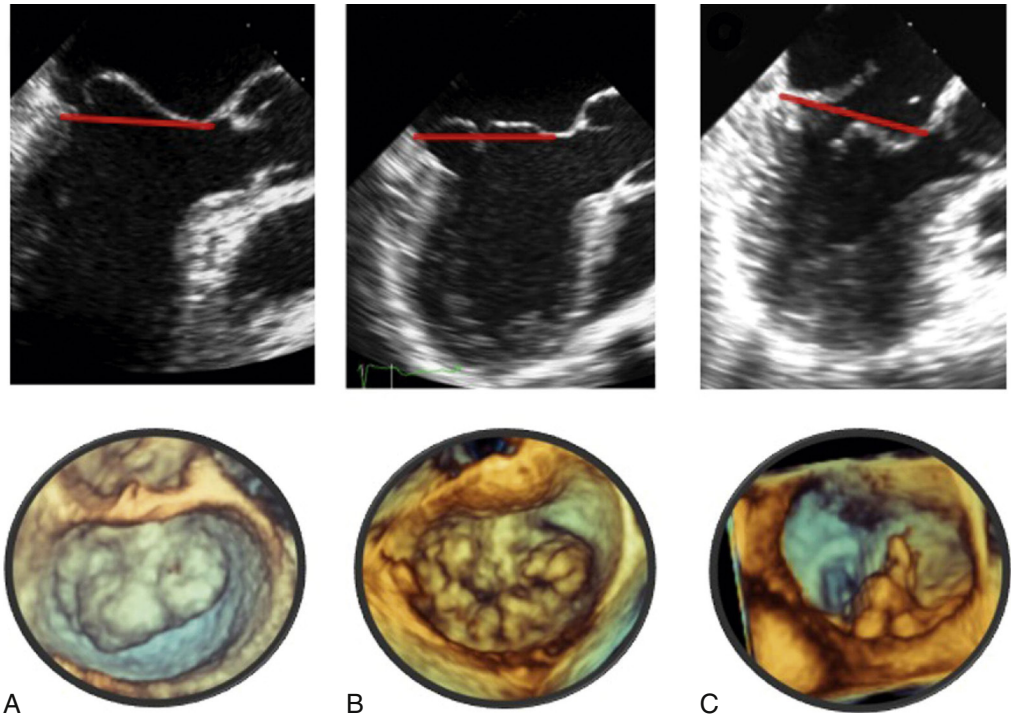

Figure 67-25. Differential diagnosis of mitral leaflet prolapse. Two-dimensional (2D) transesophageal echocardiography (TEE) long-axis view demonstrating anterior leaflet prolapse (**A,** *top*) with a three-dimensional (3D) transesophageal example as seen from the left atrium (**A,** *bottom*). Leaflet prolapse should be diagnosed when the free edge of the leaflet overrides the plane of the mitral annulus during systole. 2D TEE long-axis view demonstrating bileaflet billowing of the mitral valve with prolapse resulting from chordae tendineae elongation (**B,** *top*) with a 3D transesophageal example as seen from the left atrium (**B,** *bottom*). Leaflet billowing is diagnosed when systolic excursion of the leaflet body occurs into the left atrium resulting from excess leaflet tissue, with the leaflet free edge remaining below the plane of the mitral annulus. 2D TEE long-axis view demonstrating flail valve resulting from chordae rupture (**C,** *top*) with a 3D transesophageal example of P2 flail as viewed from the left atrium (**C,** *bottom*). *(From Lang RM, Tsang W, Weinert L, et al: Valvular heart disease: the value of 3-dimensional echocardiography,* J Am Coll Cardiol *58:1933-1944, 2011.)*

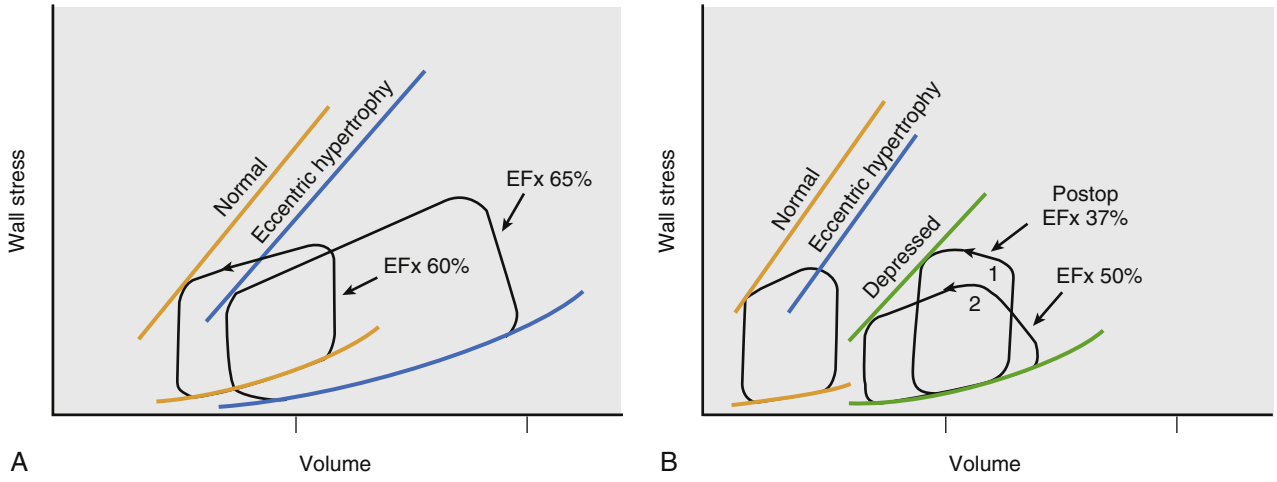

Figure 67-26. Diagram of wall stress–volume loops and end-systolic volume–wall stress relationships in severe mitral regurgitation. **A,** As in aortic regurgitation, the shift to the right of the diastolic and end-systolic relationships allows the volume-overloaded left ventricle to maintain a high stroke volume. Mean wall stress during ejection is somewhat reduced, and in mitral regurgitation the ejection fraction (EFx) is high normal when contractility is normal. **B,** With the development of depressed contractility, the end-systolic wall stress–volume relationship is shifted to the right preoperatively. Despite severely depressed contractility, the ventricle is able to deliver a nearly normal EFx because of the very large ventricular volume and the relatively low mean wall stress during ejection (beat 2, EFx = 50%). Contractility remains depressed after mitral valve replacement (Postop), and with correction of the low-impedance leak, the ventricle must now deliver the total stroke volume into the aorta against higher wall stress; the EFx therefore falls to 37% (beat 1).

during systole, and in the early stages of MR, preservation of near-normal LAP and protection of the pulmonary vasculature is likely. Progressive LA enlargement commonly leads to atrial fibrillation, which occurs in approximately 50% of patients who are about to undergo surgical correction of MR. However, patients with MR appear to be at a lower risk for thromboembolic complications than are patients with MS.

When LAP compliance thresholds are reached, LAP and PAP become elevated. Eventually, if chronically exposed to elevated PAP, the right ventricle progressively enlarges, and RV dysfunction develops.

Anesthetic Management. In the anesthetic management of MR, the primary goal is maintaining forward systemic flow. In chronic, compensated MR, maintaining preload, judiciously reducing afterload, and keeping the heart rate in the high-normal range may be adequate (Table 67-13).

As with most compensated forms of valvular heart disease, patients with hemodynamically significant MR are sensitive to ventricular loading conditions. Augmenting preload may be prudent in the interval before anesthetic induction. However, MR is dynamic; ventricular distention can lead to the expansion of an already dilated mitral annulus and thus worsen MR.

The heart rate should be maintained in the high-normal range (i.e., 80 to 100 beats/minute). Bradycardia has dual detrimental effects on MR: it lengthens the systolic period, thus prolonging regurgitation, and it increases the diastolic filling interval, which can lead to LV distention. A sinus rhythm is preferred, but with less dependency on the atrial kick in chronic, compensated MR than in stenotic valvular heart disease.

LV contractility may be preserved in early compensated MR. However, EF indices are poorly correlated with LV systolic function in patients with moderate to severe MR, and underlying systolic dysfunction may be woefully underestimated. Hypotension in patients with significant MR can be managed to a certain degree by manipulating heart rate and volume, but persistent hemodynamic instability may be best treated with inotropic support. Dobutamine, low-dose epinephrine, and milrinone are all acceptable inotropic choices, depending on the clinician's interpretation of the monitor data.

With respect to SVR, the general rule of thumb for patients with MR is to decrease afterload so that forward CO is maximized. Adequate anesthetic depth, systemic vasodilators, inodilators, and at times, mechanical reduction of afterload with an IABP may be clinical options, depending on the situation. Direct-acting α_1-agonists increase SVR and blood pressure, lower heart rate and may worsen the MR. Temporary use of small doses of ephedrine may be a better choice, after which inotropic support should be considered if a persistent need exists to augment pressure.

Both PAP and PVR may be elevated in patients with either acute or long-standing MR. Secondary changes in RV size and function may be important clinical considerations. Factors that may increase PVR and unfavorably load an already dysfunctional right ventricle (e.g., hypoxia, hypercarbia, and acidosis) should be remedied whenever possible.

Finally, in the patient with acute, severe MR and cardiogenic shock from ischemic rupture of a papillary muscle, pharmacologic support of the left ventricle, often accompanied by mechanical support with IABP counterpulsation, may be necessary.

Hypertrophic Obstructive Cardiomyopathy and the Mitral Valve. Hypertrophic obstructive cardiomyopathy (HOCM) may result in dynamic valvular insufficiency, as well as LV outflow tract (LVOT) obstruction. In addition, surgical attempts to repair an incompetent mitral valve can create iatrogenic LVOT obstruction.

Classically, HOCM is a familial disease transmitted with autosomal dominant inheritance. Inheritance and phenotypic expressions are heterogeneous and vary in their manifestations. Some mutations in genes that code for cardiac sarcomere proteins can cause hypertrophy of segments of the ventricle. Septal involvement is common, but HOCM can involve other areas of the left ventricle as well.[265] This disease is the most common cause of sudden death in young people, but it can also cause death and morbidity in older patients.

When the basal septum of the left ventricle is affected, the LVOT can narrow. Depending on the shape of the ventricle and the mitral valve, dynamic outflow tract obstruction can occur, paired with mitral valve insufficiency. As the outflow tract is narrowed by hypertrophy, the basal septum and the anterior leaflet of the mitral valve come into close proximity. The hypertrophy and the reduced septal–anterior leaflet distance can create a channel that narrows to the point of creating a pressure gradient across the outflow tract. This obstructed flow and its pressure gradient lead to progressive compensatory hypertrophy that, in turn, further narrows the outflow tract and worsens the gradient. As blood is ejected through this narrowed outflow channel during systole, the velocity of blood through the narrowed orifice increases. This increased blood velocity creates a Venturi effect that pulls the anterior leaflet of the mitral valve or the chordal structures into the outflow tract, thus leading to mechanical and dynamic obstruction of the LVOT and also causing MR because of a coaptation defect of the mitral valve.[266] Echocardiographically, this is termed systolic anterior motion (SAM) of the mitral

TABLE 67-13 PATHOPHYSIOLOGIC CHANGES ASSOCIATED WITH MITRAL REGURGITATION

LV, Left ventricular.

valve (Fig. 67-27). Such dysfunctional mitral valve motion is seen in cardiac surgical patients who present for surgical management of known HOCM (i.e., for surgical myomectomy, mitral valve repair, or both).

Sometimes, SAM is noted preoperatively or as an incidental finding at the time of surgery in patients who present for surgical revascularization or mitral valve repair. Furthermore, SAM may be created iatrogenically as a result of surgical mitral valve repair. In patients with MR who are to undergo mitral valve repair, echocardiographic assessment and surgical inspection are performed to elucidate the mechanism of the mitral insufficiency. The patient may have ruptured or elongated chordal attachments, redundant or prolapsing leaflet tissue, or annular dilation that reduces effective leaflet coaptation. Frequently, multiple contributing factors are present. Surgical treatment can involve just a simple annuloplasty ring in the case of isolated annular dilation, but it more commonly involves resection of diseased segments of the mitral valve, possibly chordal reassignment or reconstruction, and a ring valvuloplasty.

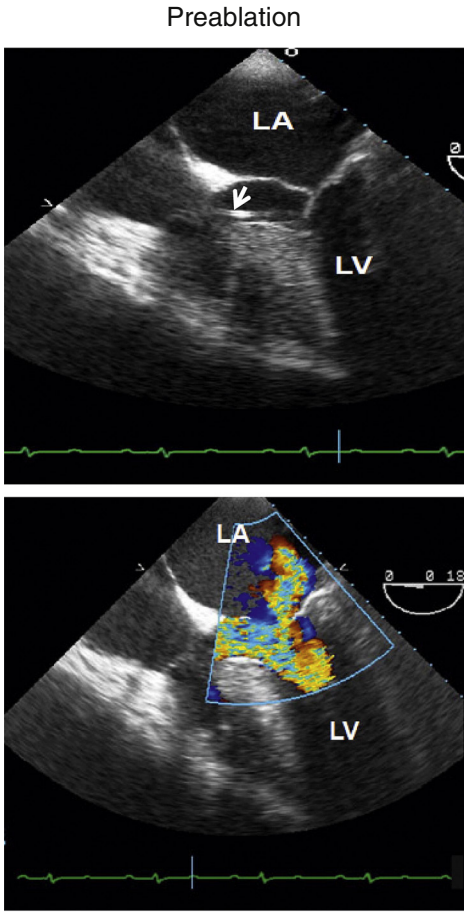

Figure 67-27. Transesophageal echocardiographic images. *Top,* Two-dimensional image shows a narrowed left ventricular outflow tract with systolic anterior motion (*arrow*). *Bottom,* Color Doppler image shows high-velocity signals in mosaic color; eccentric mitral regurgitation is directed posterolaterally. *LA,* Left atrium; *LV,* left ventricle. *(From Naguch SF, Bierig M, Budoff MJ, et al: American Society of Echocardiography clinical recommendations for multimodality cardiovascular imaging of patients with hypertrophic cardiomyopathy,* J Am Soc Echocardiogr *24: 473-498, 2011.)*

Depending on LV geometry and size and the physical characteristics of the mitral valve, surgical repair may bring the anterior leaflet and the coaptation point of the valve into close approximation with the interventricular septum and the LVOT. That septal coaptation point can narrow enough to create a gradient in the outflow tract, so that the anterior leaflet is pulled into the LVOT by the Venturi effect, leading to obstruction and secondary mitral insufficiency. This anterior displacement of the mitral coaptation point and the amount of the extra anterior leaflet have been proposed to be mechanisms for SAM, thus leading to the development of surgical techniques that can reduce the incidence of SAM in high-risk patients.[267] Anesthetic management of obstructive cardiomyopathy centers on fluid and pharmacologic interventions to decrease the magnitude of the obstruction and, at the same time, lessen the severity of the mitral insufficiency. Most patients with outflow tract abnormalities have normal to supranormal contractility.

Generally, inotropic agents should not be used. The thick, hypertrophied ventricle usually has reduced compliance and is very load sensitive, so that outflow tract obstruction increases in hypovolemic conditions. Thus, optimizing preload and ventricular filling is appropriate both in managing the patient with LVOT and in assessing the need for surgical reconstruction of the LVOT, mitral valve repair, or both. Afterload reduction should be avoided because it worsens the obstruction. Conversely, increasing the afterload decreases the trans–outflow tract gradient and leads to a reduction of SAM and outflow tract obstruction. Hence, vasoconstrictors such as phenylephrine and vasopressin should be considered. In both congenital and iatrogenic LVOT obstruction, the degree of obstruction is dynamic. Obstruction is exacerbated by hypercontractile states and elevations in heart rate; therefore, reducing the heart rate with β-adrenergic blockade should be considered.

Continuous, skilled echocardiographic assessment and interpretation are important for optimal intraoperative management of these patients. Assessing the severity and mechanism of outflow tract obstruction and determining whether to reinstitute CPB to revise the repair or replace the valve are not innocuous decisions, and they must be carefully made jointly by the anesthesiologist and the surgeon, ideally with input from the appropriate cardiologist.

Aortic Valve Disease

Aortic Stenosis

Pathophysiology. AS is the most common cardiac valve lesion diagnosed in the United States. Marked increases in the annual volume of aortic valve replacements have occurred recently, especially in older and high-risk patients.[268]

AS is often caused by congenital defects in the valve because 1% to 2% of people are born with a bicuspid aortic valve.[268] Inheritance has been found to play a role, with an autosomal dominant pattern and a variable penetrance.[269] A bicuspid aortic valve that does not yet show any signs of damage nevertheless tends to open and close with abnormal folding and creasing, leading to scarring and calcification and ultimately culminating in AS with or without aortic regurgitation (AR). Although patients with a bicuspid

aortic valve are asymptomatic until late in the disease process, severe, symptomatic AS or AR may develop in midlife. In addition, the abnormal motion of these bicuspid leaflets causes some turbulent flow into the aorta, which eventually can lead to dilatation and subsequent rupture or dissection.[270,271] A typical "fish-mouth" opening of the aortic valve in a midesophageal, cross-sectional TEE view of the valve is a telltale sign of a bicuspid aortic valve.

Acquired AS is usually the result of senile degeneration with sclerosis and calcification of the valve. The prevalence of AS increases with age; it is now seen in 2% to 4% of adults who are older than 65 years old, and this prevalence is expected to increase.[268,272] A clear association is reported between clinical risk factors for atherosclerotic disease (e.g., the process of chronic inflammation) and the development of AS.[272,273] In developed countries, rheumatic disease is a less common cause of AS, and AS is usually associated with concomitant AR.

A typical pressure-volume loop for AS is shown in Figure 67-28. In patients with AS, the obstruction of LV outflow increases peak systolic wall stress, resulting in chronic pressure overload that directly stimulates parallel replication of sarcomeres in the left ventricle and consequently causes concentric ventricular hypertrophy. The peak pressure generated by the left ventricle during systole is much higher than normal because of the high transvalvular pressure gradient. Concentric LV hypertrophy nearly always develops as a result of the increases in pressure load (Fig. 67-29). This increased load also leads to diastolic dysfunction, an increase in LVEDP, and subendocardial ischemia.

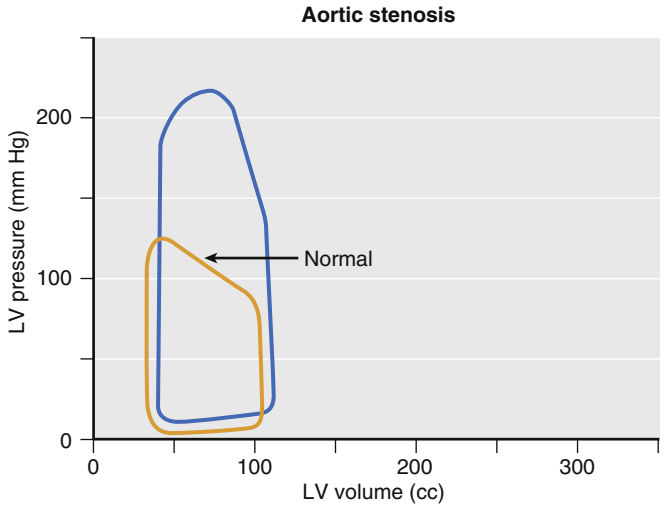

Figure 67-28. Pressure-volume loop in aortic stenosis. *LV,* Left ventricular. *(Modified from Jackson JM, Thomas SJ, Lowenstein E: Anesthetic management of patients with valvular heart disease,* Semin Anesth *1:239, 1982.)*

Echocardiography and intraoperative TEE in particular play important roles in the diagnosis and ultimate management of patients with AS, both in the outpatient setting and during surgical aortic valve replacement. The severity of AS can be assessed from various echocardiographic parameters. One that is commonly used is the aortic valve area (AVA). The normal range of the AVA is 3 to 4 cm^2; AS is graded as severe if the AVA is reduced to 1 cm^2 or less.[274] Another parameter commonly used to determine the severity of AS is the gradient across the aortic valve; AS is considered severe if the mean gradient is greater than 40 mm Hg.[259] Echocardiography can be used to examine multiple aspects of the pathophysiology of AS, including the severity of AS, any structural abnormalities of the valve causing LVOT obstruction, and any accompanying disease that can be found in the other heart valves.

With TEE, the best views for evaluating the aortic valve are the midesophageal aortic valve short-axis view, the midesophageal long-axis view, and the transgastric views. Midesophageal views are helpful in ascertaining the shape of the aortic valve and the cause of AS (Fig. 67-30), whereas transgastric views are helpful in obtaining gradient measurements across the valve and the LVOT (Fig. 67-31). In addition, both the midesophageal and the transgastric views can be used to measure the dimensions of the aortic valve annulus and the LVOT; these measurements are helpful in making surgical decisions related to the size of the valve.

Patients with AS who have not yet developed symptoms should be closely monitored over time for progression of the disease. Patients who develop symptoms (including decreased exercise tolerance and exertional dyspnea, angina, CHF, and syncope) are considered for valve replacement. A delay in surgical intervention in symptomatic patients can worsen their prognosis.[272]

ANESTHETIC MANAGEMENT. Premedication may alleviate a patient's anxiety regarding cardiac surgery, and it helps to prevent perioperative tachycardia in patients with AS.

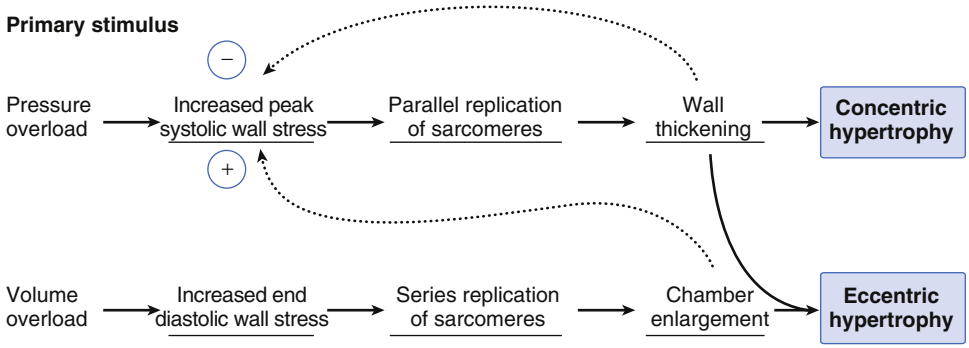

Figure 67-29. The increased peak systolic wall stress resulting from chronic pressure overload directly stimulates concentric ventricular hypertrophy, which tends to counteract or "normalize" the elevated ventricular wall stress. *(From Grossman W, Jones D, Mclaurin LP: Wall stress and pattern of hypertrophy in the human left ventricle,* J Clin Invest *56:56, 1975.)*

Monitoring in these patients includes standard noninvasive modalities and invasive monitoring of blood pressure and CVP. Depending on the severity of the AS, pulse pressure may be as low as 50 mm Hg or less. Insertion of a PA catheter may be considered to monitor PAP and CO during surgical procedures and particularly in the postoperative period. However, patients with AS are at risk for developing dangerous arrhythmias during PA catheter placement. TEE is almost always used if no contraindications to probe placement exist; the measurements obtained yield extremely valuable information (Fig. 67-32; see also Figs. 67-30 and 67-31).[275,276]

The anesthetic management of patients with AS centers on avoiding fluctuations in the patient's hemodynamics while achieving adequate anesthetic depth. Induction of anesthesia should not involve any medication that could have negative inotropic or vasodilatory effects. Any drugs that could cause tachycardia should also be avoided. Furthermore, every effort should be made to ensure that the patient stays in sinus rhythm. In patients with AS, the atrial kick may contribute as much as 40% of the total CO. Therefore, to treat any possible arrhythmia, external cardioversion pads should be considered, preferably before anesthesia is induced.

Finally, the presence of severe AS reduces the usefulness of cardiopulmonary resuscitation (CPR) for maintaining CO sufficient to meet the patient's physiologic needs. Table 67-14 summarizes the goals of anesthetic care of a patient with AS.

Aortic Regurgitation

Pathophysiology. AR is the flow of blood from the aorta backward into the left ventricle during the diastolic phase of the cardiac cycle. Chronic AR is more prevalent than acute AR and carries a much better prognosis. However, the precise prevalence of AR—acute and chronic—remains unknown.[277]

Chronic AR and acute AR have their own etiologies. Causes of chronic AR include congenital lesions, degenerative processes, and rheumatic disease, but idiopathic causes seem to be the most common.[277] These processes cause malcoaptation of the aortic valve leaflets by producing abnormalities in the leaflets themselves or dilation of the aortic valve annulus, the aortic root, or both. Abnormalities of the aortic valve leaflets include congenital conditions (e.g., bicuspid aortic valve), endocarditis, rheumatic disease, inflammatory diseases, certain connective tissue diseases, and chest wall trauma causing injury to an aortic valve leaflet. Dilation of the proximal aortic root may be caused by annuloaortic ectasia resulting from long-term chronic hypertension or simply from

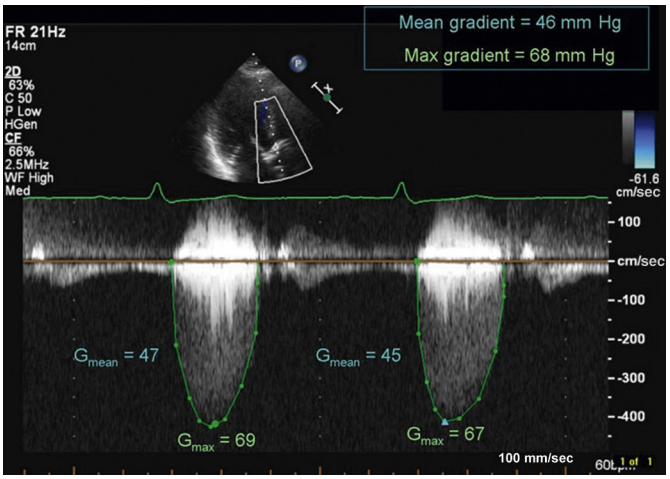

Figure 67-31. Quantification of the degree of aortic stenosis with continuous Doppler. G_{max}, maximum gradient; G_{mean}, mean gradient. *(From <http://web.stanford.edu/group/ccm_echocardio/cgi-bin/mediawiki/index.php/Aortic_stenosis_assessment>. [Accessed 21.08.14])*

the normal aging process.[278] Other aortic valve annular or aortic root causes of AR include Marfan syndrome, syphilis, congenital diseases such as osteogenesis imperfecta and Ehlers-Danlos syndrome, and idiopathic causes.[277,278]

Chronic Aortic Regurgitation. Patients with chronic AR may remain asymptomatic for years or even decades. The left ventricle undergoes a process of remodeling resulting from series replication of sarcomeres and the development of eccentric ventricular hypertrophy and chamber enlargement in the presence of a chronically increasing volume of regurgitation (see Fig. 67-29). Although the pressure-volume loop is shifted far to the right in patients with chronic AR, the LVEDP remains relatively normal because the LVEDV increases slowly (Fig. 67-33). Forward flow is improved by peripheral vasodilation. Typically, a normal EF is maintained by a large stroke volume. However, over time, increases in LV wall stress and afterload result. Eventually, as LV dilation and hypertrophy progress, irreversible LV dysfunction develops, and patients become symptomatic. As a compensatory mechanism for poor CO, sympathetic constriction of the peripheral vasculature occurs to maintain blood pressure, but this adaptation exacerbates regurgitation and further reduces CO.

In addition to a detailed history and physical examination, diagnostic modalities such as magnetic resonance imaging, radionuclide angiography, and exercise stress testing are used to assess AR. However, echocardiography remains the most important diagnostic tool (Fig. 67-34). The severity of AR is assessed qualitatively: regurgitation of less than 20% of the total LV stroke volume is considered mild, 20% to 39% is considered moderate, 40% to 60% is considered moderately severe, and more than 60% is considered severe.

Several semiquantitative echocardiographic modalities are used to assess AR. These include color flow mapping, in which the ratio of the AR jet width to the width of the LVOT is used to ascertain the severity of the condition. Jets that appear to be central in flow may appear to be larger than they actually are because of the entrainment of fluids.[277] This possibility should be considered when one is evaluating a centrally directed jet as compared with an eccentrically directed jet. The vena contracta, the narrowest part of the regurgitant jet, can be measured to determine the severity of AR (see Fig. 67-34). A vena contracta measurement of 6 mm or greater carries a sensitivity of 95% and a specificity of 90% for the presence of severe AR.[279] A vena contracta of less than 0.3 mm indicates mild AR. The pressure half-time of the AR jet can be measured echocardiographically. A pressure half-time of less than 200 msec indicates severe AR. In addition, holodiastolic flow reversal in the descending aorta signifies moderate-to-severe AR.

Although patients with chronic AR can remain asymptomatic for decades, symptoms of left-sided HF eventually occur, such as exercise intolerance, dyspnea, and paroxysmal nocturnal dyspnea or orthopnea. Afterload reduction may become necessary as the disease progresses. In addition, a few patients present with angina despite having normal coronary arteries; this angina results from poor coronary perfusion resulting from low diastolic aortic pressure. A difficult decision for the cardiologist is at what point

LV, Left ventricular.

From Townsley MM, Martin DE: Anesthetic management for the surgical treatment of valvular heart disease. In Hensley FA, Martin DE, Gravlee GP, editors: A practical approach to cardiac anesthesia, *ed 5, Philadelphia, 2013, Lippincott Williams & Wilkins, p 327.*

in the course of the disease surgery should be performed to prevent the development of irreversible LV dysfunction, especially in patients with severe chronic AR.[276,277]

Acute Aortic Regurgitation. Acute AR is less common than chronic AR but carries a more ominous prognosis. Common causes of acute AR include trauma, bacterial endocarditis, and aortic dissection. Rarely, acute AR occurs as an idiopathic complication, such as after aortic valvuloplasty. The focus of the pathophysiology of acute AR is that it causes an acute increase in the volume coming into the left ventricle. Because the left ventricle has not had time to undergo the process of eccentric hypertrophy, as it does in chronic AR, it is unprepared to accommodate this sudden increase in volume. As shown in Figure 67-33, this sudden increase in the LVEDP causes a rightward shift in the pressure-volume loop.[278] A sympathetic response is activated; tachycardia and an increased contractile state are the chief compensatory mechanisms for maintaining adequate CO. Unless acute AR is managed appropriately, these compensatory mechanisms rapidly fail. Furthermore, the sympathetic response causes sympathetic constriction of the peripheral vasculature, thereby increasing SVR and further worsening the AR. LV function can deteriorate rapidly, necessitating emergency surgery. Vasodilator therapy may temporarily stabilize the patient during transport to the operating room.[277]

Anesthetic Management. The anesthetic management of patients with AR should include maintaining a relatively fast heart rate (≈90 beats/minute) and a relatively low SVR while maintaining preload and contractility. Table 67-15 summarizes the goals of anesthetic care for a patient with AR. Light premedication is recommended. Regarding the choice of drugs for general anesthesia in these patients, medications that cause bradycardia or high blood pressure should be avoided because these changes worsen the degree of AR and can precipitate LV failure.

Preoperative placement of an arterial catheter and central venous catheter is standard, and a PA catheter may be considered if PAPs are high. In the prebypass period, TEE allows the anesthesiologist to determine the cause and severity of the AR, evaluate LV size and function, and assess the function of the other cardiac valves. Furthermore, TEE assessment in the immediate postbypass period confirms the proper positioning and function of the new aortic valve.

Weaning from CPB may be complicated by preexisting LV dysfunction. Furthermore, mechanical aortic valve replacement results in a mild transvalvular pressure gradient. Therefore, inotropic agents may be needed to improve LV function. Preload augmentation must be continued to maintain the filling of the dilated left ventricle.

Calipers measure the narrowest portion of the aortic regurgitant jet, which corresponds to an approximation of the regurgitant orifice area. *Ao,* Aorta; *LA,* left atrium; *LV,* left ventricle. *(From Perino AC, Reeves ST, editors:* A practical approach to transesophageal echocardiography, *ed 2, Philadelphia, 2008, Lippincott Williams & Wilkins, p 232.)*

Other Valvular Disease

Tricuspid Valve Disease

Tricuspid Regurgitation. Right-sided valvular disease in adults is most often a manifestation of pulmonary hypertension secondary to intrinsic lung disease, pulmonary vascular disease, or left-sided cardiac disease. Primary TR can be rheumatic, traumatic, or infectious. Secondary or functional TR can be a manifestation of cor pulmonale, primary pulmonary hypertension, or left-sided cardiac disease that results in elevated pulmonary vascular pressures. Functional TR is frequently present in patients undergoing aortic and particularly mitral valve surgery. Severe TR is now considered a class 1 indication for concomitant tricuspid valve repair or replacement in patients undergoing left-sided heart valve surgical procedures.

Tricuspid valvular disease is predominately regurgitant. Patients with significant TR may have symptoms of dyspnea and evidence of elevated RA pressure (e.g., hepatomegaly, peripheral edema). Compensatory changes with long-standing TR involve RV and RA chamber dilation. Because of RA enlargement, many patients exhibit atrial fibrillation. Long-standing TR and RV enlargement can result in RV systolic dysfunction, which leads to further chamber enlargement, tricuspid annular dilation, and worsening of TR severity. If the tricuspid insufficiency is secondary to RV pressure overload states, as with pulmonary hypertension, RV hypertrophy ensues. This hypertrophy and increased RV pressure can lead to leftward displacement of the interventricular septum and impaired *LV* systolic and diastolic performance.

Anesthetic management concerns include preload preservation and appropriate inotropic support as

dictated by the clinical situation. If the TR is secondary to elevations in pulmonary vascular pressure or resistance, efforts to reduce PVR will be beneficial. Forward flow can be maximized by high-normal heart rates. Surgical annuloplasty, although usually successful, can leave residual TR or create an elevated pressure gradient across the tricuspid valve.[279]

Tricuspid Stenosis. Tricuspid stenosis (TS) is a relatively rare clinical finding in adults. Patients with TS may have significant RA enlargement and possibly atrial fibrillation. Chronic elevation of RA pressure leads to IVC dilation, jugular venous distention, and hepatic congestion. Clinical symptoms and signs can include hepatomegaly (with or without hepatic dysfunction), ascites, peripheral edema, fatigue, and dyspnea.[279,280]

TS results in reduced RV filling. The normal tricuspid valve area is 7 cm^2, and ventricular filling is compromised once the valve area falls to less than 1.5 cm^2. The severity of TS is usually assessed echocardiographically by measuring the Doppler-derived transvalvular gradient. Mild TS is associated with a gradient of 2 mm Hg or less; moderate TS, 2 to 6 mm Hg; and severe TS, greater than 6 mm Hg.[281]

Anesthetic management centers on maintaining preload and controlling heart rate. Overt tachycardia should be avoided because it significantly shortens the interval for diastolic filling, which must be prolonged in these patients. The target heart rate is not frank bradycardia, because CO may not be optimal, but the heart rate should be in the low-normal range. When atrial fibrillation is not part of the clinical picture, preserving AV synchrony is important for maintaining RV output. Although RV inotropic failure is not usually a major concern in isolated TS, it may be when TS is a part of multivalvular heart disease or ischemic heart disease, thus warranting consideration of inotropic support. SVR should be maintained because the fixed obstruction at the level of the tricuspid valve prevents a compensatory increase in preload if afterload declines.

Pulmonic Valve Disease

Pulmonic Stenosis. Pulmonic valvular disease can be congenital or acquired. Pulmonic stenosis (PS) is caused by congenital valve abnormalities in 95% of cases.[279] Elevated transvalvular pressure gradients lead to RV hypertrophy, dilation, and eventual failure. Treatments include balloon valvuloplasty, surgical valvotomy, and valve replacement. Subvalvular muscular infundibular obstruction can result from long-standing PS. Tachycardia and hypovolemia can precipitate a dynamic clinical condition in which outflow tract obstruction is accentuated. Management strategies include judicious heart rate control, preload maintenance, and inotropic support if RV systolic failure occurs.

Pulmonic Insufficiency. Pulmonic insufficiency (PI) can result when pulmonic valves are rendered incompetent during childhood balloon valvuloplasty for congenital PS or surgical valvotomy for tetralogy of Fallot or its variants. PI may also be associated with rheumatic heart disease, pulmonary embolus, carcinoid syndrome, trauma, Marfan syndrome, idiopathic dilation of the pulmonary trunk, and endocarditis.[279] Most patients are asymptomatic, but long-standing severe PI can lead to symptomatic RV dilation and failure, warranting replacement of the pulmonic valve.

Anesthetic management requires being mindful of the primary cardiac or pulmonary disease that led to the pulmonic valvular insufficiency (e.g., endocarditis, emboli, and multifactorial causes of pulmonary hypertension). In primary PI, anesthetic management goals may include maintaining preload, supporting contractility, and reducing PVR by lowering the $Paco_2$ and increasing the fraction of inspired oxygen (FiO_2).

Minimally Invasive Valve Surgery

Cosgrove, Sabik, and Cohen were among the first surgeons to modify the traditional approach to cardiac surgery and pioneer the concept of minimally invasive cardiac surgery.[282] The rapid development and refinement of minimally invasive techniques have resulted in the realizations that minimally invasive cardiac surgery does not compromise patients' safety or surgical exposure and that results are comparable to those of traditional open procedures. Mihaljevic and colleagues published a series of 1000 minimally invasive valve operations performed between 1996 and 2003 and noted the following benefits: reduced bypass and cross-clamp times, reduced stroke and MI rates, reduced length of hospital stay, and a higher rate of discharges home rather than to another facility.[283]

Minimally Invasive Aortic Valve Surgery. The surgical approach to the aortic valve can be made through several different incisions, including a right parasternal incision, upper hemisternotomy, or lower hemisternotomy.[282] To achieve arterial access, a surgical decision may be made to cannulate the femoral artery.[283] Alternatively, if aortic atheromatous disease precludes retrograde aortic arterial flow, the surgeon may attempt aortic cannulation through an incision directly into the aorta, or through the axillary artery.[282,284] Venous bypass drainage can be accomplished by cannulating the right atrium (if surgical exposure is not compromised) or through the femoral vein. Positioning of the distal drainage portion of the femoral vein cannula in the IVC, right atrium, or distal segment of the SVC is guided and confirmed by TEE (Fig. 67-35).[283] To reduce the incidence and magnitude of retained intracavitary LV air, carbon dioxide can be insufflated into the surgical field.[282] Because surgical exposure is limited, sterile transcutaneous defibrillator pads should be placed before preparing and draping, should the need to defibrillate arise.[284]

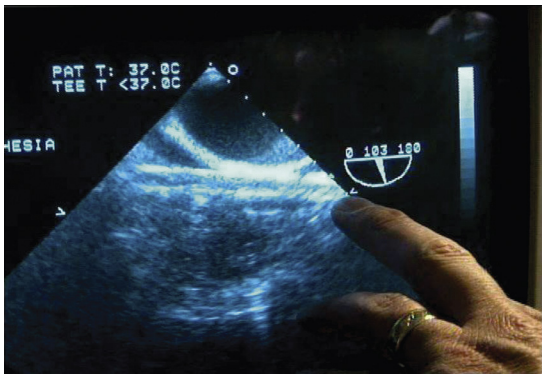

Figure 67-35. Venous cannula placement through the inferior vena cava–right atrium into the superior vena cava.

In general, anesthetic monitoring considerations are similar to those for standard approaches to valvular heart surgery. However, in the absence of direct visualization, TEE is even more valuable in these procedures because of the importance of assessing bypass cannula placement and ensuring adequate ventricular de-airing.[284] If retrograde cardioplegia is required, TEE may be used to guide a transjugular retrograde catheter into the coronary sinus.

One report of a large series of minimally invasive aortic valve procedures included more than 900 patients. Compared with the national average, these patients had decreased blood product use (with 53% of first-time aortic valve surgery patients receiving no blood products) and higher rates of discharge home (including 40% of the octogenarian patients).[285]

Minimally Invasive Mitral Valve Surgery. The mitral valve can be accessed through a lower hemisternotomy, a right parasternal incision excising the cartilaginous portions of the third and fourth ribs, or a right thoracotomy through a 4-cm incision.[286] The mitral valve is then exposed through the left atrium or by a transseptal approach through the right atrium. Visualization of the valve for repair or replacement can be achieved in the following ways: by direct inspection and instrumentation; by "port access" under thoracoscopic guidance and video assistance, which can involve voice-activated, robotic movement of the thoracoscopic instruments; or by a more complete endoscopic technique using the DaVinci robotic system (Intuitive Surgical, Inc., Sunnyvale, Calif) (see also Chapter 86). The DaVinci system uses robotic arms and instrumentation controlled by the surgeon sitting at a remote, computer-enhanced, three-dimensional imaging console to assist in completing the surgery.[287]

Endoscopic or minimally invasive mitral procedures usually involve CPB with aortic and venous cannulas placed through the femoral artery and vein. In addition, the surgeon may choose to use novel aortic occlusion devices that allow a bloodless operative field and the delivery of cardioplegia (Fig. 67-36). However, this catheter is challenging to position in the aortic root and necessitates intraoperative fluoroscopy or echocardiography to confirm the catheter's position definitively. Known concerns and risks include catheter migration into the heart across the aortic valve and distal migration with occlusion of the brachiocephalic trunk.[284] Alternatively, the aorta can be occluded directly with flexible cross-clamps introduced through small chest wall incisions. The Chitwood transthoracic aortic cross-clamp (Scanlan International, Inc., St. Paul, Minn) and the Cosgrove Flex Clamp (Cardinal Health, McGaw Park, IL) are being used for this purpose (Fig. 67-37).[286] Cardioplegia needles may be inserted under direct vision or thoracoscopic guidance.[284] Retrograde cardioplegia, although not necessarily used in all patients, can be accomplished by directly cannulating the coronary sinus with a retrograde catheter at the operative site (RA approach) or by placing a percutaneous coronary sinus catheter in the internal jugular vein and positioning it under echocardiographic guidance. Secondary operative considerations include the unique positioning of the patient for the use of robotic instrumentation. Most minimally invasive approaches require a 30-degree "right side up" position.

Regarding anesthetic management, adequate surgical visualization often necessitates offering selective lung ventilation with the use of a double-lumen tube or bronchial blocker. Monitoring considerations are similar to those for standard approaches to valvular heart surgery, including a five-lead ECG, an invasive arterial catheter, and central venous access. Furthermore, a PA ventilation (PA vent) catheter is placed in a manner similar to placement of a PA catheter.[284] These two catheters differ in two important ways. First, the PA vent is flimsier than a PA catheter; therefore, during its placement, the anesthesiologist will encounter a significant amount of noise in the tracings. Second, the PA vent does not have as many ports as a PA catheter does, which means that the cardiac anesthesiologist cannot monitor the $S\bar{v}O_2$ and CO or cardiac index.

The outcomes of minimally invasive mitral valve surgery have been encouraging**.** Although prospective trials comparing minimally invasive mitral valve surgery and standard approaches are limited, developments in technology and an integrated team approach may facilitate favorable postoperative outcomes.[286] Reports describe mortality and morbidity rates comparable to those of full-sternotomy approaches, with reduced postoperative bleeding and trends toward reduced length of hospital stay and a higher rate of discharge home.[282,283]

Transcatheter Aortic Valve Implantation. Symptomatic patients with severe AS have a poor prognosis; the mortality at 1 year in medically treated patients is

50%.[288] Transcatheter aortic valve implantation (TAVI) is an alternative treatment option in patients with severe AS for whom cardiac surgery and traditional aortic valve replacement pose substantial risks, particularly patients of advanced age who have extreme comorbidities (e.g., porcelain aorta, prior radiation therapy, frailty, severe hepatic or pulmonary disease).[289-291] The technologic advances made in the development of TAVI procedures are ingenious. However, the procedure is associated with significant 30-day mortality (8% to 10%), as well as short-term and long-term morbidity, including stroke, need for permanent pacemaker insertion, access complications, valve embolization, renal failure, cardiac rupture, aortic rupture, cardiac tamponade, and bleeding.[292,293] Published guidelines regarding the TAVI procedure recommend specialized multidisciplinary heart teams that include cardiologists, cardiac surgeons, anesthesiologists, intensivists, nurses, and others.[294] The hybrid operating room or cardiac catheterization laboratory (CCL) where the procedure is performed must have adequate space, expert echocardiography, emergency supplies, support from colleagues, and immediate access to CPB technicians and a cardiac surgeon if necessary.

The TAVI procedure requires either retrograde (through the femoral artery) or anterograde (through the apex of the left ventricle) access to the aortic valve annulus (Fig. 67-38).[294,295] Typically, general anesthesia is needed for transapical procedures.[292] Large-bore intravenous access, an arterial catheter, and central venous access are essential, as is a PA catheter in patients with preexisting pulmonary hypertension. A TEE probe is introduced after induction. External defibrillation pads are placed and connected to the defibrillator before the procedure begins (ventricular fibrillation can result from manipulation of catheters within the heart or from rapid ventricular pacing).[292] Because a period of rapid ventricular pacing is required during deployment of the valve, a transvenous lead for temporary pacing is inserted, typically through the femoral or subclavian vein (or, in the case of transapical procedures, sewn directly on the epicardial surface).[292]

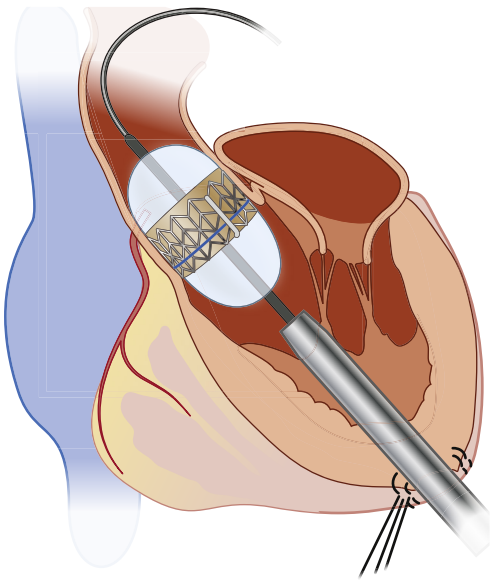

Figure 67-38. Schematic of transapical aortic valve implantation. The prosthesis is implanted within the native annulus by balloon inflation. *(From Walther T, Ralk V, Borger MA, et al: Minimally invasive transapical beating heart aortic valve implantation: proof of concept,* Eur J Cardiothorac Surg *31:9-15, 2007.)*

TEE has a central role in evaluating annulus size, aortic disease, ventricular function, and MR, as well as determining reasons for hemodynamic instability.[295,296] A balloon valvuloplasty of the aortic valve precedes the insertion of a bioprosthetic valve, which is crimped on a valvuloplasty balloon catheter and implanted by inflation. The device is guided into position through the combined use of real-time TEE and fluoroscopy. Immediately after inflation, TEE is employed to measure the degree and source of any AR and to examine the aorta for any aortic dissection.[295,296]

A major challenge during the TAVI procedure is maintaining hemodynamic stability. In patients with severe concentric LV hypertrophy and intravascular volume depletion, hemodynamic status may deteriorate rapidly because of ventricular pacing, intracardiac guidewire or catheter manipulation, or balloon aortic valvuloplasty itself.[292] Avoiding prolonged hypotension and the cycle of hypotension, subendocardial ischemia, and low output is critical to prevent hemodynamic collapse. The frequency and duration of rapid ventricular pacing episodes may need to be limited to allow enough time between episodes for spontaneous circulation to recover. Vasopressors (norepinephrine, epinephrine, or phenylephrine), administered as incremental boluses or as a continuous infusion, may be necessary. Constant communication among team members is essential throughout this multidisciplinary procedure.

Although general anesthesia is used for transapical procedures, some experienced institutions are performing transfemoral implantation with conscious sedation and monitored anesthesia care.[297] The advantages of this approach include the ability to monitor the awake patient's neurologic status continuously, greater hemodynamic stability, and possibly reduced postprocedure length of stay in the ICU compared with an approach using general anesthesia.[297] However, general anesthesia is required if TEE is necessary during a procedure (not all centers use TEE for transfemoral TAVI).

The TAVI procedure requires state-of-the-art imaging capability, as well as the immediate availability of personnel to secure surgical access and institute CPB.[291] The short-term efficacy of TAVI, as shown by echocardiographic measurements, is good.[293] However, evidence on long-term outcomes awaits further data collection in national TAVI registries.[292,294]

Other Uses of the Minimally Invasive Approach. Minimally invasive surgical approaches can also be used to treat tricuspid valve disease,[298] as well as ASDs. Newer developments in the operative treatment of ischemic heart disease have led to the consideration of hybrid procedures in patients with multivessel CAD. This essentially means that patients with multivessel CAD can undergo percutaneous coronary intervention with a LIMA graft to the LAD coronary artery during the same hospital admission.[299] Additionally, some clinicians have attempted to combine minimally invasive valvular surgery with

percutaneous catheter intervention for coexisting ischemic heart disease.

Notably, early trials of Heartport technology with endoaortic occlusion catheters showed an elevated risk for intraluminal aortic injury and aortic dissection.[284] Although clamps such as the Chitwood transthoracic aortic cross-clamp and the Cosgrove Flex Clamp are being increasingly used, endoaortic occlusion technology may offer an alternative when standard aortic cross-clamping is contraindicated.[286]

HEART FAILURE

HF can be defined as a complex clinical syndrome caused by any structural or functional cardiac disorder that impairs the ability of the heart (as a pump) to meet the metabolic demands of the body. Thus, HF can result from an impairment of diastolic filling, systolic ejection, or both. Once HF is present, progressive cycles of deterioration and transient compensation ensue that may continue for years. Essentially, increases in end-diastolic volumes are compensated for by endogenously promoted diuresis, which is compensated for by sympathetic activation. This activation promotes further diuresis, which then requires compensation by further sympathetic activation, and so on. As the syndrome progresses, the hemodynamic changes, the cycles of fluid retention and relative hypovolemia, and bodily hypoperfusion perturb many neuroendocrine, humoral, and inflammatory feedback loops (Box 67-9), with resulting progressive and inexorable cycles of physical and functional deterioration of the heart and major bodily organs. In the United States, more than 6 million people currently have HF, and its prevalence is estimated at 10% in people older than 65 years old. Although survival with HF has improved, the mortality associated with heart failure remains high, and at least 50% of patients with HF are expected to die within 5 years of diagnosis.

3. Clinical heart failure milieu
   a. Pump performance
   b. Circulatory dynamics
   c. Metabolic abnormalities

The ACC/AHA guidelines for the evaluation and management of chronic HF place patients in four classes based on the stages of the syndrome (Box 67-10).[300] Early in the course of the disease, ventricular contractility is maintained by adrenergic stimulation and activation of the renin-angiotensin-aldosterone and other neurohormonal and cytokine systems.[301,302] Patients in this stage would be considered to be in ACC/AHA class B. However, these compensatory mechanisms become less effective over time, and ventricular dilatation and fibrosis occur, progressively worsening cardiac function. This produces a chronic state of low perfusion and, ultimately, refractory end-stage HF, labeled class D in the ACC/AHA classification scheme. The New York Heart Association (NYHA) functional classification system is also used to assess the severity of functional limitations and correlates fairly well with prognosis (Box 67-11). Some patients may remain asymptomatic for years despite ventricular remodeling, dilatation, and decreased EF.

Medical Management of Heart Failure

Medical strategies for treating developing HF aim to limit disease progression, prolong life, and improve quality of life as the syndrome progresses. Medical therapies, such as ACEIs, β-blockers, diuretics, inotropic agents, and antiarrhythmics, represent the usual standard of care for HF patients. In general, β-blockers, ACEIs, and ARBs (for those who cannot tolerate ACEIs) are class I indications in the current ACC/AHA guidelines for class A and

BOX 67-10 ***American College of Cardiology/ American Heart Association Classification of Chronic Heart Failure Stages***

A: High risk for heart failure
Hypertension, diabetes mellitus, coronary artery disease, family history of cardiomyopathy
B: Asymptomatic heart failure
Previous myocardial infarction, left ventricular dysfunction, valvular heart disease
C: Symptomatic heart failure
Structural heart disease, dyspnea, fatigue, impaired exercise tolerance
D: Refractory end-stage heart failure
Marked symptoms at rest despite maximal medical therapy

From Hunt SA, Abraham WT, Chin MH, et al: 2009 Focused update incorporated into the ACC/AHA 2005 guidelines for the diagnosis and management of heart failure in adults: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines developed in collaboration with the International Society for Heart and Lung Transplantation, J Am Coll Cardiol *53:e1-e90, 2009.*

BOX 67-11 ***New York Heart Association Heart Failure Symptom Classification System***

NYHA Class	Level of Impairment
I:	Ordinary physical activity not limited by symptoms
II:	Ordinary physical activity somewhat limited by dyspnea
III:	Exercise limited by dyspnea during a mild workload
IV:	Dyspnea at rest or with very little exertion

NYHA, New York Heart Association.

B patients with HF who have cardiac structural abnormalities and who have not yet developed symptoms of HF.[300] Signs and symptoms of HF (class C) are class I indications for the use of certain β-blockers that have been shown to prolong life (e.g., bisoprolol, carvedilol, and sustained release metoprolol), ACEIs, and ARBs. Diuretics and salt restriction should be added for patients with fluid retention. The implantation of devices for cardiac resynchronization therapy and defibrillatory capability is recommended, and revascularization and valve repair or replacement should be performed as appropriate. In both symptomatic and asymptomatic patients, current ACC/AHA guidelines list several additional potential therapies with class II and III indications.

However, even multidrug regimens may not prevent progression toward class D HF. A patient who has reached this category has a 2-year mortality risk greater than 75%. Thus, surgical intervention at less advanced stages of HF has become common in an attempt to prevent the inexorable progression of the syndrome.

Surgical Management of Heart Failure

In previous years, the only established surgical treatment option for advanced HF was cardiac transplantation,[300] which is associated with excellent survival rates and functional capacity. However, certain surgical interventions can retard or even potentially reverse progression of the disease (in conjunction with pharmacologic and other strategies), and the 2009 ACC/AHA guidelines stated that all stages of HF are class I indications for specific surgical interventions (e.g., coronary revascularization, valve repair or replacement).

CAD is the most common cause of HF,[303] and it is the second most common indication for heart transplantation in the United States; CAD accounted for approximately 24% of all transplants performed between January 1988 and May 2012.[304] (The first most common indication is idiopathic dilated cardiomyopathy, which accounted for approximately 33% of all cases.) Worldwide, ischemic cardiomyopathy is now the second most common indication for heart transplantation, accounting for 38% of all registered cases.[305] Similar to the U.S. experience, nonischemic cardiomyopathy has been the most common indication worldwide, accounting for 53% of all registered cases.

Where viable myocardium and feasible targets exist, revascularization of the failing heart can improve cardiac function and NYHA functional class.[306,307] It can also slow remodeling and decrease the incidence of arrhythmias,[308] and it has been demonstrated to improve survival. For example, Liao and associates found that among patients with CHF, survival was improved in patients who underwent revascularization compared with those who did not.[306] The optimal method of revascularization has not been conclusively determined, however, and studies continue to examine the issue of whether percutaneous coronary stenting is as effective as the gold standard intervention, CABG, in promoting long-term survival. The issue may be further complicated in certain subpopulations of patients (e.g., those with diabetes), by surgical technique (e.g., on-pump versus off-pump CABG), and by the type of stent used (e.g., bare metal versus drug coated).

Carefully selected patients with advanced CHF and MR receive several benefits from mitral valve repair or replacement, including a progressive decrease in LVEDV, a progressive improvement in LVEF, improvements in functional status (decreased NYHA class, improved 6-minute walk-test performance, and improved peak oxygen consumption), reverse remodeling, and lower long-term mortality risk.[309,310] The importance of appropriate patient selection is paramount, however, if optimal benefits are to be realized; the best results occur when mitral valve repair or replacement is undertaken before the geometric and functional derangements of the valve reach certain levels. Several key predictors of lack of reverse remodeling have been identified: LV end-diastolic dimension greater than 6.5 cm, LV end-systolic dimension greater than 5.1 cm, large LA volume, high LV sphericity index, and severely depressed LVEF.[233,311-313] The optimal type of repair remains a subject of ongoing study, as does the issue of whether mitral repair or replacement affords the greater survival benefit to these often older and highly comorbid patients. Clearly, the quality of any repair greatly influences its outcome.

The effectiveness and potential survival benefits of combining revascularization with other surgical procedures (e.g., valve repair or replacement, ventricular reshaping) have been and continue to be the subject of large, multicenter investigations. Surgical ventricular restoration (reshaping) has thus far not been shown to improve survival, decrease symptoms, or increase exercise tolerance in patients with HF when the procedure is performed in conjunction with revascularization.[314]

In addition to common surgical interventions, electrophysiologic interventions play a key role in the modern management of HF. Large, international, multicenter trials have demonstrated improved survival, decreased risk of hospitalization, decreased incidence of sudden cardiac death, improvements in LVEF, decreased LV volumes, and decreased symptoms in both symptomatic and asymptomatic patients with HF treated with cardiac resynchronization therapy (biventricular pacing), ICDs, or both.[315-319]

Today, when pharmacologic, electrophysiologic, and surgical interventions fail to stave off the inevitable progression of HF, mechanical circulatory support (MCS) with VADs is commonly used. Short-term MCS is generally used as a "bridge to immediate survival," a "bridge to recovery," or a "bridge to next decision" after an acute cardiac event. Patients with advanced HF who have little expectation of ventricular recovery (or who have not recovered despite short-term support) now regularly receive intermediate- and long-term VAD support as a potential bridge to transplantation. Since 2002, transplant-ineligible patients may receive approved LVADs as "destination therapy," a final treatment strategy shown to confer a survival advantage compared with medical management alone. Heart transplantation remains, of course, the ultimate surgical intervention for end-stage HF, but the number of patients with HF far exceeds the number of donor organs available each year worldwide, and MCS with a VAD is currently the best option for most patients with advanced and end-stage HF.

The use of VADs as a bridge to cardiac transplantation was previously shown to improve the survival rates and outcomes of patients with decompensated HF and was also found to improve multiorgan function during the time spent on VAD support.[320-325] This has been the rationale for the tremendous increase in the use of bridging technology.

However, the most recent analyses from the International Society for Heart and Lung Transplantation (ISHLT) indicated that among patients who received transplants between July 2004 and June 2009, bridging to transplantation with pulsatile or nonpulsatile VADs did not actually confer a statistically significant survival advantage.[305] Further, in an analysis of survival in patients who received transplants between January 2002 and June 2009, those who were bridged with pulsatile or nonpulsatile VADs actually had poorer 6-month posttransplant survival than (but equivalent 7-year survival to) patients who were not bridged. However, as discussed in the 2011 ISHLT report, the preponderance of deaths in the early years of this technology and the statistical methods used to perform the analyses may have great bearing on our current thinking, and further analyses are currently under way because overall, there *does* seem to be a survival advantage in more recent years with modern devices and our more extensive collective experience with patient management. Thus, the indication for bridging (e.g., elective versus "required" because of severe decompensation) may be a vitally important part of the selection criteria going forward. In this regard, the Interagency Registry for Mechanically Assisted Circulatory Support (INTERMACS) profile plays an important role in appropriate patient selection and the timing of intervention.[326] The INTERMACS profile characterizes patients with HF on the basis of clinical status and symptoms (Table 67-16).[327]

With regard to destination therapy in the United States, the most recent statistics from the INTERMACS registry indicate that overall survival has dramatically increased since the introduction of continuous flow devices: 1-year survival is 74%, and 2-year actuarial survival is 80%.[328] This finding is extremely significant considering the approximate 25% rate of 1-year survival originally shown in the Randomized Evaluation of Mechanical Assistance for the Treatment of Congestive Heart Failure (REMATCH) trial, which led to FDA approval of the HeartMate VE for destination therapy in September 2002.

First-generation, pulsatile VADs were approved as bridges to recovery beginning in the early 1990s (e.g., the ABIOMED BVS 5000 in 1992) and as bridges to transplantation in the middle to late 1990s (e.g., the HeartMate IP in 1995, the Novacor in 1998, and the HeartMate VE in 1998). These devices have now been supplanted worldwide by second- and third-generation, nonpulsatile devices, which generate continuous flow and have the advantages of being small, silent, valveless, and fully implantable. In addition, the current generation of devices is associated with significantly fewer perioperative and long-term complications than were pulsatile support devices.

At the time of this writing, the most commonly used long-term VAD in the United States is the HeartMate II (Thoratec Laboratories, Pleasanton, Calif.). The HeartMate II is a small axial flow pump that continuously draws blood from the LV apex by the action of a rapidly rotating impeller and returns the blood to the ascending aorta in a nonpulsatile fashion. It has been approved in the United States as a bridge to transplantation since 2008 and as destination therapy since 2010. Complication rates with the HeartMate II are dramatically lower than with the previous generation of pulsatile devices, and the durability of the device far exceeds that of the HeartMate I (>5 years, compared with only approximately 18 months). The current rate of successful bridging to transplantation with the HeartMate II is approximately 79%.

Total artificial hearts exist (e.g., the CardioWest temporary Total Artificial Heart [TAH-t], Syncardia Systems, Tucson, Ariz.; and the AbioCor Implantable Replacement Heart [IRH], Abiomed, Inc., Danvers, Mass.). The CardioWest TAH-t is FDA approved (and approved and available in Europe and Canada) as a bridge to transplantation and has had renewed popularity because of its 79% successful rate of bridging patients to transplantation, with a lower incidence of adverse neurologic events than is associated with approved VADs. According to the manufacturer, more than 1100 TAH-t devices have been implanted. The AbioCor IRH is currently approved in the United States only as destination therapy under a Humanitarian Device Exemption for transplant-ineligible patients with end-stage HF. At the time of this writing, very few AbioCor IRHs have been implanted, so relatively little experience exists with this device in humans.

TABLE 67-16 INTERAGENCY REGISTRY FOR MECHANICALLY ASSISTED CIRCULATORY SUPPORT: PROFILES FOR PATIENT SELECTION*

Profile	Description
1	Critical cardiogenic shock
2	Progressive decline on inotropic support
3	Stable but inotrope dependent
4	Resting symptoms home on oral therapy
5	Exertion intolerant
6	Exertion limited
7	Advanced NYHA class III symptoms

From Kirklin JK, McGiffin DC, Pinderski LJ, et al: Selection of patients and techniques of heart transplantation, Surg Clin North Am *84:257-287, xi-xii, 2004.*

NYHA, New York Heart Association.

*The use of mechanical circulatory support (MCS), frequent arrhythmias, and being a "frequent flyer" can modify the profile. In general, patients with Interagency Registry for Mechanically Assisted Circulatory Support (INTERMACS) profiles 3 and 4 currently are believed to represent the best balance between risk and indication for MCS in attempts to optimize survival.

Cardiac Transplantation

Discovery of the immunosuppressive agent cyclosporine in the early 1980s made cardiac transplantation an accepted surgical option for end-stage HF.[329] Currently, 1-year survival is 85% or more, and 5-year survival is approximately 70%.[305] Patients 30 to 59 years old tend to have the best survival, as do recipients who required transplantation because of nonischemic cardiomyopathy.

Most candidates for cardiac transplantation have class D HF that has been maximally treated medically but is nevertheless likely to result in death in less than 1 year.

Such patients typically are in cardiogenic shock or have a chronic low-output state that necessitates mechanical or inotropic support, but candidates also include patients with advanced symptomatic HF and peak oxygen uptake less than 10 mL/kg/minute (with the achievement of an anaerobic threshold), patients with NYHA class IV HF caused by advanced hypertrophic or restrictive cardiomyopathy, patients with refractory angina pectoris and inoperable CAD, and patients with life-threatening ventricular arrhythmias that are refractory to all appropriate medical and surgical treatment. Usually, the patient's EF is less than 20%. However, patients with NYHA class III HF who are at risk for sudden death related to malignant arrhythmias are sometimes placed on the waiting list.

In the United States, cardiac transplantation is performed in member centers of the United Network for Organ Sharing (UNOS), an umbrella organization responsible for coordinating organ procurement, organ allocation, and statistical information. The UNOS allocates donor hearts according to each patient's priority status, ABO group compatibility, body size match, and distance from the donor center. The highest priority is given to inpatients supported by mechanical circulatory assist devices for acute hemodynamic decompensation, patients maintained on assist devices who have significant device-related complications, patients requiring continuous infusion of single or multiple high-dose intravenous inotropic medications, and patients with a life expectancy of less than 7 days without transplantation.

The most common diagnoses in adult patients with HF who require cardiac transplantation include idiopathic or ischemic cardiomyopathy and complex congenital heart disease (CHD). Less common diagnoses include viral cardiomyopathy, postpartum cardiomyopathy, refractory valvular disease, primary myocardial diseases (e.g., sarcoidosis, amyloidosis), and drug-induced myocardial disease.

The selection criteria have been broadened for both heart recipients and heart donors.[327] For example, patients with HF in two previously excluded categories—those with diabetes and those older than 65 years old—are now considered transplantation candidates in many centers.[330] In addition, although centers generally prefer donors to be younger than 35 years old, the age criterion has been expanded to include suitable donors (e.g., those without cardiac risk factors or evidence of CAD) who are 60 years old or older. Major contraindications to heart transplantation that continue to steer patients toward destination therapy with a VAD instead of transplantation include older age, renal dysfunction, and high body mass index.[327] Modifiable risk factors (e.g., pulmonary hypertension) remain the subject of ongoing clinical investigation. Classically, a PVR greater than 5 dyne•sec•cm^{-5} that is unresponsive to pulmonary vasodilators indicates a "fixed" elevated PVR, which has been associated with an increased risk for early mortality after orthotopic heart transplantation.[331]

The manner in which the donor heart is implanted has also changed, with a shift away from the classic biatrial technique (originally described by Lower and Shumway in 1960) to the bicaval Wythenshawe technique described in the early 1990s (Fig. 67-39). The advantages of a bicaval implantation technique include shorter hospital stays, reduced postoperative dependence on diuretics, and lower incidences of LA dilatation, atrial dysrhythmias, conduction disturbances, mitral and tricuspid valve incompetence, and RV failure. Furthermore, several series that compared the classic Shumway technique with the bicaval technique showed greater 12-month survival in the bicaval group.[332,333]

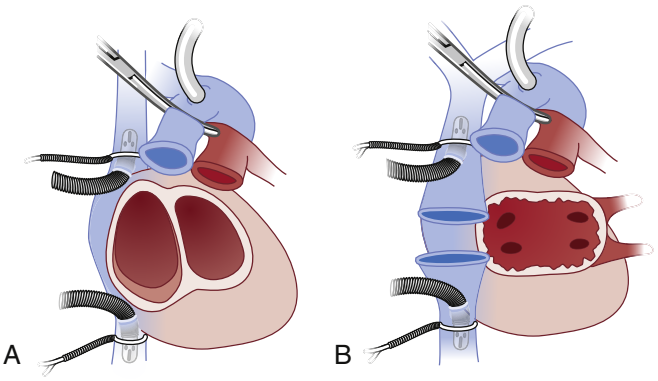

Figure 67-39. Surgical techniques for cardiac transplantation. **A,** Biatrial technique. The donor heart is anastomosed to the main bulk of the recipient's native right and left atria. **B,** Bicaval technique. The donor left atrium is anastomosed to a single left atrial cuff, including the pulmonary veins, in the recipient.

An even more recent implantation technique further reduces the size of the native LA remnant to two islands containing the pulmonary veins on either side. This is called a total technique.

Because the recipient sinoatrial node is no longer routinely retained with either of the modern bicaval techniques, the concept of two P waves on the posttransplant ECG is now only of historical interest. Posttransplantation physiology, however, remains unchanged: the requisite denervation of the donor organ during harvesting results in the absence of both direct afferent and efferent neural innervation via autonomic or somatic neural pathways after implantation in the recipient. In plain English, the transplanted heart functions in isolation from the recipient's nervous system, although the potential for direct activation of myocardial receptors (e.g., myocardial adrenergic receptors) by circulating factors is retained, as are all intrinsic myocardial reflexes and mechanisms (e.g., the Starling mechanism, the Anrep effect, the Bowditch effect, the vasoconstrictive effect on coronary arteries of hypocarbia). The loss of parasympathetic tone in the transplanted heart means that the resting heart rate is faster than normal, and heart rates of approximately 90 to 110 beats/minute are usual (and, in fact, are necessary to maintain CO in many cases).

A clear understanding of what remains intact and what is lost in the transplanted heart dictates and guides posttransplant anesthetic management. Adequate preload is critical. Direct-acting drugs (e.g., epinephrine, dobutamine, norepinephrine, isoproterenol) and pacing are maximally and immediately effective when needed to increase inotropy or chronotropy, respectively, in the transplanted heart. Primarily indirect-acting drugs (e.g., ephedrine, dopamine) rely mostly on the release of epinephrine and norepinephrine from the adrenal glands. Digoxin retains

its direct inotropic effect on the heart through inhibition of sodium-potassium adenosine triphosphatase, with resultant buildup of intramyocardial calcium, but loses its potential to decrease chronotropy (a parasympathetically mediated effect on the AV node). One should not expect a decrease or increase in heart rate after the administration of medications that cause bradycardia (e.g., fentanyl) or tachycardia (e.g., meperidine, pancuronium) as a side effect. Anticholinergic medications (e.g., atropine, glycopyrrolate) are not expected to increase heart rate in the denervated heart but are always administered at the time of reversal of muscle relaxation by acetylcholinesterase inhibitors (e.g., neostigmine) to decrease the potential adverse extracardiac cholinergic effects of the anticholinesterase group.

The denervated heart is subject to accelerated atherosclerotic disease, causing a significant 5-year incidence of CAD in transplant recipients, but these recipients do not experience angina. Significant dysrhythmias or arrhythmias in a transplanted heart should be considered harbingers of ischemia until proven otherwise.

CONGENITAL HEART DISEASE IN ADULTS

Background and Current Perspective

Medical and surgical advances in CHD surgery since the 1960s have significantly reduced the death rates of patients with CHD. Today, 85% to 95% of babies born with CHD can reach adulthood, and the number of adults with CHD now exceeds the number of children.[334] Adult patients who present with CHD can have extremely complex conditions that require careful assessment and operative planning. They may present for cardiac surgery for the first time or for further palliative correction, either definitively or for residua. Most patients with CHD face a lifetime of significant challenges,[335] ranging from the complications of long-term antibiotic prophylaxis to thromboembolic ventricular dysfunction resulting from cardiac arrhythmias and pulmonary hypertension.

Preoperative Anesthetic Considerations

The unique problems of this population include the multisystem effects of single-ventricle physiology, cyanosis, systemic right ventricle, complex intracardiac baffles, and failing subpulmonary right ventricle.[334] The initial assessment, history taking, and physical examination of an adult patient with CHD must be broadly systemic to capture any noncardiac organ involvement. A full review of each organ system is beyond the scope of this chapter, but readers are referred to the excellent review articles by Chassot and Bettex[335] and by Lovell.[336] Appropriate consultation with the patient's cardiologist (pediatric or adult), as well as access to old medical records, is valuable, especially for patients who have complex CHD or have undergone complex surgical procedures. Preoperative echocardiography is extremely helpful in understanding the anatomy and cardiac function, both primary and compensatory, of patients with CHD.

One of the early clinical decisions to be made for an individual patient involves determining the appropriateness of surgical care in a given institution. Obviously, emergency procedures give very little latitude, but elective procedures should warrant careful assessment, especially of the abilities and experience of the anesthesiologist who will be caring for a patient with complex corrected or palliated CHD. In 2001, the Thirty-second Bethesda Conference on CHD advocated the creation of regional centers for the care of adults with CHD (ACHD centers), whose personnel would include a cardiac anesthesiologist and other subspecialists with expertise in the management of patients with CHD.[337] The conference recommended that all adult patients with complex (Box 67-12) and moderate (Box 67-13) CHD be referred to such ACHD centers. Current U.S.[338] and Canadian[334] updates to these guidelines echo these recommendations.

BOX 67-12 *Types of Adult Congenital Heart Disease of Great Complexity*

- Conduits, valved or nonvalved
- Cyanotic congenital heart disease (all forms)
- Double-outlet ventricle
- Eisenmenger syndrome
- Fontan procedure
- Mitral atresia
- Single ventricle (also called double inlet or outlet, common, or primitive)
- Pulmonary atresia (all forms)
- Pulmonary vascular obstructive disease
- Transposition of the great arteries
- Tricuspid atresia
- Truncus arteriosus or hemitruncus
- Other abnormalities of atrioventricular or ventriculoarterial connection not included here (i.e, crisscross heart, isomerism, heterotaxy syndromes, ventricular inversion)

From Warnes CA, Williams RG, Bashore TM, et al: ACC/AHA 2008 guidelines for the management of adults with congenital heart disease: executive summary: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to Develop Guidelines for the Management of Adults with Congenital Heart Disease). Developed in collaboration with the American Society of Echocardiography, Heart Rhythm Society, Angiography and Interventions and Society of Thoracic Surgeons, Circulation *118:2395-2451, 2008.*

Intraoperative Anesthetic Considerations

In-depth discussion of the anesthetic management of particular congenital heart defects in adult patients is not the purpose of this section. However, a few basic principles are essential for all anesthesiologists to know, especially those who do not have specialized training in cardiac anesthesia or CHD but who may be faced with an older patient with CHD who needs urgent noncardiac surgery.

The anesthetic care presents a challenge and requires detailed knowledge of the anatomy and physiology of the lesion.[336] A skilled multidisciplinary team is very helpful for providing optimal management.[339,340] During the preoperative assessment of an adult with CHD, an extensive review should be conducted to elicit signs of CHF, cyanosis, or compromised peripheral vascular disease. Anesthetic considerations are lesion specific and are discussed in several reviews.[336,341,342]

Principle 1: The Presence or Absence of Cyanosis. Cyanosis is usually a marker for complex CHD. Chronic cyanosis can lead to the development of abnormalities of

BOX 67-13 ***Diagnoses in Adult Patients With Congenital Heart Disease of Moderate Complexity***

Aorto–left ventricular fistula
Anomalous pulmonary venous drainage, partial or total
Atrioventricular septal defect (partial or complete)
Coarctation of the aorta
Ebstein anomaly
Infundibular right ventricular outflow obstruction of significance
Ostium primum atrial septal defect
Patent ductus arteriosus (not closed)
Pulmonary valve regurgitation (moderate to severe)
Pulmonary valve stenosis (moderate to severe)
Sinus of Valsalva fistula or aneurysm
Sinus venosus atrial septal defect
Subvalvular or supravalvular aortic stenosis (except HOCM)
Tetralogy of Fallot
Ventricular septal defect with:
- Absent valve or valves
- Aortic regurgitation
- Coarctation of the aorta
- Mitral valve disease
- Right ventricular outflow tract obstruction
- Straddling tricuspid or mitral valve
- Subaortic stenosis

HOCM, Hypertrophic obstructive cardiomyopathy.

RBC production and hemostasis. Elevated levels of erythropoietin in cyanotic patients can lead to a hyperviscosity syndrome and elevated neurologic risk. Risk factors include coexistent systemic hypertension, atrial fibrillation, and a history of phlebotomy and microcytosis.

In any patient with cyanotic CHD, the anesthesiologist should establish intravenous fluid therapy and monitor urine output to minimize the circulatory effects of perioperative fasting, dehydration, and intraoperative hypovolemia. These conditions cause hyperviscosity, which can be associated with hemostatic abnormalities. Long-term administration of antiplatelet medications to ensure conduit patency should be noted. Arterial pressure monitoring should be considered. The decision whether to measure CVPs should be approached with caution and should involve consultation with a cardiologist familiar with CHD and with the patient's diagnosis. This decision also requires a complete understanding of the patient's anatomy and underlying cardiac function, as well as the proposed surgical intervention. A caval-pulmonary connection, such as the bidirectional Glenn shunt or Fontan procedure, elevates the patient's risk of thrombosis from indwelling venous catheters.

Principle 2: The Presence or Absence of Intracardiac or Extracardiac Shunts. Intracardiac shunts are classically located at the level of the atria or ventricles. The magnitude of the shunt is often expressed in terms of the ratio of pulmonary blood flow (Qp) to systemic blood flow (Qs): Qp/Qs. Balanced flow is the hallmark of normal physiology. A Qp/Qs ratio greater than 1 is generally consistent with acyanotic heart disease and luxuriant pulmonary blood flow. A Qp/Qs ratio less than 1 would be consistent with the clinical manifestation of cyanotic heart disease. Chassot and Bettex remind us in their review article of important subcharacteristics of intracardiac shunts[335]:

1. The direction of shunt flow is important. Shunts can be right, left, or bidirectional. Shunt flow can be influenced by changes in driving pressure across a shunt or pressure in the receiving chamber. The high intrathoracic pressure that can occur with mechanical ventilation, coughing, the Valsalva maneuver, bronchospasm, or positive end-expiratory pressure can actually reverse the direction of a left-to-right shunt or at least make it bidirectional. Therefore, paradoxical embolization by clot or air is a real risk in patients with intracardiac shunts and warrants fastidious attention to de-airing intravenous lines and careful administration of drugs by syringes through ports in intravenous lines.
2. The size of the intracardiac defect is important. Shunts are commonly labeled as restrictive or nonrestrictive according to their blood velocity or pressure characteristics measured at catheterization or by echocardiography. Large defects with associated low pressure gradients across them have nonrestrictive flow. In addition, larger defects can be expected to have a greater effect on downstream structures and pressures. Small defects with high pressure or gradients restrict the amount of blood flow. The mainstays of the anesthetic management of shunt lesions are understanding and controlling factors that may influence the direction and magnitude of the shunt. Shunt flow and direction are directly influenced by both PVR and SVR. Elevated SVR and decreased PVR generally increase the magnitude of and propensity for left-to-right shunting. Conversely, decreased SVR decreases the magnitude of left-to right shunting, as do elevations in PVR. Mechanical ventilation, the inspired oxygen concentration, carbon dioxide levels, and the hemodynamic effects of anesthetic drugs are all used to achieve certain therapeutic goals in relation to shunt management. Oxygen is a potent pulmonary vasodilator, as is a lower $Paco_2$. If the clinical problem is luxuriant pulmonary blood flow, a high FiO_2 is not optimal and should be avoided. Similarly, the direction and magnitude of the shunt flow determine whether one should hyperventilate a patient to achieve a low $Paco_2$ or tolerate a high-normal $Paco_2$.
3. In the presence of a shunt, the potential enlargement of receiving chambers and high downstream pressure are important. A shunt above the level of the AV valves, such as a left-to-right shunt at the atrial level, usually causes right-sided chamber enlargement. Defects or shunts below the AV valves, such as a VSD or patent ductus arteriosus (PDA), initially result in

left-sided chamber enlargement. Shunts at both locations increase pulmonary blood flow and, with time, can lead to potentially irreversible elevations in PVR and pulmonary pressure. Furthermore, exposure to elevated pulmonary pressure and afterload leads to RV enlargement, RV failure, bidirectional shunting, and in the most extreme cases, reversal of shunt direction and cyanosis, as in patients with Eisenmenger syndrome.

Extracardiac shunts can be native to CHD (e.g., aberrant pulmonary venous return), surgically created (e.g., Blalock-Taussig shunt placement in some cases of cyanotic heart disease), or compensatory (e.g., aortopulmonary collateral formation with long-standing cyanotic heart disease). Special mention of certain aortopulmonary shunts, used commonly in the past to palliate some forms of cyanotic heart disease, is warranted. The proximal connection may be to the ascending aorta, brachiocephalic trunk, or subclavian artery. Because blood flow through this type of shunt is dependent on systemic blood pressure, systemic hypotension may lead to worsening hypoxemia. Furthermore, long-term exposure to these extracardiac shunts can result in left-sided chamber enlargement and dysfunction secondary to chronic volume overload.

Principle 3: The Presence of Pulmonary Hypertension. Pulmonary arterial hypertension is defined as a mean PAP greater than 25 mm Hg or greater than 30 mm Hg with exercise. Some degree of pulmonary hypertension develops in 5% to 10% of adult patients with CHD. This is associated with exercise intolerance and decreased functional capacity, which appear to have important prognostic implications.[340]

The anesthetic management of patients with pulmonary hypertension can be challenging. Invasive monitoring and careful anesthetic titration may be required. Regional anesthesia may be used for appropriate procedures, but neuraxial blocks should be administered with caution. Patients with significant pulmonary hypertension are very sensitive to preload; therefore, hypovolemia, whether primary (from blood loss) or secondary (from vasodilation), should be treated immediately and aggressively. Pulmonary hypertension can be managed pharmacologically and mechanically. Factors associated with decreasing PVR and, subsequently, reductions in PAP are listed in Box 67-14.[336]

Principle 4: The Presence of Ventricular Dysfunction. As in adult patients with heart disease that is not congenital, the presence of ventricular dysfunction is an important risk factor for morbidity and mortality, both in the perioperative period and in the long term. Regarding RV dysfunction, predictors of a poor outcome may include pulmonary hypertension, pulmonic valve incompetence, and consequent dysfunction of the subpulmonic ventricle.[342] LV dysfunction has been observed in patients with repaired tetralogy of Fallot, which is associated with male gender, LV enlargement, duration of shunt before repair, history of arrhythmia, QRS duration, ICD, and moderate to severe RV dysfunction.[343]

BOX 67-14 ***Factors Associated With Decreasing Pulmonary Vascular Resistance and Reductions in Pulmonary Artery Pressure***

Decrease in Pulmonary Vascular Resistance

- Increasing PaO_2
- Hypocapnia
- Alkalemia
- Minimizing intrathoracic pressure
  - Spontaneous ventilation
  - Normal lung volumes
  - High-frequency and jet ventilation
  - Avoidance of sympathetic stimulation
  - Deep anesthesia
- Pharmacologic methods
  - Isoproterenol
  - Phosphodiesterase III inhibitors
  - Prostaglandin infusion (PGE_1 and PGI_2)
  - Inhaled nitric oxide

Increase in Pulmonary Vascular Resistance

- Sympathetic stimulation
  - Light anesthesia
  - Pain
- Acidemia
- Hypoxia
- Hypercapnia
- Hypothermia
- Increased intrathoracic pressure
  - Controlled ventilation
  - Positive end-expiratory pressure
  - Atelectasis

OTHER CARDIAC PROCEDURES

Surgical Ablation of Atrial Fibrillation

In the United States, 2.7 to 6.1 million persons are estimated to have atrial fibrillation.[1] Among Medicare patients 65 years old or older, the prevalence of atrial fibrillation increased from 3.2% in 1992 to 6.0% in 2002 and is higher in older patients.[344] Stroke remains the most feared complication of atrial fibrillation; stroke risk is fourfold to fivefold higher in patients with atrial fibrillation than in patients without this arrhythmia. Additionally, atrial fibrillation causes 24% of strokes in patients older than 80 years old.[1]

With regard to persistent atrial fibrillation, both the left atrium and the pulmonary veins have been implicated in the pathogenesis and maintenance of persistent atrial fibrillation. Paroxysmal atrial fibrillation, conversely, may result from the juxtaposition of the pulmonary vein endothelium and the LA endocardium. The transition of the electrical signal from one type of tissue to the other is probably responsible for this arrhythmia.

The classic Maze procedure is currently the most effective curative therapy for atrial fibrillation.[345,346] To simplify the procedure and improve its results, Cox and colleagues modified the operation twice, hence its current name, the Cox-Maze III procedure.[345] This procedure appears to cure atrial fibrillation in 99% of cases.[346] Current indications for the Cox-Maze III operation include

drug intolerance, arrhythmia intolerance, and recurrent embolic events.[347]

Ablative treatments for atrial fibrillation involve making RA and LA incisions and cryolesions to interrupt the multiple reentrant circuits that cause atrial fibrillation. Isolating the pulmonary veins and excising the LA appendage (LAA) are integral parts of the Maze procedure, which requires CPB (for 45 to 60 minutes, if the operation is performed by an experienced surgeon) and cardiac arrest.[348-350] This procedure can be performed through a minimally invasive chest incision, as an alternative to sternotomy, while the patient is undergoing CPB and is in cardiac arrest with cardioplegia.

A study done by Prasad and co-workers found that the Cox-Maze III procedure effectively cured atrial fibrillation when the operation was performed alone or concomitantly with coronary or valve procedures.[347] In patients who underwent such concomitant operations, the Cox-Maze III procedure did not significantly add to the mortality or morbidity associated with the revascularization or valve repair procedure.

The underuse of the Maze procedure in the past probably reflected the procedure's perceived complexity. Currently, newer technologies enable the rapid creation of lines of conduction blockade, which surgeons use to ablate atrial fibrillation in patients undergoing concomitant cardiac surgical procedures. These technologies include alternate energy sources such as radiofrequency (RF) and microwave energy, ultrasound, cryotherapy, and laser (Table 67-17). These technologies are also used in minimally invasive surgical ablation procedures to cure isolated atrial fibrillation.[346] Furthermore, the development of epicardial probes has facilitated off-pump ablation of atrial fibrillation in the beating heart.

Because cardiac structures can be visualized directly during open surgical procedures, ablation lines can be created safely, thus avoiding the complication of pulmonary vein stenosis. An epicardial approach to ablation eliminates the risk of esophageal injury.[345,346] The advantage of a surgical approach is the ease of excising the LAA, which virtually eliminates the risk of stroke. However, isolation of the pulmonary vein and excision of the LAA can now be done through the minimally invasive "keyhole approach" (Fig. 67-40) or a thoracoscopic approach.[351] Both approaches can be used without the need for CPB.[346] As experience with the Cox-Maze procedures increases and the technology continues to advance, the goal is to improve patients' quality of life and free them from the need for antiarrhythmic and anticoagulant medications.

TABLE 67-17 ENERGY SOURCES FOR SURGICAL ABLATION OF ATRIAL FIBRILLATION

Energy Type	Endocardial Application	Epicardial Application	Flexible Probe	Assess Transmural	No Char	Rapid
Radiofrequency*	+	+	+	+	–	+
Microwave	+	+	+	–	+	+

"Keyhole" approach for minimally invasive epicardial pulmonary vein isolation with excision of the left atrial appendage. **A,** Access to the right pulmonary veins is gained through a keyhole incision under endoscopic guidance. **B,** A bipolar radiofrequency clamp is used to isolate the left atrial cuff adjacent to the right pulmonary veins. **C,** Stapled excision of the left atrial appendage after the left pulmonary veins are isolated with a technique similar to that shown for the right pulmonary veins. *(From Gillinov AM, Wolf RK: Surgical ablation of atrial fibrillation,* Prog Cardiovasc Dis *48:169-177, 2005.)*

Pericardial Tamponade and Constrictive Pericarditis

Pericardial Tamponade. The pericardial sac has two layers: the outer, parietal pericardium; and the inner, visceral pericardium (epicardium), which is directly adherent to the surface of the heart. The normal amount of fluid between the two layers is 15 to 30 mL, which generates a pressure that is 5 mm Hg less than the CVP and approximates the pleural pressure.

Cardiac tamponade occurs when the volume of fluid trapped in the pericardial sac increases and compresses the heart, thereby compromising CO.[352] In classic tamponade, the circulation adapts by increasing the systemic venous and pulmonary venous pressures to equalize with the pericardial pressure so that total collapse of the cardiac chambers is prevented.[353] The PCWP and the LV, RV, and RA diastolic pressures increase to equalize with the pressure in the pericardium. As a result, the atrial and ventricular diastolic transmural pressures are essentially zero, a hallmark of pericardial tamponade. Although this virtual loss of pressure reduces the stroke volume, high adrenergic tone helps to partially preserve CO by increasing the heart rate.

If enough fluid accumulates, the pericardium reaches a stage at which it can no longer distend; therefore, the total pericardial volume no longer changes throughout the respiratory cycle.[353] This results in a phenomenon referred to as ventricular interdependence, wherein any change in the volume of one side of the heart causes the opposite change in the volume of the other side. During inspiration, increased venous return and filling of the right heart cause the interatrial and interventricular septa to bulge to the left, and opposite changes occur during expiration. Such ventricular interdependence is evident on echocardiography.

Ventricular interdependence manifests clinically as pulsus paradoxus,[354] an exaggeration of the normal diminution of the radial pulse on inspiration (Fig. 67-41). *Pulsus paradoxus* is defined as a drop in systolic blood pressure exceeding 10 mm Hg during inspiration.[355] In particularly severe cases, no brachial or radial pulse may be palpable on inspiration.[356]

Cardiac tamponade is not necessary to cause pulsus paradoxus. Wide swings in intrathoracic pressure and conditions such as pulmonary embolism or hypovolemic shock can also give rise to the phenomenon. Additionally, patients with cardiac tamponade may not have pulsus paradoxus if they have coexisting aortic insufficiency, ASD, or preexisting elevated LVEDP resulting from LV hypertrophy or dilatation.

Figure 67-42 illustrates the pressure-volume relationship in the pericardium, depending on whether the effusion is accumulating slowly or rapidly.[356] This "J"-shaped curve suggests that a sudden increase in pericardial fluid volume of 100 to 200 mL can increase pericardial pressure to 30 mm Hg or more and cause severe cardiac tamponade. The faster the fluid accumulation, the more severe is the hemodynamic compromise. Causes of this type of acute tamponade include rupture of a thoracic aortic aneurysm, traumatic mediastinal injury, and accidental puncture of a cardiac chamber or blood vessel in the CCL.[353]

When accumulation of pericardial fluid is slower, compliance of the parietal pericardium is greater, and changes in volume produce smaller rises in pressure than they would if fluid accumulated more rapidly. As pericardial volume increases, so does intrapericardial pressure, with

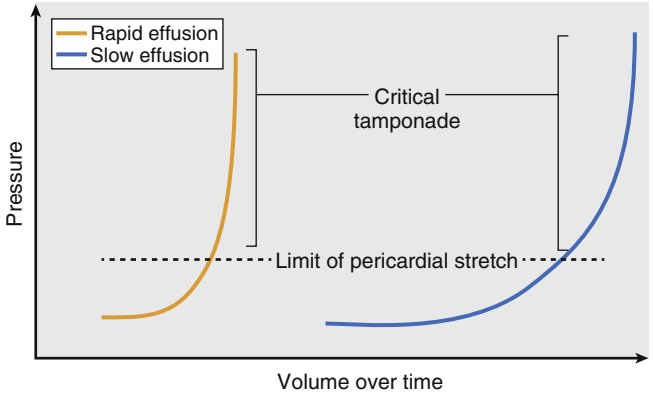

Figure 67-42. Cardiac tamponade. Pericardial pressure-volume (or strain-stress) curves are shown in which the volume increases slowly or rapidly over time. On the *left,* rapidly increasing pericardial fluid first reaches the limit of the pericardial reserve volume (the initial flat segment) and then quickly exceeds the limit of parietal pericardial stretch, thus causing a steep rise in pressure, which becomes even steeper as smaller increments in fluid cause a disproportionate increase in the pericardial pressure. On the *right,* a slower rate of pericardial filling takes longer to exceed the limit of pericardial stretch because more time is available for the pericardium to stretch and for compensatory mechanisms to become activated. *(From Spodick DH: Acute cardiac tamponade,* N Engl J Med *349:684-690, 2003).*

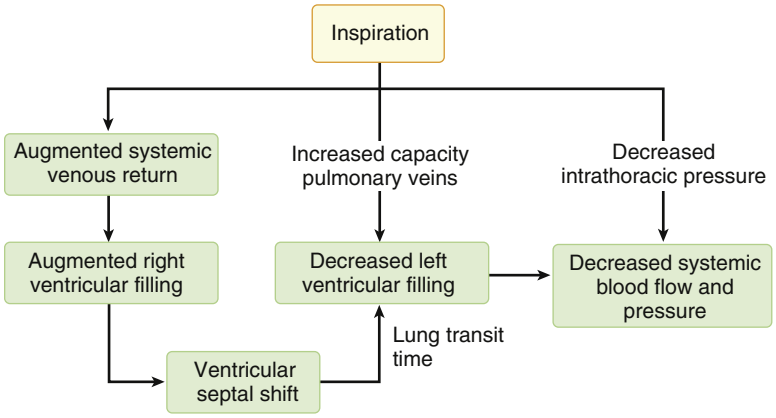

Figure 67-41. Physiology of paradoxical pulses in cardiac tamponade. *(From Fowler NO: Diseases of the pericardium. In Harvey WP, de Leon AC Jr, Leonard JJ, et al, editors:* Curr Probl Cardiol *2:6-38, 1978.)*

a compensatory increase in CVP to maintain a gradient to allow cardiac filling.[352] When pericardial compliance cannot increase further, the intrapericardial pressure gradually equalizes with the pressures in the cardiac chambers. CO gradually declines, accompanied by a compensatory tachycardia, peripheral vasoconstriction, and increased contractility.

Symptoms and Signs of Pericardial Tamponade. Patients with pericardial tamponade may present with pain or feelings of fullness in the chest, dyspnea, lethargy, fever, cough, weakness, fatigue, anorexia, or palpitations.[352] The Beck triad may appear as a combination of three signs of severe tamponade: low blood pressure, increased jugular venous pressure, and distant heart sounds. However, patients whose tamponade develops secondary to a chronic medical condition (e.g., malignant disease, end-stage renal disease, collagen vascular disease) may not present with the classic findings of the Beck triad.

Echocardiographic Features of Pericardial Tamponade. Of the various echocardiographic signs of cardiac tamponade (Box 67-15), one of the best established is diastolic collapse of the right atrium or right ventricle. RV collapse, seen in early diastole, appears as an invagination of the RV free wall (Fig. 67-43). In contrast, RA collapse is seen in late diastole and early systole and appears as an invagination of the RA wall (see Fig. 67-43). The timing of the collapse of the two chambers is related to the lowest intracavitary pressures in those chambers (i.e., early diastole for the right ventricle and late diastole for the right atrium). The presence of both RV and RA collapse indicates hemodynamically significant pericardial effusion. Left-sided heart collapse is rarely seen, both because the thickness and stiffness of the left ventricle enable it to resist collapse and because the left atrium is located posteriorly. However, in patients with very large effusions, fluid does accumulate behind the left atrium and eventually collapses this chamber.[357] The presence of LA collapse is highly specific for tamponade.[356]

Anesthetic Management of Pericardial Tamponade. Indications for pericardiocentesis (surgical drainage of the pericardial effusion) were summarized by Soler-Soler and co-workers (Box 67-16).[358] Surgical intervention for pericardial disease warrants invasive monitoring, which should involve an intraarterial catheter and possibly a central venous catheter.

In patients who are severely hemodynamically compromised, one surgical option is to perform pericardiocentesis or subxiphoid exploration using local anesthesia[359] and inducing general anesthesia after the tamponade has

BOX 67-15 *Doppler Echocardiographic Signs of Cardiac Tamponade*

- Exaggerated inspiratory variation of the two ventricles (inspiratory expansion of the right ventricle and simultaneous compression of the left ventricle; reciprocal changes in the expiratory phase)
- Right atrial collapse
- Right ventricular collapse
- Left atrial collapse
- Left ventricular collapse
- Inferior vena cava plethora
- Abnormal increased respiratory variation in transvalvular blood flow velocities (mitral and aortic flow reduction in the inspiratory phase)

From Pepi M, Muratori M: Echocardiography in the diagnosis and management of pericardial disease, J Cardiovasc Med (Hagerstown) *7:533-544, 2006.*

BOX 67-16 *Indications for Pericardiocentesis and Surgical Drainage*

Pericardiocentesis is indicated in patients with overt clinical tamponade, in patients with suspected purulent pericarditis, and in patients with idiopathic chronic large pericardial effusion.

Indications for surgical drainage are tamponade, either unresolved or relapsing after pericardiocentesis, and persistent active illness 3 weeks after hospital admission.

Pericardial drainage does not seem to be warranted in the initial management of patients with large pericardial effusions without clinical tamponade because of its low diagnostic yield and poor influence on the evolution of pericardial effusion. Even the presence of echocardiographic right chamber collapse (suggesting raised intrapericardial pressure) does not by itself warrant pericardial drainage because most of these patients do not develop overt tamponade.

Modified from Soler-Soler J, Sagrista-Sauleda J, Permanyer-Miralda G: Management of pericardial effusion, Heart *86:235-240, 2001.*

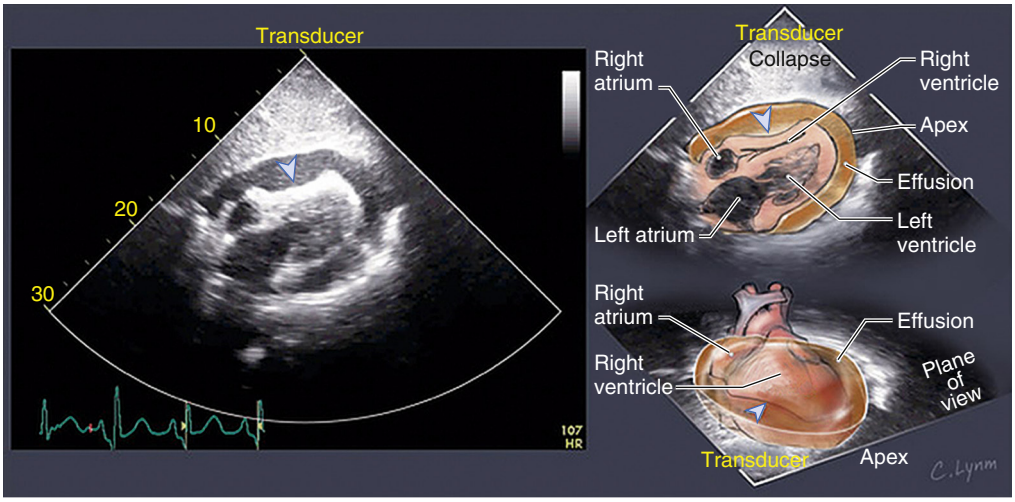

Figure 67-43. Echocardiogram (and drawings) showing pericardial effusion causing cardiac tamponade. A subcostal view in early diastole shows a large circumferential pericardial effusion compressing the heart, with the right ventricle completely collapsed (*arrowheads*). *(From Roy CL, Minor MA, Brookhart MA, et al: Does this patient with a pericardial effusion have cardiac tamponade?* JAMA *297:1810-1818, 2007.)*

been partially relieved. If general anesthesia is planned, the watchwords in the management of cardiac tamponade are *fast*, *full*, and *strong*. Intravenous fluids should be administered before induction of anesthesia to optimize preload. Increasing intravascular volume helps to increase the effective filling pressures of the heart, restore the gradient between the chambers, and increase arterial pressure.

Any manipulation that can decrease venous return to the heart should be avoided. This includes controlled positive-pressure ventilation with large tidal volumes, which may significantly decrease preload and CO.[359] Instead, if general anesthesia is required, one option is to allow the patient to breathe spontaneously until the pericardial sac is opened.[359] Alternatively, a ventilation pattern of high rate and low tidal volumes can be used to minimize mean airway pressure.

Drugs that may cause myocardial depression should be avoided. Additionally, bradycardia should be avoided because tachycardia is the most important compensatory mechanism for preserving CO. The use of ketamine to induce general anesthesia for creation of a pericardial window has been described.[360]

Once cardiac tamponade is relieved, endogenously generated and exogenously administered catecholamines may cause sudden, severe increases in blood pressure and heart rate. This phenomenon should be anticipated and treated.

Constrictive Pericarditis

Pathophysiology. Constrictive pericarditis is said to be present when the diastolic filling of the heart is restricted by a thickened and adherent pericardium. Several causes of constrictive pericarditis have been identified, including infectious processes. In addition, radiation to the chest area and cardiac surgery itself have emerged as additional causes of constrictive pericarditis over the past few decades.[361] If the two pericardial layers—visceral and parietal—become adherent as a result of fibrosis and calcification of the pericardium, the space between the two layers is obliterated.[361]

Signs and Symptoms of Constrictive Pericarditis. Typically, patients with constrictive pericarditis present with signs and symptoms of right-sided HF. A high driving pressure across the valves causes a rapid filling of the ventricles in diastole and results in sudden increase in the ventricular pressures. As the ventricular pressures exceed the atrial pressures, flow abruptly stops, and pressures are elevated and equalized in all four chambers.[361]

Another sign seen in constrictive pericarditis is the Kussmaul sign (an exaggeration of the *x* and *y* descent on the CVP tracing), which is elicited in response to increased blood return to the right side of the heart on inspiration. Because the thickened pericardium no longer allows the heart to expand to accommodate all the blood flowing into it, the pressure generated by this returning volume is transmitted to the central venous system.[362]

As in pericardial tamponade, pulsus paradoxus is also usually seen in constrictive pericarditis. However, in some cases, thickening of the pericardium can shield the myocardium from the effects of the respiratory cycle; therefore, pulsus paradoxus may not be that obvious. Dyspnea and orthopnea are common in patients with constrictive pericarditis because the low CO caused by constrictive pericarditis severely reduces the patient's exercise tolerance and, in extremely advanced cases, causes cardiac cachexia and muscle wasting.[363] Ascites and peripheral edema may also be seen. Echocardiography is particularly helpful in differentiating constrictive pericarditis from other disease processes with similar presenting symptoms, such as restrictive cardiomyopathy.[363,364]

Anesthetic Considerations for Pericardiectomy. The definitive treatment for constrictive pericarditis is pericardiectomy.[365] This procedure is usually performed through a sternotomy, but it can also be performed through a left thoracotomy incision. In patients with severe cases of the disease, pericardiectomy may involve stripping the pericardium off the heart, which may necessitate the use of CPB.

The anesthetic management of a patient undergoing pericardiectomy for constrictive pericarditis is similar to that of a patient having a surgical intervention for pericardial effusion and tamponade. However, because the pericardium may need to be "peeled" from the surface of the heart, pericardiectomy carries an additional risk of arrhythmia and injury to the myocardium itself, including rupture of one of the chambers. Measures should be taken to avoid and treat arrhythmias and massive intraoperative bleeding.

Cardiac and Aortic Trauma

Penetrating Cardiac Injury. With the increase in violent crime over the past few decades, the number of cases of gunshot and stab wounds to the heart has risen. Patients with penetrating cardiac injury may be critically unstable because of hemorrhage or cardiac tamponade, or they may have a benign injury to the heart.[366] Hemodynamic and ECG changes may be deceptively absent in many cases. The absence of these changes does not rule out the presence of life-threatening injury to the heart or its surrounding structures.[367] Echocardiography can identify fluid or blood around the heart and can inform the surgical decision regarding whether to perform a sternotomy or to use an alternative approach.[366,368]

The anesthetic management of patients with penetrating cardiac injury is similar to that of other trauma patients. Unstable patients require emergency surgical intervention. The anesthesiologist must ascertain that blood is available on first knowledge of impending surgery for penetrating cardiac injury. With critically unstable patients, the anesthesiologist must secure the airway, establish intravenous access, and place the monitoring lines while the surgical incision is being made. An assistant can be very helpful in efficiently caring for such a patient. In planning the induction of anesthesia and the securing of the airway, the anesthesiologist should assume that the patient probably has a full stomach and volume depletion. Monitoring lines should include an arterial line and a central venous catheter. Barring any contraindications, on the basis of the scant history that may be available at that time, TEE should be considered as an additional monitor. Anesthesia management involves attempting to maintain stable hemodynamics and prevent recall. As in any trauma case, if the patient is unstable, controlled postoperative ventilation is usually preferred, including transportation to the ICU with full monitoring and ventilatory support.

Traumatic Aortic Injury. Blunt aortic injury, which can result in either traumatic aortic transection (TAT) or acute rupture, is one of the most common causes of death from blunt trauma, second only to head injury. On arrival at the hospital, only 25% of patients with blunt thoracic trauma and resultant aortic injury (TAT or acute rupture) are alive.[369] Furthermore, the prognosis of patients who survive the initial injury and remain untreated is poor: 30% die within the first 6 hours, 50% die in the first 24 hours, and 90% die within the first 4 months.[370]

In blunt trauma to the chest, the mechanism of injury to the thoracic aorta is sudden traction on the relatively immobile portion of the aorta, the isthmus, as a result of sudden deceleration.[369] The isthmus is distal to the left subclavian artery, proximal to the third intercostal artery, and fixed to the left PA by the ligamentum arteriosum. This area of attachment of the ligamentum arteriosum acts as a hinge for movement of the aortic arch; thus, it receives the brunt of the shearing force during violent injury to the chest area. Hence, it is the most common location for rupture of the aorta (50% to 70%), followed by the ascending aorta or the aortic arch in 18% and the distal thoracic aorta in 14% of cases.[369] The spectrum of injuries to the thoracic aorta in blunt thoracic trauma ranges from simple subintimal hemorrhage to complete aortic transection.

The diagnosis of the aortic injury may be made on the basis of a plain chest radiograph, computed tomography, angiography, or TEE. TEE can also detect cardiac tamponade, left pleural effusion, hypovolemia, ventricular dysfunction from myocardial contusion, or vascular injuries from penetrating chest wounds.[371] Diagnosing TAT with TEE requires recognition of a mural flap at the site of intimal disruption and corresponding deformities of the aortic wall caused by a contained rupture. A gap of more than 7 mm between the probe and the aorta at the level of the proximal descending thoracic aorta, in addition to blood between the aortic wall and the pleura, strongly suggests disruption of the aorta. TEE can also be useful in monitoring the progression of a small intimal tear or as a screening tool for patients who have a normal mediastinum after blunt thoracic trauma.

Management of TAT focuses on the high risk of rupture that this injury entails. The unpredictable timing of this event adds to the concerns regarding these patients. Aggressive management of blood pressure in the preoperative period is necessary to minimize the risk of rupture.[372] Systolic blood pressure should not exceed 100 mm Hg, and the heart rate should not exceed 100 beats/minute. The use of β-blockers and nitroglycerin or sodium nitroprusside infusions is recommended.

Intraoperative monitoring should include an arterial catheter and central venous access. The keys to anesthetic management of patients with TAT are avoiding wide swings in systolic blood pressure and continuously monitoring the patient for end-organ ischemia. Because many operations on patients with TAT are performed on an emergency basis, it may be necessary to use a modified rapid-sequence induction. Despite all precautions, marked swings in blood pressure are often seen during induction and laryngoscopy. Agents such as nitroglycerin and esmolol should be immediately available to treat any undesirable hypertension during endotracheal intubation, TEE probe insertion, and surgical incision.

Surgical repair of injuries to the ascending aorta or aortic arch typically requires CPB with DHCA. Injuries to the descending thoracic aorta may require open repair of a short segment. Challenges include preservation of vital organs, particularly the spinal cord. In open procedures, use of partial LHB can facilitate the operation and at the same time preserve visceral organ and spinal cord perfusion. This technique also prevents aggravation of any other injuries that the patient may have sustained because this type of bypass does not require heparin.[370] Although open repair is possible, transcutaneous endovascular aortic repair has emerged as the preferred intervention whenever possible, (STS class I recommendation; level of evidence B)[373,374] (see Chapter 69).

Ischemic and Other Emergencies in the Cardiac Catheterization Laboratory

With rapid advances in interventional cardiology, the number of patients in the United States and Europe who undergo interventional therapy in a CCL is increasing. Such emergencies include coronary artery dissection, free rupture, tamponade, foreign body embolism, and wire entrapment. Patients may be at high risk for complications in the CCL if they have unfavorable coronary anatomy or severe ventricular dysfunction. In some cases, cardiac surgery and cardiac anesthesia services should be consulted and placed on standby for a possible emergency intervention. Rapid surgical intervention, such as revascularization or temporary mechanical support, is crucial to reducing the mortality and morbidity of patients who suffer angiography-related accidents.

When ischemic complications occur during cardiac catheterization with percutaneous transluminal coronary angioplasty and stenting, pharmacologic intervention and, possibly, a device such as an IABP or VAD may be used to stabilize the patient's hemodynamic condition before the patient is transferred to the operating room on an urgent or emergency basis for open coronary revascularization. Patients may be intubated on an emergency basis in the CCL. Patients with coronary dissection or severe ischemia may require CPR during transport to the operating room.[375] Although the anesthesiologist, cardiologist, or both may lead these resuscitative efforts, all members of the catheterization team—physicians, nurses, and technologists—should complete a course in basic CPR; additionally, certification in advanced cardiac life support, with annual recertification, is strongly urged.[376]

If the patient is not already intubated, the choice of induction agents should be tailored to the patient's hemodynamic condition; one should avoid hypotension and tachycardia while keeping in mind the patient's NPO (nothing by mouth) status. Perioperative monitoring of these patients should include an arterial line and central intravenous access, which should be established as soon as possible. TEE can be of immense importance in both diagnosing the cardiac problem and monitoring the patient intraoperatively.

Other procedures performed in the CCL, invasive vascular laboratory, and electrophysiology laboratory—notably aortic aneurysm stenting and ablation procedures—may

also require operating room backup. A dedicated surgical team should be available in the event of a life-threatening complication. Planning for the possibility of conversion to an open procedure, such as in cases of an aneurysm leak or catheter perforation of a major blood vessel or cardiac chamber, is imperative. A hybrid interventional cardiovascular suite is ideal for such events.[291] In institutions without such a hybrid suite, urgent transportation to a general operating room may be necessary.

Optimal care also depends on the ready availability of a stat laboratory. Blood gas analysis, as well as the assessment of electrolytes and hemoglobin or hematocrit, is important in urgent situations. Patients undergoing procedures for coronary revascularization may be receiving platelet inhibitor drugs. Conventional coagulation tests may not be sufficient for diagnosing clinical bleeding in these patients; tests that evaluate platelet function are useful.[377]

Compared with elective cardiac surgical procedures, emergency cardiac surgery carries higher mortality and morbidity risks, especially if the patient is in cardiogenic shock.[378] Identifying high-risk patients going to the CCL for interventional procedures, as well as communication about these high-risk patients among the interventional cardiologists, cardiac surgeons, and cardiac anesthesiologists, is of prime importance in improving the outcome of these emergency procedures.

PROCEDURES IN THE CARDIAC CATHETERIZATION LABORATORY AND THE HYBRID OPERATING ROOM

GENERAL CONSIDERATIONS

Since the 1990s, the scope of activity in the CCL and electrophysiology laboratory has greatly increased and has diverged considerably from the simple diagnosis and evaluation of valvular heart disease, CAD, and CHD.[289,290,376,379] Procedures and interventions in these settings are more complex and often involve acutely ill patients.[290] Cardiac anesthesiologists may find themselves in a relatively isolated environment with bulky equipment, subdued lighting, and limited access to the patient.[375,379] Assistance from surgical colleagues, if required, may not be readily available, nor may the services of anesthesia support personnel, the pharmacy, and the stat laboratory. Finally, for patients with moderate or severe cardiac disease who have undergone heavy sedation or general anesthesia, a suitable recovery area may be in a distant location.

Because fluoroscopy is frequently used during interventional procedures in the CCL and hybrid operating rooms, it can present a significant risk of radiation exposure to both patients and health care workers. The potential hazards of ionizing radiation include skin injuries and cellular mutation, which can lead to leukemia, bone cancer, and birth defects. The radiation safety program at the Centers for Disease Control and Prevention (CDC) has developed the concept that radiation doses should be "as low as reasonably achievable" (ALARA). Exposure to radiation can be minimized by three means: distance, time, and shielding.[376] The distance between the person and the source should be maximized because the dose rate varies with the inverse square of that distance. In addition, the person's exposure time should be minimized because the dose rate and time are directly related. Finally, personal shielding and shielding of the radiation source should be maximized.

The rad is a unit of absorbed dose, which is the energy imparted to matter by ionizing radiation per unit mass of irradiated material at the point of interest.[376] The rem is a unit of effective dose, which is the estimated total body dose. Health care personnel in a radiation environment must wear a dosimeter badge to track cumulative radiation exposure. The dosimeter should be worn on areas at highest risk for frequent exposure, such as the thyroid collar, and outside any shielding garments. Corrective action is recommended if an individual (patient or provider) receives more than 5 rem/year to the whole body (Box 67-17).[376] In the case of pregnant women, the total radiation exposure to the fetus throughout gestation should be no more than 0.05 rad/month or 0.5 rad total.

Identifying patients at risk for a reaction to iodinated contrast material is another consideration unique to procedures performed in the CCL or hybrid suite. A previous anaphylactoid reaction and a history of atopic conditions such as asthma are the most significant risk factors for acute hypersensitivity reactions.[376] Premedication regimens with histamine (H_2) blockers and steroids are recommended for the highest-risk atopic patients, particularly those with a known prior reaction. Current options include giving 50 mg oral prednisone 13 hours, 7 hours, and 1 hour before the procedure or 200 mg intravenous hydrocortisone, with or without H_2 blockers, 2 hours before the cardiac catheterization.[376]

In patients with renal insufficiency, radiocontrast media–induced nephropathy is a concern, and diabetic patients are at particularly high risk for acute renal failure after exposure to contrast agents.[375,376] These effects can be minimized through careful contrast administration and limitation of the total dose. Preprocedural and postprocedural hydration with normal saline solution, sodium bicarbonate, or both is recommended.[376] However, in patients with severe HF or near–end-stage

BOX 67-17 ***Maximum Allowable Radiation Limits for Medical Workers***

Whole body	5 rem/yr (50 mSv/yr)
Skin	50 rad/yr (500 mGy/yr)
Lens of eye	2 rad/yr (20 mGy/yr)
Fetus (for pregnant worker)	0.5 rad (5 mGy) for total pregnancy or 0.05 rad/mo (0.5 mGy/mo) (estimated by abdominal badge under lead apron
Cumulative exposure (lifetime)	1 rem × age (10 mSv × age)

Modified from Bashore TM, Balter S, Barac A, et al: 2012 American College of Cardiology Foundation/Society for Cardiovascular Angiography and Interventions expert consensus document on cardiac catheterization laboratory standards update: a report of the American College of Cardiology Foundation Task Force on Expert Consensus documents, J Am Coll Cardiol *59:2221-2305, 2012.*

renal disease, one must be careful to avoid volume overload.[375,376] Elevated serum creatinine levels are common after the administration of radiocontrast media, and these levels should be monitored for 72 or more hours in patients at risk. Two definitions (an incremental increase >0.5 mg/dL or a rise >25% in serum creatinine level) are now accepted as indicators of contrast-induced nephropathy. Fortunately, renal dysfunction is usually transient and rarely progresses to acute renal failure.

HYBRID OPERATING ROOM

To address some of the issues regarding the technologic and procedural demands regarding surgical and imaging equipment for selected endovascular and transcatheter procedures, hybrid operating rooms have been built in many institutions. These rooms have complete dual capabilities for procedures that require fluoroscopy, open surgery, or both. Ideally, such rooms are within or adjacent to the regular surgical suite. The physical location of such hybrid rooms may represent an advance in care in that key personnel are more readily available to handle unanticipated complications and emergencies.

The types of procedures that are performed in the CCL or the hybrid operating room vary according to institutional preferences but may include (1) electrophysiology procedures, (2) percutaneous management of valvular lesions, (3) the use of occlusion or umbrella devices to close an ASD or VSD or a PDA, (4) percutaneous VADs, and (5) stenting of abdominal or thoracic aortic aneurysms.[289-291]

Although requirements vary depending on the nature of the procedure, sedation or anesthesia improve the efficacy and safety of many procedures.[379] Providing stable hemodynamics for organ perfusion and preservation during anesthesia is an important goal. Some procedures can be performed with the aid of monitored anesthesia care or regional blocks, provided a certain patient comfort level can be achieved. However, during difficult and lengthy procedures, patients may have trouble staying still. In many cases, a general anesthetic regimen may be the best option. If indicated, general anesthesia with endotracheal intubation provides a controlled situation: the patient's comfort is maximized, and the airway is secured.[375] Use of a laryngeal mask or a standard mask airway is also possible, but the constant diaphragmatic movements that occur during spontaneous ventilation may interfere with fluoroscopic visualization of cardiac and vascular structures. In the absence of significant complications or comorbid conditions, the patient may be allowed to emerge from anesthesia before being transferred to the CCL recovery area and, eventually, to a hospital floor. In more complex cases, the patient may be transferred to an ICU.

Percutaneous mitral valve repairs (e.g., correction of MR and commissurotomy for MS) share the same advantages as TAVI with respect to avoiding sternotomy, implementing CPB, and cross-clamping the aorta.[289] These procedures are similarly performed with the patient under general anesthesia, with fluoroscopic and TEE guidance.[290]

Percutaneous closure procedures are used to close ASDs and, less commonly, VSDs, as well as PDAs and fenestrations.[290,379] Echocardiography is used to help guide device placement and confirm a successful result. If TEE is used, general anesthesia is necessary. If intracardiac echocardiography is used, the procedure can potentially be performed with sedation only.[290] Large-bore peripheral or femoral venous access is needed, and a radial arterial line is often placed.

Percutaneous VADs (TandemHeart, Cardiac Assist, Inc., Pittsburg, Pa., and Impella Recover LP 2.5 and 5.0, Abiomed, Inc., Danvers, Mass.) are placed in patients undergoing high-risk coronary interventions or ablation procedures or who are in cardiogenic shock.[290] These devices can produce CO that completely replaces LV function with nonpulsatile blood flow. Hence, pulse oximetry and noninvasive blood pressure measurement may not work properly. Either sedation or general anesthesia can be used, depending on the patient's hemodynamic status and ability to cooperate. Invasive monitoring is available because arterial cannulation is used during the procedure.[290] Large-bore intravenous access is desirable because a large amount of blood loss is possible. Surgical backup is necessary during these procedures.

Endovascular abdominal aortic aneurysm repair is a minimally invasive but high-risk procedure. Further details of endovascular repair of abdominal aortic aneurysms appear in Chapter 69.

ELECTROPHYSIOLOGIC PROCEDURES

Anesthetic Considerations for Supraventricular Arrhythmia Surgery and Ablation Procedures

Invasive cardiac electrophysiology studies are now common procedures in the CCL. RF catheter ablation has, in many cases, replaced pharmacologic antiarrhythmic therapy for the treatment of recurrent or persistent tachyarrhythmias. Tachyarrhythmias appropriate for this treatment include those with a focal origin and, more commonly, those with a reentrant circuit. Electrophysiologic studies in the CCL usually involve inducing the tachycardia, mapping it, and performing transcatheter RF ablation. Three to five electrode catheters are inserted percutaneously by venous access or by retrograde aortic catheter insertion and a transseptal approach. The catheters are positioned within the heart to allow induction of the arrhythmia and recording at key sites. The arrhythmia may be induced with pacing maneuvers that introduce critically timed ectopic beats to establish reentrant excitation. Heightened adrenergic tone, usually achieved by administering isoproterenol, may be necessary.

Arrhythmia induction is unpleasant and requires some sedation. Although many procedures in the CCL and electrophysiology laboratory are performed by using mild to moderate sedation (with fentanyl and midazolam) administered by trained nonanesthesia personnel and local anesthetic infiltration at the site of catheter placement by the cardiologist, an anesthesiologist is needed for patients and procedures with complications.[290] General anesthesia with endotracheal intubation is generally chosen for longer procedures and those that absolutely require the patient's immobility during critical lesion

placement.[380] Usually, a small dose of opioid, an induction agent, an intermediate-duration muscle relaxant, and a volatile agent are used.[380] However, many agents commonly used as part of the anesthetic technique may affect cardiac rhythm (e.g., lidocaine), and the use of such agents should be discussed with the electrophysiologist. All inhalational agents affect the conduction system of the heart, whereas most intravenous induction agents have little effect on this system.[379] Once the arrhythmia's site of origin has been identified, the electrode catheter is positioned in direct contact with this site, and RF energy is delivered through the catheter. Any patient movement during ablation can result in catheter dislodgment and potential damage to normal conduction tissue.

Monitoring of patients undergoing catheter-based ablation of atrial fibrillation includes direct arterial pressure monitoring. Furthermore, LAA thrombus must be excluded with TEE examination before catheter-based ablation and surgical manipulations. Finally, esophageal temperature monitoring is critical because even a small increase in temperature (0.1° C) is reported to the electrophysiologist, who immediately terminates RF energy and cools the catheter tip with intraprobe saline.[380]

If catheter RF ablation fails, pulmonary vein foci isolation and catheter ablation or a surgical approach may be required. Further details are provided in the section of this chapter on surgical ablation of atrial fibrillation.

Pacemaker or Automated Implantable Cardioverter-Defibrillator Insertion, Generator Change, and Laser Lead Extraction

ICDs are capable of pacing, as well as detecting and correcting, tachyarrhythmias (e.g., with shocks or antitachycardia pacing) (Box 67-18).[380] Considerable progress has been made with respect to reducing device size, lengthening battery life, and improving treatment algorithms. Such devices are often indicated for patients with advanced HF to decrease their risk of sudden death.[315] Thus, many of these patients have multiple comorbidities, including a history of ventricular tachycardia (VT) or ventricular fibrillation, low EF, and CAD.

BOX 67-18 ***Implantable Cardioverter-Defibrillator***

- Implantable cardioverter-defibrillators (ICDs) are capable of pacing, as well as providing tiered therapy for tachyarrhythmias (e.g., shocks, antitachycardia pacing).
- Modern devices are inserted almost exclusively with percutaneous techniques.
- ICDs are indicated for the primary or secondary prevention of sudden cardiac death.
- ICDs have been shown to reduce the incidence of total mortality compared with standard treatment alone.
- ICDs are indicated for individuals who survive sudden cardiac death without a reversible cause, individuals with ischemic cardiomyopathy and an ejection fraction ≤30%, and individuals with ischemic or nonischemic cardiomyopathy, an ejection fraction ≤35%, and New York Heart Association class II or III heart failure symptoms.

From Kaplan JA, Reich DL, Savino JS, editors: Kaplan's cardiac anesthesia: the echo era, *ed 6, St. Louis, 2011, Saunders, p 92.*

The insertion of current devices usually involves percutaneous techniques performed in the CCL.[380] The procedure includes defibrillation testing. External cardioverter-defibrillator pads are placed and connected before the procedure begins.[290,380] These pads are used to induce ventricular fibrillation and to serve as backup if the implanted device fails. Monitored anesthesia care is usually chosen, but brief unconsciousness is needed for defibrillation testing. If the patient has severe comorbidities or anxiety, general anesthesia may be needed. Such patients require close monitoring, often involving an arterial catheter, because of the potential for rapid blood pressure changes during the testing process. It may take some time for hemodynamic variables to return to baseline after tests involving purposeful fibrillation followed by defibrillation.

Laser extraction of an ICD lead that is infected or damaged is another procedure that may be of long duration and require general anesthesia. The lead may be firmly attached to the endocardium, thus necessitating the use of a special coaxial laser device that slides over the lead to help burn it free. Myocardial perforation with ensuing cardiac tamponade is a rare but potentially lethal complication of this procedure.[375]

Biventricular Pacing

In many patients with advanced HF, defects in sinus or AV node function, intraventricular conduction defects (commonly left bundle branch block), or both delay the onset of LV or RV systole.[381] This lack of coordination between the left and right ventricles further reduces CO and may increase mortality risk in these patients.[318] Cardiac resynchronization therapy is a variant of traditional AV pacing that involves placing additional pacing leads on the lateral wall of the left ventricle in a coronary vein (accessed through the coronary sinus). Both ventricles can then be paced in a carefully timed manner to resynchronize RV and LV contraction, thus improving mechanical efficiency and CO.

Anesthesiologists are sometimes asked to provide sedation during these procedures, which may be somewhat lengthy. These patients have extremely low EFs and may have associated comorbidities, including valvular heart disease, pulmonary hypertension, and RV dysfunction.[290] Patients may not be able to breathe comfortably while lying flat, and they may easily become hemodynamically unstable because of vasodilation or hypercapnia as sedation is administered. As noted by Shook and Savage,[290] the anesthesiologist must be ready to convert to general anesthesia at any time during the case.

PROBLEMS IN THE POSTOPERATIVE PERIOD

LOW CARDIAC OUTPUT SYNDROME

Although improvements in myocardial protection have occurred during the past decades, it is well documented that significant declines in LV function after CABG and other cardiac operations occur in the first 8 to 24

postoperative hours.[382] A combination of ischemia and reperfusion injury after cardiac surgery contributes to an energy deficit state in the myocardium that limits uptake of exogenous energy substrates from blood (Box 67-19). Prolonged aortic cross-clamp time, incomplete revascularization, or poor myocardial preservation adds additional risk. In particular, patients with preexisting LV dysfunction experience a delay in myocardial recovery after cardiac surgery and require measures to relieve the workload of the heart. Furthermore, preexisting diastolic dysfunction is associated with an increased risk of difficulty in weaning from CPB and ongoing need for vasoactive support during the postbypass period and in the ICU.[383]

Criteria used to define low CO syndrome (LCOS) include a cardiac index of less than 2.4 L/minute/m^2, elevated lactate levels, and urine output of less than 0.5 mL/hour for more than 1 hour.[384] In addition, $S\bar{v}O_2$ is a good indicator of LCOS in that it reflects the balance between CO and systemic O_2 demand.

Postoperative management of patients at high risk for LCOS requires a physiologic approach. Optimizing preload and reducing afterload help maximize cardiac function. Both tachycardia and bradycardia should be avoided, and postoperative arrhythmias should be treated. In addition, shivering should be prevented because it raises the heart rate by increasing oxygen demand. Postoperative deep sedation and muscle relaxation are often used to reduce myocardial workload by reducing the body's overall metabolic demand by 25% to 30%.

BOX 67-19 ***Risk Factors for Low Cardiac Output Syndrome After Cardiopulmonary Bypass***

- Preoperative left ventricular dysfunction
- Valvular heart disease requiring repair or replacement
- Long aortic cross-clamp time and total cardiopulmonary bypass time
- Inadequate cardiac surgical repair
- Myocardial ischemia and reperfusion
- Residual effects of cardioplegia solution
- Poor myocardial preservation
- Reperfusion injury and inflammatory changes

From Kaplan JA, Reich DL, Savino JS, editors: Kaplan's cardiac anesthesia: the echo era, *ed 6, St. Louis, 2011, Saunders, p 1028.*

Pharmacologic support is often needed to improve contractility as the patient is weaned from CPB and, eventually, recovering in the ICU (Table 67-18).[384,385] Catecholamines (β-adrenergic agonists) and phosphodiesterase inhibitors are the main classes of pharmacologic agents used for this purpose. Catecholamines (e.g., epinephrine, norepinephrine, dopamine, dobutamine, dopexamine, isoproterenol) are often the first line of therapy. They exert positive inotropic action by stimulating the β_1 receptor, which leads to increased intracellular cyclic adenosine monophosphate (cAMP). The predominant hemodynamic effect of a specific catecholamine depends upon the degree to which the α, β_1, β_2, and dopaminergic receptors are stimulated (see Chapters 16 and 20 for specific drug pharmacology and doses.) Phosphodiesterase inhibitors (e.g., milrinone, amrinone), sometimes termed inodilators, may be used either as first-line therapy or added to β-adrenergic therapy. Phosphodiesterase inhibitors augment β-adrenergic stimulation by inhibiting the breakdown of cyclic adenosine monophosphate. When these drugs are added to catecholamine infusions, the result is an additive or possibly synergistic increase in inotropy. Phosphodiesterase inhibitors also induce systemic and pulmonary vasodilation. Hence, they are particularly useful in patients with pulmonary hypertension, RV failure, or aortic or mitral valve regurgitation.

Although not yet available in the United States, a newer class of drugs—calcium sensitizers, such as levosimendan—exhibits potent inodilatory properties.[386,387] Levosimendan works by increasing myocyte sensitivity to calcium by stabilization of the calcium binding to troponin C. This increases calcium sensitivity during systole and enhances myocardial contractility without causing calcium overload during diastole. Therefore, inotropic performance is enhanced, whereas diastolic performance is preserved. Like phosphodiesterase inhibitors, levosimendan may augment inotropy without significantly increasing myocardial oxygen consumption.

RV failure may also be present in patients with LCOS, and it manifests as elevated PA and CVP pressures. Echocardiography can be diagnostic—findings include an enlarged and poorly contracting right ventricle, often with significant TR. The management of RV failure consists of ensuring adequate RV filling and maintaining adequate systemic pressures to prevent RV ischemia. Afterload reduction with agents effective in the pulmonary

circulation is helpful. Milrinone may reduce PVR and improve CO. Nitric oxide and inhaled prostaglandins are selective for pulmonary vasodilation. Other measures to decrease PVR include hyperventilation (higher respiratory rate) to induce mild hypocapnia and aggressive treatment of hypoxemia and acidosis.

ARRHYTHMIAS

Atrial Arrhythmias

Postoperative arrhythmias (Table 67-19) are seen in a significant number of patients who undergo cardiac surgery; atrial fibrillation is the most common (27% to 40%).[388,389] Patients are at highest risk for new-onset atrial fibrillation 2 to 3 days after cardiac surgery.[389] This arrhythmia can potentially prolong the patient's hospital stay and increase management costs by causing hemodynamic compromise or thromboembolic complications in the postoperative period.[390]

Many potential risk factors have been studied in efforts to predict the occurrence of postoperative atrial fibrillation. With advancing age, dilatation of the atrium interrupts cell-to-cell electrical coupling between atrial muscle fibers. Other preoperative risk factors for postoperative atrial fibrillation include a history of atrial fibrillation, chronic obstructive pulmonary disease, valve surgery, and postoperative withdrawal of a β-blocker or ACEI.[389] Perioperative factors include inadequate atrial protection during surgery, pericardial inflammation, autonomic imbalance during the postoperative period, change in atrial size with fluid shifts, electrolyte (potassium and magnesium) abnormalities, and excessive production of catecholamines.[391] Reduced risk has been associated with the postoperative administration of β-blockers, ACEIs, potassium supplementation, and nonsteroidal antiinflammatory drugs (NSAIDs).[389]

Treatments for atrial fibrillation include both pharmacologic agents and electrical stimulation. Many studies have shown that β blockade significantly reduces the incidence of postoperative atrial fibrillation and that withdrawal of β-blockers increases risk.[392,393] The use of amiodarone for prophylaxis or treatment has also been studied.[394] Most recently, an inexpensive antiinflammatory drug, colchicine, has been studied as a means to prevent postoperative atrial fibrillation.[170] Synchronized cardioversion is reserved for patients who show signs of hemodynamic instability during atrial fibrillation.[395] In the absence of hemodynamic instability, pharmacologic agents are used with the goal of preventing a rapid ventricular response. Drugs usually employed for this purpose include calcium channel blockers, β-blockers, magnesium, and amiodarone. Expert consultation should be obtained before treatment is initiated, especially in a stable patient.[393,395]

Ventricular Arrhythmias

Although ventricular arrhythmias occur after cardiac surgical procedures, sustained ventricular arrhythmias are relatively uncommon. Associated factors may include hemodynamic instability, electrolyte abnormalities, hypoxia, hypovolemia, ischemia or infarction, acute graft closure reperfusion, and the use of inotropic agents.[395]

Ventricular arrhythmias can range from simple premature ventricular complexes (PVCs) to VT. Simple PVCs do not pose a significant risk of life-threatening ventricular arrhythmia. Conversely, complex ventricular arrhythmias, including both frequent PVCs (>30/hour) and nonsustained VT, may make patients prone to sudden death, especially in the long term. Sudden death is even more likely if ventricular function is also compromised. A study of 126 patients with postoperative complex ventricular ectopy found a mortality rate of 75%.[395] Patients with sustained ventricular arrhythmias have a poor prognosis in both the short and the long term.

Patients who are asymptomatic and hemodynamically stable do not usually require immediate treatment for PVCs or even short runs of nonsustained VT, although any reversible causes should be corrected. Conversely, patients with VT accompanied by hemodynamic instability need immediate synchronized cardioversion.[396] Amiodarone is reserved for hemodynamically stable

TABLE 67-19 POSTOPERATIVE RATE AND RHYTHM DISTURBANCES

Disturbance	Usual Causes	Treatments
Sinus bradycardia	Preoperative or intraoperative β blockade	Atrial pacing β-Agonist Anticholinergic
Heart block (first, second, and third degree)	Ischemia Surgical trauma	Atrioventricular sequential pacing Catecholamines
Sinus tachycardia	Agitation or pain Hypovolemia Catecholamines	Sedation or analgesia Volume administration Change or stopping of drug
Atrial tachyarrhythmias	Catecholamines Chamber distention Electrolyte disorder (hypokalemia, hypomagnesemia)	Change or stopping of drug Treatment of underlying cause (e.g., vasodilator, give K^+/Mg^{2+}) Possible need for synchronized cardioversion or pharmacotherapy
Ventricular tachycardia or fibrillation	Ischemia Catecholamines	Cardioversion Treatment of ischemia; possible need for pharmacotherapy Change or stopping of drug

patients with VT or an uncertain rhythm. Ventricular fibrillation should be treated promptly with electrical defibrillation.[395] For long-term management of ventricular arrhythmias, in addition to antiarrhythmic agents, electrophysiologic studies or placement of an ICD should be considered.

Bradyarrhythmias

Bradyarrhythmias are not uncommon in the immediate postoperative period. In most cases, a temporary epicardial pacemaker is sufficient. In a small percentage of patients, a permanent pacemaker may be necessary, especially in patients with sinus node dysfunction or AV conduction disturbances after either CABG or valve repair.[395] Patients who need a permanent pacemaker may receive either a single-chamber or a dual-chamber pacemaker. Multiple factors dictate which particular device would most benefit an individual patient.[397]

BOX 67-20 ***Vasodilators Available for the Treatment of Perioperative Hypertension***

Adenosine
α_1-Adrenergic antagonists

**Intravenous vasoactive therapies in widespread use to treat perioperative hypertension.*

HYPERTENSION

Immediately after cardiac surgery, the patient remains prone to hemodynamic instability, including hypertension.[398] Causes of postoperative hypertension are often multifactorial and may include withdrawal from preoperative antihypertensive medications (e.g., β-blockers and centrally acting α_2-agonists), pain, hypoxemia, hypercarbia, and hypothermia. However, arterial vasoconstriction usually plays a central role in acute postoperative hypertension.[399] The hazards of untreated postoperative hypertension include increased myocardial work and oxygen consumption, MI, rhythm disturbances, cerebrovascular accidents, increased bleeding, and even suture line disruption. In the postoperative period, deepening sedation to control a hypertensive episode may not be the best or the only possible approach, particularly if early extubation (fast tracking) is desirable.[398,399]

Several pharmacologic agents are available for use as antihypertensive agents (Box 67-20). The drugs most commonly used in clinical practice are the nitrovasodilators and the dihydropyridine-type calcium channel blockers. Because of its antiischemic effects and familiarity, nitroglycerin is often the first agent used to treat hypertension in patients who have undergone coronary revascularization. However, nitroglycerin is not always effective in such patients because it primarily causes venodilation rather than arterial dilation. In addition, patients tend to develop tolerance to nitroglycerin.[399]

Because arterial vasoconstriction plays an important role in the development of hypertension after cardiac surgery, the therapeutic agent chosen should usually be one that effectively reduces this vasoconstriction. Sodium nitroprusside, a nonspecific venous and arterial vasodilator, is a common choice. However, theoretically, nitroprusside can cause coronary steal.[399] Furthermore, patients with renal failure eliminate sodium nitroprusside more slowly than normal, which makes them vulnerable to the toxic effects of this drug's metabolites (cyanide and thiocyanate).

Fenoldopam is a short-acting dopamine agonist that causes arterial-specific vasodilation by stimulating D_1-receptors. Unlike sodium nitroprusside, fenoldopam increases renal blood flow to produce diuresis and natriuresis.[400] Nevertheless, the results of most clinical trials regarding the renal protective effects of fenoldopam are equivocal. In addition, severe hypertension may require higher doses of fenoldopam, which may be associated with undesirable increases in heart rate.

Dihydropyridine-type calcium channel blockers, such as nicardipine and clevidipine, selectively relax arterial resistance vessels without negative inotropic or dromotropic (conduction) effects and cause generalized vasodilation of the renal, cerebral, intestinal, and coronary vascular beds. Although these drugs cost more than the older agents (nitroglycerin and nitroprusside), nicardipine and clevidipine are recommended by some experts as first-line treatment for cardiac surgical patients with acute hypertension that requires immediate control.[399]

It is important to ensure that the patient's intraarterial pressure is monitored adequately when any vasoactive agent is administered. Vasoconstriction or poor perfusion of the extremities may create a discrepancy between central aortic and peripheral arterial pressures. In addition, a radial arterial catheter may be "positional" if hand positioning is suboptimal, or "dampening" of the tracing may result from poor perfusion of the distal extremities. Occasionally, during the perioperative period, the cardiac anesthesiologist or surgeon must replace a distal peripheral arterial catheter (e.g., with a femoral arterial catheter) to ensure that the effects of vasoactive therapy are monitored accurately.

RENAL INSUFFICIENCY

Perioperative renal failure that necessitates dialysis occurs in approximately 2% of patients.[193] Although the definition of renal insufficiency or failure varies among studies, three useful criteria are (1) a serum creatinine level more than 44 mmol/L (>0.5 mg/dL) higher than its preoperative value, (2) a serum creatinine level more than 50% greater than its preoperative value, and (3) a serum creatinine level more than 177 mmol/L (>2.0 mg/dL).[401] Another definition of acute renal insufficiency involves a classification scheme that uses the acronym RIFLE (Table 67-20).[402]

TABLE 67-20 RIFLE* CLASSIFICATION SCHEME FOR ACUTE RENAL FAILURE

	GFR Criteria	Urine Output Criteria
Risk	Plasma creatinine increased 1.5× or GFR decrease >25%	<0.5 mL/ kg/hr × 6 hr
Injury	Plasma creatinine increased 2× or GFR decrease >50%	<0.5 mL/kg/hr × 12 hr
Failure	Plasma creatinine increased 3×, acute plasma creatinine ≥350 μmol/L, or acute rise ≥44 μmol/L	<0.3 mL/kg/hr × 24 hr or anuria × 12 hr
Loss	Persistent acute renal failure = complete loss of kidney function >4 wk	
ESKD	End-stage kidney disease (>3 mo)	

From Kuitunen A, Vento A, Suojaranta-Ylinen R, Pettilä V: Acute renal failure after cardiac surgery: evaluation of the RIFLE classification, Ann Thorac Surg *81:542-546, 2006.*

ESKD, End-stage kidney disease; *GFR,* glomerular filtration rate.
*Acronym for risk, injury, failure, loss, and end-stage kidney disease.

BOX 67-21 ***Aims of and Treatment Modalities to Reduce or Prevent the Development of Postoperative Renal Dysfunction***

1. Maintain adequate oxygen delivery—by ensuring adequate cardiac output, adequate oxygen-carrying capacity, and proper hemoglobin saturation.
2. Suppress renovascular constriction—by ensuring adequate volume preload and use of infusions of mannitol, calcium entry blockers, and angiotensin-converting enzyme inhibitors.
3. Promote renal vasodilation—by dopaminergic agents, prostaglandins, and atrial natriuretic peptide.
4. Maintain renal tubular flow—by loop diuretics and mannitol (which may act to prevent tubular obstruction, which can cause cellular swelling, ischemia, and death).
5. Decrease oxygen demand—by the use of loop diuretics and mild cooling.
6. Attenuate ischemic reperfusion injury—as a result of the release of oxygen free radicals and calcium ions.

Modified from Sear JW: Kidney dysfunction in the postoperative period, Br J Anaesth *95:20-32, 2005.*

Preoperative risk factors that are commonly associated with postoperative renal dysfunction after cardiac operations include preexisting renal insufficiency, type 1 diabetes mellitus, age older than 65 years, major vascular surgery, arteriopathy, genetic predisposition, and recent exposure to nephrotoxic agents (e.g., radiocontrast dyes, bile pigments, aminoglycoside antibiotics, and NSAIDs).[193,401] Ejaz and colleagues showed that in addition to serum creatinine, serum uric acid is a significant predictor of AKI.[403] In addition, several intraoperative factors may predispose a patient to renal dysfunction, including the need for emergency surgery, repeat cardiac surgery, valve surgery, and a CPB time exceeding 3 hours.[193,401] Other perioperative risk factors for renal dysfunction after cardiac surgery are hypovolemia, hypotension resulting from either hypovolemia or LCOS, and embolic phenomena. Furthermore, damage to nephrons in the medullary region of the kidney results in acute tubular necrosis; hypoxia is a common cause of damage to the nephrons in this region.[401]

Postoperative renal insufficiency in cardiac surgical patients is associated with longer ICU stay, longer overall hospital stay, and increased mortality.[193,401] Thus, this disorder should be prevented whenever possible. On the basis of studies conducted in patients with radiocontrast nephropathies, investigators theorized that hydration before radiocontrast media are administered may protect the kidneys.[401] Because the mechanism of renal injury after CPB appears similar to that triggered by the administration of radiocontrast dyes, it is thought that adequate hydration and maintaining normovolemia can help to prevent postoperative renal dysfunction in cardiac surgical patients.[401]

Several treatment modalities have been suggested to prevent or ameliorate postoperative renal dysfunction (Box 67-21).[401] Basic supportive therapy involves ensuring adequate CO, perfusion pressure, and intravascular volume. Discontinuing any nephrotoxic drug (NSAIDS, certain antibiotics) is usual. Diuretics are not helpful and may be harmful.[404] Although dopamine has no demonstrated efficacy, some studies suggest that fenoldopam, a D_1-receptor agonist, may improve renal function in cardiac surgical patients.[405] Unproven pharmacologic therapies include mannitol, calcium channel blockers, ACEIs, atrial natriuretic peptide, and *N*-acetylcysteine. Finally, if dialysis is needed, continuous dialysis may be better than intermittent dialysis.[406]

CENTRAL NERVOUS SYSTEM DYSFUNCTION

The risk of overt postoperative stroke has decreased to 1% to 2% since the 1980s.[32,407] However, an increased risk of neurologic complications remains in older patients,[408] as well as in patients undergoing combined CABG and valvular heart surgery or other complex cardiac surgical procedures.[409] Risk factors for overt neurologic complications are listed in Box 67-4. Importantly, 40% of strokes do not occur intraoperatively but manifest in the postoperative period.[200,407] The impact of overt stroke is profound in terms of worse adjusted hospital outcomes, longer ICU and postoperative stays, and poorer downstream survival.[407]

A less well-defined entity, POCD, is far more common. Delirium is included in the definition of POCD, as are deficits of memory, concentration, and psychomotor speed. Early cognitive loss, once thought to be transient, may persist for 5 years after cardiac surgery in as many as 40% of patients.[410] Formerly, POCD was assumed to be caused by physiologic disturbances resulting from CPB. However, more recent studies have confirmed that POCD occurs with similar frequencies after on-pump cardiac surgery, off-pump cardiac surgery, coronary stenting, and noncardiac surgery.[33] Hence, current attention focuses on factors related to surgical stress, anesthetic agents, and patient-related predisposing factors, particularly the degree of preoperative cerebrovascular disease.[33,411] In fact, surgical procedures are likely to uncover a patient's

susceptibility to cognitive loss that was already present and would eventually manifest even without surgery, usually as a result of the progression of cerebrovascular disease.[411] Although POCD is less devastating than stroke, its potential impact on quality of life and overall health care resource use is still profound.[47]

Neuroprotection Strategies

Numerous strategies have been tried to decrease the incidence and severity of neurologic injury in cardiac surgical patients. The most common nonpharmacologic approaches emphasize the reduction of macroemboli and microemboli. As described in earlier sections of this chapter, these strategies include avoiding aortic atheroma by using transesophageal or epiaortic echocardiography, optimizing the placement of the aortic cannula in the aorta, avoiding partial occlusion clamping of the aorta for proximal anastomoses by using a single cross-clamp, and, in selected patients, avoiding all cross-clamping of the aorta (the "no touch" technique).[44-46] Other strategies to minimize particulate microemboli include the routine use of arterial filtration in the cardiopulmonary circuit and use of the cell saver before reinfusing blood suctioned into the cardiotomy, to remove particulate and lipid material.[412] Strategies to minimize air microemboli include carefully removing air after any procedure involving opening a cardiac chamber, and flooding the field with carbon dioxide to minimize embolism of air entrained into the heart from the surgical field.[413] Eliminating CPB by performing off-pump CABG surgery has been touted as a means to reduce emboli in selected patients, but this approach has not decreased POCD rates at 1 or 5 postoperative years.[414] Because approximately 40% of strokes occur in the postoperative period,[200,407] embolism prevention remains important after surgical procedures. Many of these late-occurring strokes are probably caused by atrial fibrillation. Early pharmacologic or electrical correction and adequate anticoagulation are mandatory (see the section on arrhythmias in the postoperative period).

Other nonpharmacologic approaches include perioperative temperature control, as well as blood gas management (alpha-stat or pH-stat) during hypothermic CPB. These considerations are discussed in the section on CPB.

Diabetes is recognized as a risk factor for stroke and delirium after cardiac operations.[415] Even in nondiabetic patients, hyperglycemia is extremely common during cardiac surgical procedures because of the stress response to surgery (as well as CPB), the resultant increases in circulating catecholamines and cortisol, and hypothermia-induced reductions in insulin effectiveness.[200] Experimental evidence has revealed a relationship between hyperglycemia and worse outcome after different types of neurologic injury. However, attenuating the hyperglycemic response to cardiac surgery or CPB has proved difficult. Furthermore, concerns exist regarding inducing even a single episode of severe hypoglycemia with aggressive attempts to control glucose levels.[416] Furthermore, in a randomized, prospective study of 400 cardiac surgical patients managed with either tight glucose control (the use of intravenous insulin to maintain intraoperative glucose levels at 80 to 100 mg/dL) or conventional management (glucose level <200 mg/dL), the investigators found a significantly higher incidence of stroke in the tight-control group.[74] More recent STS guidelines recommend that in both diabetic and nondiabetic patients, blood glucose levels should be maintained at 180 mg/dL or lower.[76] Hyperglycemia is usually controlled more easily during the postoperative period than in the intraoperative period during and immediately after CPB.

The influence of intraoperative hemodynamics may influence neurologic and other outcomes. The prospective, randomized trial conducted by Gold and colleagues compared maintaining "normal" MAP (minimum of 50 mm Hg) with keeping the MAP elevated (target of 80 to 100 mm Hg).[417] These investigators found that the overall incidence of combined cardiac and neurologic complications was significantly lower in the high-MAP group. In another study,[418] investigators noted a higher frequency of hypoperfusion-type "watershed" strokes in patients who underwent cardiac surgical procedures with a MAP that was at least 10 mm Hg lower during CPB than before CPB. The current recommendation is to maintain higher targets for MAP (i.e., >50 mm Hg) in patients at high risk for neurologic injury.[200] More recent evidence suggests a wide range of MAP at the lower limit of autoregulation in individual patients, thus making estimation of this target difficult. Real-time monitoring of autoregulation with the cerebral oximetry index may provide a more rational means for individualizing MAP during CPB.[57]

Numerous studies of cardiac surgical patients have tested drugs aimed at ameliorating neurologic injury.[419] Because high-risk patients can be identified and a defined therapeutic window exists, pharmacologic protection would be very desirable. However, no definitively proven drug therapy currently exists for the prevention or treatment of neurologic injury after cardiac surgery.

Postoperative Management of Central Nervous System Injury or Dysfunction

Postoperative stroke may be suggested by the patient's inability to follow commands or move all extremities shortly after the surgical procedure. Neurologic consultation should be obtained, including diagnostic imaging. Diffusion-weighted magnetic resonance imaging is the most sensitive and accurate imaging technique for postoperative cardiac surgical patients.[420] It detects more microembolic lesions than does conventional magnetic resonance imaging and is better able to find multiple watershed lesions.

Management of CNS injury or dysfunction after cardiac operations consists of general supportive measures. Hypotension should be avoided, and consideration should be given to using volume expansion, inotropic augmentation (pharmacologic or mechanical), or vasoactive medications (vasopressin or phenylephrine) to support blood pressure and brain perfusion. The brain oxygen supply-demand balance should be optimized through adequate oxygenation, sedation, and strict temperature control. Hyperthermia (fever) should be aggressively controlled. Both hyperglycemia and hypoglycemia should be avoided. Lytic therapy is of little use in cardiac surgery because it poses a risk of postoperative surgical bleeding.

POCD can manifest subtly, being evident only with psychometric testing, or, at the other extreme, it can manifest as postoperative delirium. *Delirium* is defined as an acute and overt change in cognition and attention, which may include alterations in consciousness and disorganized thinking.[421] In the cardiac surgical literature, the reported incidence of delirium depends greatly on the methods used for delirium assessment, varying from 3% (chart review only) to 8% (interviews with nurses); however, with rigorous daily mental status testing and the application of a validated diagnostic algorithm, the incidence may be as high as 53%.[422]

Risk factors include preexisting cognitive impairment, poor preoperative functional status, prior stroke or transient ischemic attack, depression, alcohol abuse, and abnormal preoperative laboratory values (glucose, sodium, potassium, and albumin).[421] Precipitating factors for delirium in the postoperative period include intraoperative and postoperative medications, particularly sedatives and analgesics. The postoperative environment in the ICU often results in sleep deprivation and overstimulation, contributing to the onset of delirium.[421] Complications of hospitalization and surgical procedures, including those that result in prolonged controlled ventilation and reduced mobility, also contribute to the development and severity of delirium.

Nonpharmacologic postoperative strategies to prevent delirium are listed in Table 67-21. Medications, including those used to control pain and anxiety, are a common cause. Some studies have found that using dexmedetomidine for sedation in the ICU reduces the incidence of delirium compared with using benzodiazepines (midazolam and lorazepam).[423,424] For patients who develop agitation, the mainstay of treatment is a thorough review of medications, as well as removing other precipitating factors, such as low CO or perfusion state, metabolic disorders (e.g., hyperglycemia), fluid and electrolyte disturbances (hypoglycemia or hyperglycemia and uremia), constipation, urinary retention, and environmental noise. For patients in whom these nonpharmacologic interventions are not sufficient, an antipsychotic, usually haloperidol, is considered first-line therapy for agitation associated with delirium.[425]

Delirium may accelerate cognitive decline in patients with Alzheimer disease or cause a type of posttraumatic stress disorder in younger patients.[421] The long-term mental health implications of delirium have not been fully studied but may include impairment of functional recovery.

TABLE 67-21 **PREVENTION OF DELIRIUM AFTER SURGICAL PROCEDURES**

Module	Postoperative Interventions
Cognitive stimulation	Orientation (clock, calendar, orientation board) Avoidance of cognitively active medications
Improvement in sensory input	Glasses Hearing aids and amplifiers
Mobilization	Early mobilization and rehabilitation
Avoidance of psychoactive medication	Elimination of unnecessary medications Pain management protocol

Other Nerve Injuries

Peripheral nerve injury frequently follows cardiac surgical procedures.[426] In a review article, Sharma and coauthors reported injury rates of 1.5% to 24% for the brachial plexus.[427] Numbness, weakness, pain, decreased reflexes, and diminished coordination in an extremity are suggestive of peripheral nerve injury. Sensory findings in the fourth and fifth fingers, consistent with ulnar neuropathy, are most common. The mechanisms of injury are most often related to the use of a sternal retractor and compression of the brachial plexus, although upper extremity neuropathy can occur as a consequence of arm positioning as well.

Other neurologic complications include injury to the phrenic nerve, which can result from use of slushed ice in the pericardial well to provide surface cooling for the heart.[426,427] Furthermore, injuries to the recurrent laryngeal nerve, sympathetic chain neuropathy (Horner syndrome), and saphenous nerve injury after harvesting of the long saphenous vein have been reported.[426] Symptoms of peripheral nerve injuries are usually self-limited and improve with time and, if needed, with physical therapy.

RESPIRATORY INSUFFICIENCY

Even after uncomplicated cardiac surgery, a midline sternotomy (or thoracotomy) and lung manipulation cause significant reductions in total lung capacity, vital capacity, forced expiratory volume in 1 second (FEV_1), and functional residual capacity, as well as atelectasis and increased intravascular lung water.[428] These changes may result in arterial hypoxemia because of a mismatch between ventilation and perfusion, which diminishes lung compliance and increases the work of breathing.[429] More severe postoperative respiratory insufficiency that causes difficulty in weaning may reflect intrinsic pulmonary problems (e.g., COPD, atelectasis, pneumonia, surgical trauma to the lungs), ARDS related to CPB or transfusion (transfusion-related acute lung injury), pulmonary embolism, or cardiogenic pulmonary edema secondary to low CO.

Preoperative efforts to minimize pulmonary complications after cardiac surgery include optimizing pulmonary function for patients undergoing elective surgical procedures. With regard to the surgical approach, investigators have theorized that off-pump surgery causes fewer changes in pulmonary mechanics than on-pump surgery. In fact, the use of CPB[430,431] and the duration of CPB[432] have been identified as risk factors for prolonged ventilation (>48 hours).

In previous decades, management after cardiac surgery included overnight mechanical ventilation. Certainly, it is clinically important to have a period of controlled ventilation to allow rewarming and emergence from anesthesia, optimize cardiac function, and ensure hemodynamic stability and the absence of unacceptable bleeding. However, many patients are currently extubated within 3 to 6 hours of arriving in the postoperative care unit (fast tracking), if appropriate criteria have been met (Box 67-22). In planning for fast tracking, one should avoid using high-dose narcotic anesthetic techniques; in addition, the postoperative administration of analgesics and sedatives, as well as any muscle relaxants, must be done at appropriate doses and with appropriate timing.[433] Furthermore, strategies to avoid ventilator-associated pneumonia should be employed. These include formal infection control programs, handwashing, maintaining adequate endotracheal tube cuff pressure, avoiding gastric overdistention, semirecumbent positioning of the patient, scheduled drainage of condensate from ventilator circuits, daily sedation "vacation," adequate nutritional support, early removal of endotracheal and nasogastric tubes, and avoiding unnecessary reintubation.[429,430]

Pain management should be included in postoperative efforts to minimize pulmonary complications. Sternotomy pain may limit the patient's ability to cough and perform deep breathing exercises, and incisional leg pain resulting from saphenous vein harvesting may prevent early ambulation, thus increasing the risk of pulmonary complications. The reader is referred to the later section on pain after cardiac surgery for other options for improving postoperative pain control and thereby minimizing splinting and complications such as lobar collapse, pneumonia, and increased duration of hospitalization.

Fortunately, only a few patients require prolonged mechanical ventilation after cardiac surgical procedures. Data from the STS National Adult Cardiac Surgery Database,[434] the Cardiac Surgery Registry of the New York State Department of Health,[432] and the Cardiothoracic Centre-Liverpool[430] show that approximately 5.5% of patients who undergo CABG require mechanical ventilation for more than 48 postoperative hours. Independent preoperative risk factors for prolonged ventilation include advanced age, preoperative ventilation, elevated serum creatinine levels, EF less than 30%, valve surgery, previous cardiac surgery, urgent or emergency surgery, recent MI, peripheral vascular disease, current smoking, FEV_1 less than 70% of the predicted value, and the use of CPB.[430]

Prolonged postoperative ventilation is most commonly caused by cardiac dysfunction.[435] Patients with marginal cardiac function may require diuresis, afterload reduction, or inotropy. Pulmonary-related reasons for the inability to wean from mechanical ventilation include noncardiogenic pulmonary edema, pneumonia, severe COPD, ARDS, and pulmonary embolism. Nonpulmonary complications such as persistent postoperative bleeding, neurologic complications (including stroke and delirium), renal insufficiency or failure, gastrointestinal complications, and sepsis also may result in a need for prolonged mechanical ventilation. In a large study of ventilator dependency (i.e., ventilation for >72 hours) after cardiac surgery, survival was 76% at 30 days, 49% at 1 year, and 33% at 5 years.[435]

BOX 67-22 ***Criteria to Be Met Before Early Postoperative Extubation***

Neurologic: Awake, neuromuscular blockade fully dissipated (head lift ≥5 sec), can follow instructions, able to cough and protect airway
Cardiac: Stable without mechanical support, cardiac index ≥2.2 L/min/m^2, MAP ≥70 mm Hg, no serious arrhythmias
Respiratory: Acceptable chest radiograph and ABGs (pH ≥7.35), minimal secretions, comfortable on CPAP or T-piece with spontaneous respiratory rate ≤20 breaths/min, MIP ≥25 cm H_2O; alternatively, a successful SBT defined as RSBI <100 and a PaO_2/FiO_2 ≥200
Renal: Diuresing well, urine output >0.8 mL/kg/hr, not markedly fluid-overloaded from operative or CPB fluid administration or SIRS
Hematologic: Chest tube drainage minimal
Temperature: Fully rewarmed, not actively shivering

BLEEDING AND COAGULOPATHY

Bleeding is common after cardiac surgery and CPB. Of the blood product usage in the United States, 15% to 20% occurs in association with cardiac surgery.[436-438] Yet despite ongoing clinical research and economic concerns, the management of coagulopathy and bleeding continues to vary substantially among institutions and across the globe. Spiess and associates found that the frequency of transfusion varies from 3% to 92% among institutions,[439] a similar variation to that shown in an international cardiac surgery database.[440]

Transfusion to treat coagulopathy or anemia is sometimes indicated, but it carries a cost in terms of health care resources and patients' outcomes. A study of more than 1900 cardiac surgical patients found that patients who received transfusions had a 70% increased risk of death and a doubling of their 5-year mortality rate, after adjustment for comorbidities, compared with patients who received no transfusions.[85] A multinational study showed that differences in transfusion practices among countries may account for differences in outcomes.[441] A study of 10,000 patients who underwent CABG from the Cleveland Clinic database confirmed the association of transfusion with early and late (i.e., 10-year) mortality; this study used a balancing score to account for confounding.[442] In addition, Marik and Corwin performed a meta-analysis of 45 trials that examined complications of transfusion therapy and found that mortality was increased in transfused patients (odds ratio, 1.7, 95% confidence interval, 1.4 to 1.9).[443]

Guidelines and Recommendations

The STS and the Society of Cardiovascular Anesthesiologists (SCA) published a joint statement in 2007 and an update in 2011 regarding practice guidelines for transfusion and blood conservation in cardiac surgery.[82,444] They

noted six factors that appear to be important predictors of blood product transfusion in cardiac surgery:

1. Advanced age
2. Low preoperative RBC volume (i.e., preoperative anemia or low body surface area)
3. Preoperative antiplatelet or antithrombotic medications
4. Complex or redo operation
5. Emergency operation
6. Noncardiac comorbidities

The Task Force gave specific recommendations on blood conservation that included the following five points[444]:

1. Consideration should be given to the use of drugs that either increase preoperative blood volume (e.g., erythropoietin) or decrease postoperative bleeding (e.g., antifibrinolytic drugs).
2. Techniques of conserving blood, including cell saver sequestration and retrograde priming of the pump, should be included in the operative plan.
3. To spare the patient's blood from the insult of CPB, normovolemic hemodilution or platelet-rich plasmapheresis can be considered.
4. Institutions should implement transfusion algorithms supported with POC testing.
5. A multimodal application of all of the previously mentioned guidelines is the best way to conserve blood.

These recommendations are parallel to and completely congruous with the tenets of patient blood management, which is a novel approach to blood transfusion that focuses on patient-centered therapies. The three pillars of patient blood management are as follows:

1. Preoperative optimization of RBC mass
2. Perioperative minimization of RBC loss
3. Perioperative optimal treatment of anemia

Definition of Bleeding and Transfusion Triggers

The decision to transfuse the cardiac surgical patient is one that should be made with great caution and careful consideration because allogeneic transfusion has several associated risks. The excessively bleeding patient who has a surgical source of bleeding should be carefully assessed, and often, allogeneic blood products are required to maintain hemoglobin and the integrity of hemostasis until the source of bleeding is found. Patients who have excessive microvascular bleeding from a coagulopathic cause should have careful testing of the hemostatic system, usually with POC monitoring, to assess which blood products or pharmacologic products are needed. (This subject is discussed in the following section on transfusion algorithms.) The problem in defining a trigger for transfusion is the ambiguity of the definition of bleeding. Many sources state that excessive chest tube drainage can be defined as more than 250 mL of bleeding per hour for at least 2 consecutive hours, or 300 mL of bleeding in a single hour. In addition to defining the severity of bleeding, these criteria also often help clinicians determine whether to return the patient to the operating room for surgical exploration.

Knowing when to transfuse RBCs is equally challenging because the triggers for transfusion often rely on hemoglobin level, which is a poor surrogate for tissue oxygen delivery. It is well known that cardiac surgery and CPB are associated with anemia, which poses certain risks.[445] These risks include renal failure,[446] other end-organ morbidity, and even mortality,[445] all of which have been demonstrated observationally in well-designed multivariate analyses. However, the lowest tolerable hemoglobin level clearly differs among patient populations and remains ill-defined in the literature. Nevertheless, the STS/SCA guidelines for blood conservation provide a framework for transfusion triggers within which most patients are treated appropriately. These triggers include a hemoglobin level of at least 6 g/dL during CPB and 6 to 7 g/dL before and after CPB.[444] However, underlying comorbidities can and do raise the minimum safe hemoglobin or hematocrit level.

Coagulation Monitoring

If only standard laboratory testing is available, monitoring the coagulopathic patient in the operating room is limited to monitoring hemoglobin concentration, prothrombin time or International Normalized Ratio, activated PTT, platelet count, and levels of fibrinogen and fibrin degradation products. These parameters are of limited utility in the post-CPB patient because they do not interrogate platelet function and because their turnaround time is too slow to allow timely initiation of therapy. For these reasons, without POC testing of hemostasis, transfusion therapy is often initiated empirically and indiscriminately.

The platelet count provides quantitative information about platelet concentrations but little, if any, qualitative information about platelet function. Platelet counts lower than 100,000/μL are often viewed as the cutoff for thrombocytopenia, but counts greater than 50,000/μL do not correlate with postoperative bleeding. Laboratory measures of platelet function, including bleeding time, aggregometry, and cytometry, are not rapid (requiring >1 hour to produce results) and therefore are impractical for obtaining timely information intraoperatively. When unacceptable microvascular bleeding occurs, no matter what the platelet count, CPB-induced platelet dysfunction is often assumed to be the culprit; however, platelet function can now be measured at the point of care.

POC monitors may be able to provide more timely information about the coagulation cascade than can laboratory measures and to assess the dynamic nature of platelet function sequentially. Such monitors are designed to test segments of the hemostatic system. The viscoelastic tests are dynamic measures of whole blood clot formation and can measure platelet integrity and the strength of the platelet-fibrinogen bond. These tests include thromboelastography (TEG; Haemonetics, Braintree, MA), Sonoclot (Sienco, Arvada, CO), and rotational thromboelastometry (ROTEM; Tem Innovations GmbH, Munich, Germany). The response of platelets to an agonist stimulus is another means of measuring platelet function. Platelet function can be measured at the point of care in this manner by the Platelet Function Analyzer-100 (PFA-100; Siemens Healthcare, Malvem, PA), PlateletWorks

(Helena Laboratories, Beaumont, TX), VerifyNow (Accriva Diagnostics, San Diego, CA), and the Multiplate analyzer (Roche Diagnostics, Rotkreuz, Switzerland).[447] POC monitors have also shown promise in stratifying bleeding risk for patients who come to the operating room after receiving antithrombotic drugs, such as clopidogrel, prasugrel, or Gp IIb/IIIa receptor inhibitors.[448-452] Finally, POC monitors provide data to support the implementation of institutional policies and practices directed at blood conservation and transfusion in cardiac surgical patients.[444]

Pharmacologic Treatment

Pharmacologic drugs used for hemostasis in CPB are used both prophylactically to prevent hyperfibrinolysis and therapeutically to treat bleeding. Antifibrinolytic drugs are used before CPB to prevent the inevitable activation of fibrinolysis and coagulation that result from contact between blood and the extracorporeal circuit. The STS/SCA guidelines provide the strongest evidence-based support for the use of synthetic antifibrinolytic agents in blood conservation. The evidence for the use of aprotinin for reducing perioperative bleeding in cardiac operations was reappraised in the updated guidelines because of conflicting reports of renal dysfunction and other adverse outcomes.[82]

In structural terms, the synthetic antifibrinolytic agents are lysine analogues. They bind to plasminogen and plasmin, thus inhibiting their ability to bind to lysine residues on fibrin and thereby impeding fibrinolysis. The two synthetic antifibrinolytic agents that are used clinically are EACA (Amicar) and TA. They differ primarily in potency and elimination half-life: TA is 6 to 10 times more potent and has a longer half-life than EACA.[453]

Dose regimens for the synthetic antifibrinolytic agents are anything but standardized. Generally, the dose of EACA is a 50 to 150 mg/kg load followed by an infusion of 15 to 25 mg/kg/hour; the dose of TA may be a 10 to 30 mg/kg load followed by an infusion of 1 to 15 mg/kg/hour. However, many other dosing strategies are described in the literature.[454-459]

Meta-analyses of the literature on antifibrinolytic drugs have come to different conclusions about the relative safety of these drugs[129]:

- Aprotinin, TA, and EACA significantly reduce blood loss compared with placebo.
- Aprotinin, EACA, and TA reduce PRBC transfusion rates by approximately 25% to 50%.
- Aprotinin and EACA reduce rates of surgical reexploration; reductions also were seen with TA but were not statistically significant.
- Another systematic review revealed that when observational trials are added to the meta-analyses of randomized controlled trials, aprotinin appears to have an adverse effect on survival and renal function.[460]

Because both EACA and TA are renally excreted, they should not be given to patients with upper urinary tract bleeding; the concentration of the drug in the renal collection system could cause thrombosis and obstructive nephropathy.[109]

Regarding aprotinin, Royston and associates published the first findings of reduced bleeding in cardiac surgical patients in 1987.[461] Numerous subsequent studies demonstrated that aprotinin reduces the bleeding associated with cardiac surgery and CPB.[444] Aprotinin is a bovine-sourced protein, and episodes of anaphylaxis have been reported.[462-464] The risk of anaphylaxis with reexposure is reported to be approximately 2.8%.[465] However, aprotinin was a routine part of perioperative care in cardiac surgical patients until 2006, when published reports suggested adverse outcomes that had not been found in previous randomized controlled studies.[130,466] After several observational studies confirmed these adverse outcomes and a single randomized controlled trial suggested an increase in mortality associated with aprotinin, the FDA and other global agencies suspended the marketing of aprotinin.[131]

Other pharmacologic drugs that may be used in cardiac surgical bleeding are mentioned in the STS/SCA Task Force guideline update.[82] Using desmopressin was classified as "not unreasonable" in patients with characteristics known to be responsive to desmopressin (von Willebrand factor or factor VIII deficiencies, cirrhosis, aspirin use, and uremic platelet dysfunction).[444] Desmopressin is administered in doses of 0.3 to 0.4 μg/kg, which are usually given slowly over 20 to 30 minutes to reduce the drug's propensity to cause hypotension. The use of recombinant factor VIIa (factor rVIIa) was reevaluated, but the published class IIb recommendation was unchanged in the update.[82] Factor VIIa use was classified as "not unreasonable" for treating intractable life-threatening hemorrhage that is unresponsive to traditional therapies.[444]

Factor rVIIa increases the amount of thrombin to promote hemostasis. It was initially developed as a therapy for patients with hemophilia and has since been used "off-label" to treat cardiac surgical patients with intractable bleeding after operation and CPB. Factor VIIa may serve as an activator of factors IX and X and may also bind directly to platelets, thus leading to localized activation of factor X and subsequent generation of thrombin on the surface of platelets (Fig. 67-44).[467]

A few observational studies have associated factor rVIIa administration with reductions in bleeding in patients

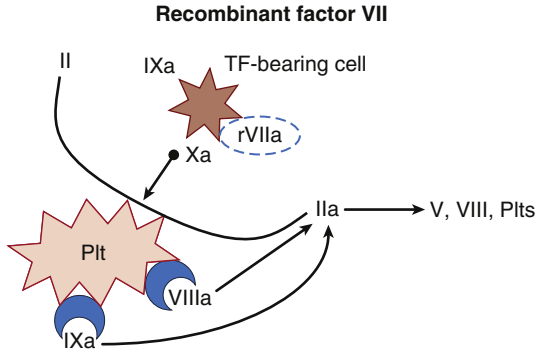

Figure 67-44. The use of factor rVII promotes cell-based hemostasis and active potentiation of coagulation activity. The initiation stage takes place when tissue-factor (TF)–bearing cells present tissue factor to its ligand, factor VII. The subsequent activation of factors IX and X occurs on the TF-bearing cell. Thrombin is activated and feeds back to activate factors VIII and V and platelets (Plts). The activated platelet phospholipid surface then provides the receptors for the activated factors VIIIa and IXa and for coagulation to continue.

with significant perioperative hemorrhage during cardiac surgery, and a systematic review of cardiac surgical studies recommended the use of this substance when standard therapies have failed.[437,468-470] A multicenter randomized trial in cardiac surgery found that patients treated with factor rVIIa had less bleeding than did control patients; however, a nonsignificant trend toward increased adverse events in the treated patients caused the study to be halted and the recommendations to proceed with caution when considering administration of this drug.[471] Meta-analysis of randomized trials in patients without hemophilia (but not solely cardiac surgical patients) suggested that prophylactic factor rVIIa use can reduce bleeding and transfusions, but therapeutic use caused a nonsignificant increase in thrombosis. Prophylactic use of factor rVIIa is not recommended in cardiac surgery.

Point-of-Care Algorithms

The STS/SCA blood conservation guidelines strongly encourage multimodal efforts to reduce transfusion rates and conserve blood products (see also Chapters 61 to 63). Studies that used transfusion algorithms paired with POC data to guide therapy have found these measures to be both efficacious and cost effective.[82,444] Examples of standard POC algorithms, one using the TEG and one using the ROTEM, are shown in Figures 67-45 and 67-46, respectively. Algorithms can be constructed to incorporate any particular dynamic POC monitor or monitors.[173,174,472-476] Studies that have incorporated many different varieties of POC tests have generally shown a reduction in or even the elimination of transfusions when POC is used.[474] As a general recommendation, the POC instrument or instruments used should be able to measure some aspect of platelet function. This can be a standard whole blood platelet test such as the PFA-100 or the VerifyNow, or it can be a viscoelastic test of dynamic clot formation. The viscoelastic test in the TEG measures both platelet function and the platelet response to ADP and arachidonic acid. Many TEG-guided algorithms have been studied and shown to reduce blood product use effectively in cardiac surgery-related hemorrhage. A more recent approach to POC algorithm includes using ROTEM and an algorithm that includes early treatment with fibrinogen and prothrombin complex concentrates (see Fig. 67-46).[477] This sort of approach to bleeding postpones the moment when allogeneic blood products are needed and thus has been successful in reducing their use. Preliminary work suggests that no increase in thrombotic events occurs with this "pharmacologic" approach to bleeding, but large-scale studies have not yet been conducted.

In summary, interdisciplinary approaches to blood conservation are vital to the care of cardiac surgical patients. Perioperative and critical care personnel must use a series of combined approaches to reduce transfusions and the adverse effects of transfusion and anemia. Important to this approach is a sound algorithmic procedure that incorporates POC testing, pharmacology, and rational blood product use to improve outcomes.

PAIN

Pain after cardiac surgery can have many sources, including the sternotomy incision, chest tubes, vascular cannulation sites, and leg incisions (see also Chapter 98).[478] Chest surgical procedures through thoracotomy are especially debilitating because of pain and consequent respiratory dysfunction.[479] Some of the deleterious effects of postoperative pain after cardiac surgery are caused by the stress response and resultant inflammation and enhanced sympathetic tone, which can increase the heart rate, PVR, myocardial work, and myocardial oxygen consumption, all leading to myocardial ischemia.

Pain after cardiac surgical procedures can also cause respiratory complications related to diaphragmatic dysfunction. Moreover, the patient's pain may cause voluntary reduction of muscular movement in the thorax and abdomen, a phenomenon often described as "splinting," which may interfere with the patient's ability to cough and clear secretions. However, at present, evidence to state definitively that any postoperative analgesic technique significantly affects morbidity or mortality after cardiac surgery is insufficient.[480]

Unrelieved pain does have psychological effects. Pain-related anxiety, depression, and sleep deprivation may contribute to delirium in patients in the intensive care setting. A primary benefit of effective pain control is patient satisfaction. So-called fast-track anesthesia, entailing

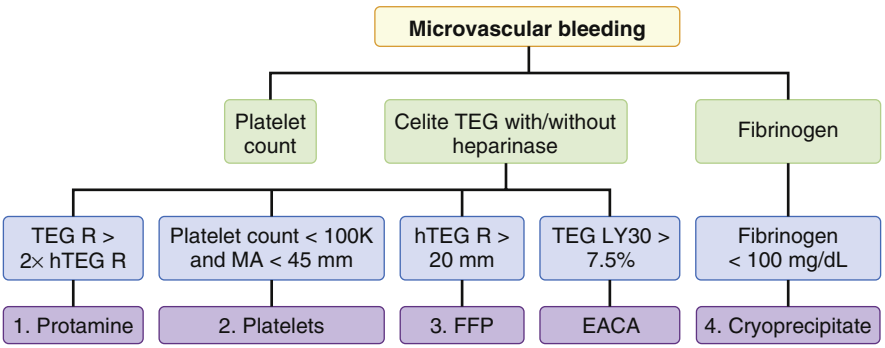

Figure 67-45. Algorithm for transfusion requirements in the thromboelastography (TEG) group in a study. Once bleeding was diagnosed, patients received transfusions based on the results of tests in the algorithm. Based on the assumption that bleeding is often platelet related and on the finding that the platelet count and TEG results return promptly, therapy was given in the numbered order of priority. *EACA,* ε-Aminocaproic acid; *FFP,* fresh-frozen plasma; *hTEG,* heparinase-activated TEG; *LY30,* lysis index at 30 minutes; *MA,* maximum amplitude; *R,* reaction time. *(From Shore-Lesserson L, Manspeizer H, DePerio M, et al: Thromboelastography-guided transfusion algorithm reduces transfusions in complex cardiac surgery,* Anesth Analg *88:312-319, 1999).*

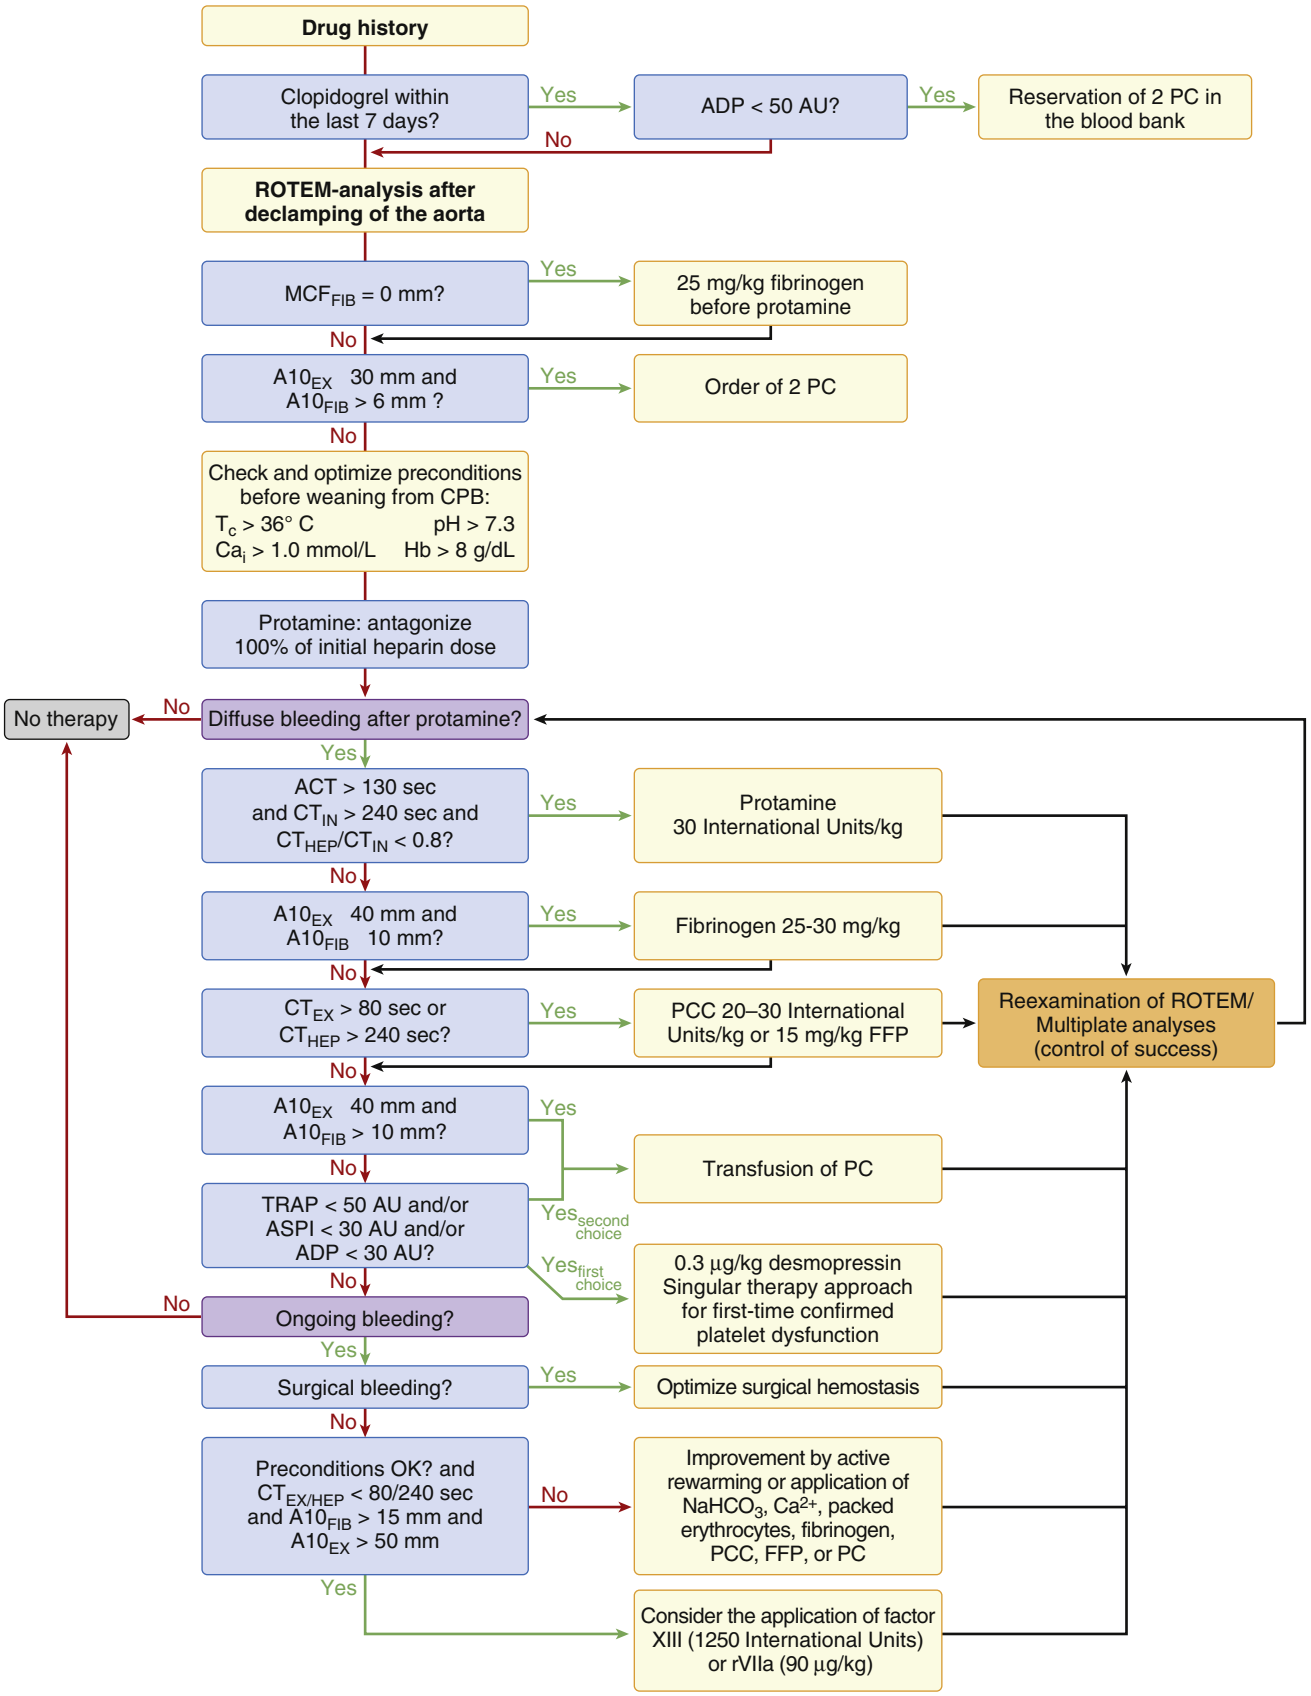

Figure 67-46. Hemostatic therapy algorithm using point-of-care testing. *ACT,* Activated clotting time; *ADP,* ADPtest; *ASPI,* ASPitest; *AU,* aggregation unit; *A10,* amplitude of clot firmness 10 minutes after clotting time; *Ca^{2+},* calcium; *Ca_i,* ionized calcium; *CPB,* cardiopulmonary bypass; *CT,* clotting time; *EX,* EXTEM; *FFP,* fresh frozen plasma; *FIB,* FIBTEM; *Hb,* hemoglobin concentration; *HEP,* HEPTEM; *IN,* INTEM; *MCF,* maximum clot firmness; *$NaHCO_3$,* sodium bicarbonate; *PC,* pooled platelet concentrate; *PCC,* prothrombin complex concentrate; *TRAP,* TRAPtest. The manufacturers of ROTEM (rotational thromboelastometry) and Multiplate were Tem International GmbH and Verum Diagnostica GmbH, respectively, both of Munich, Germany. *(From Weber CF, Gorlinger K, Meininger D, et al: Point-of-care testing: a prospective, randomized clinical trial of efficacy in coagulopathic cardiac surgery patients,* Anesthesiology *117:531-547, 2012.)*

earlier extubation, a relatively brief stay in the ICU, faster discharge from the hospital, and lower overall cost, has become a standard of care for the cardiac anesthesiologist. Effective pain control probably helps achieve these goals.

Opioids remain the gold standard for pain control after cardiac surgery, but these drugs have side effects that include nausea, vomiting, urinary retention, decreased gastric motility, pruritus, sedation, and respiratory depression. A meta-analysis showed small incremental benefits for morphine analgesia that was patient controlled compared with nurse controlled in the treatment of postoperative pain after cardiac surgery.[481]

Intrathecal and epidural local anesthetics and narcotics have increasingly been used to improve analgesia in patients undergoing cardiac surgical procedures. However, neither meta-analyses nor randomized trials of central neuraxial analgesia in cardiac surgical patients have shown that these techniques improve outcome.[482-484] Nevertheless, in some studies, thoracic epidural analgesia did significantly reduce pain and the risk for dysrhythmias, pulmonary complications, and time to tracheal extubation, and it reduced analog pain scores at rest and with activity. Intrathecal analgesia modestly decreased systemic morphine use and pain scores but significantly increased the incidence of itching.[482,483] Although a major concern with the use of intrathecal and particularly epidural analgesia in cardiac surgery is the administration of anticoagulation during the operation and consequent fear of spinal cord damage from a possible epidural hematoma,[484] this complication is rare.[483] Other techniques include the use of bilateral single-shot paravertebral blocks[485] or intercostal nerve blocks followed by a subcutaneous continuous infusion of local anesthetic agents.[486]

Because all analgesics have side effects, some authors have suggested that it is better to use combinations of drugs or techniques (i.e., multimodal analgesia; see also Chapter 98). Theoretically, multimodal analgesia may allow the use of smaller doses of all analgesics and thus reduce the severity of the dose-related side effects of any single drug used.[487] However, despite the appeal of the idea of multimodal analgesic techniques, cyclooxygenase-2–selective inhibitors, as well as nonselective NSAIDs, are contraindicated after cardiac surgery because of the potential for thromboembolic adverse effects.[488]

Chapter 68

Anesthesia for Correction of Cardiac Arrhythmias

SAMUEL A. IREFIN

Key Points

- Cardiac arrhythmias are caused by disorders of impulse formation, disorders of impulse conduction, or both. Cardiac arrhythmias may be life-threatening because of a reduction in cardiac output and/or myocardial blood flow or precipitation of a more serious arrhythmia.
- Radiofrequency ablation is the therapy of choice for many types of cardiac arrhythmias.
- Electrophysiologic studies are used to map out normal and abnormal intracardiac structures. In this process, the mechanism of arrhythmia is delineated and ablation can be performed at the same time.
- Pacing technologies have been developed to treat heart failure resulting in increases in pulse pressure, left ventricular stroke volume, cardiac index, and wedge pressure.
- Implantable pacemakers are placed for treatment of symptomatic bradycardia with the ability to respond to changing hemodynamic demands.
- The development of implantable cardioverter-defibrillators (ICDs) to terminate ventricular tachyarrhythmias by delivering high-voltage shocks to the ventricle has revolutionized therapy for cardiac arrhythmias.
- The main purpose of ICD placement is to prevent sudden cardiac death resulting from hemodynamically unstable ventricular arrhythmias.
- An ICD can be placed for cardiac resynchronization. Cardiac resynchronization therapy improves heart failure symptoms, quality of life, exercise capacity, and electrocardiographic variables.
- Anesthetic management of patients for correction of cardiac arrhythmias depends on associated comorbid illness and the procedure that is planned.

Cardiac arrhythmias are caused by disorders of impulse formation, disorders of impulse conduction, or both. Disorders of impulse formation include enhancement or depression of automaticity, parasystolic activity, and triggered activity. Disorders of conduction include decremental conduction, reentry, entry block, exit block, concealed conduction, and supernormal conduction.[1]

At the present time, radiofrequency catheter ablation has replaced antiarrhythmic drug therapy as the treatment of choice for many types of cardiac arrhythmias. Before the 1980s, cardiac electrophysiology was primarily used to confirm mechanisms of arrhythmias, with management mainly by pharmacologic means. As a result of shortcomings in antiarrhythmic drug therapy (including the results of randomized trials), radiofrequency ablation and implantable cardioverter-defibrillators (ICDs) were developed.[2,3]

HISTORICAL PERSPECTIVES

The treatment of cardiac arrhythmias with device-based therapy may have begun in 1899, when Prevost and Batteli[4] noted almost as an afterthought that direct electric shock could terminate ventricular fibrillation in dogs. Hooker and colleagues[5] showed 3 decades later that the passage of electric current across the heart can initiate and terminate ventricular fibrillation. In 1947, Beck[6] saved the first human life by the successful use of cardiac defibrillation in a 14-year-old boy who developed ventricular fibrillation during a thoracic procedure and went on to achieve full recovery. These early achievements provided the foundation for the landmark work of Mirowski and Mower,[7] which ultimately led to the development of ICDs

in humans in 1980. During the past 3 decades, an increase has occurred in the numbers of patients with pacemakers and ICDs for the correction of cardiac arrhythmias.

SCOPE OF CARDIAC ARRHYTHMIAS

Cardiac arrhythmias are common (see also Chapters 47 and 48). Some cardiac arrhythmias are life-threatening, and others are merely a nuisance. Cardiac arrhythmias are caused by abnormalities in impulse formation or conduction that lead to slow or fast, regular or irregular heart rhythms. At the present time, it is not difficult to treat slow rhythms because available pacemakers are able to adapt slow function to the needs of the body.[8] The situation is different, however, for patients with rapid rhythms. Rapid rhythms may originate anywhere in the heart and result from various mechanisms. These mechanisms may be focal, meaning that the abnormal impulse formation is confined to a small area, or they may be the result of an impulse running in a circuit composed of several interconnected cardiac cells. Such a circuit may be small or large, as in atrial flutter and in arrhythmias in which the normal atrioventricular conduction system and an extra connection between the atrium and the ventricle are incorporated into the circuit of the arrhythmia.[9]

Pharmacologic interventions originally were used to terminate and prevent rapid rhythms. However, antiarrhythmic drugs may have serious side effects and sometimes may even facilitate the occurrence of life-threatening arrhythmias and sudden death.[10] As a result of these effects, techniques were developed for localizing the site of origin or pathway of an arrhythmia and then isolating or destroying the tissue that is responsible. By employing an intracardiac catheter, the site of origin or pathway of an arrhythmia can be identified and the rhythm disturbance corrected by applying radiofrequency, laser, ultrasound, microwave energy, or freezing temperatures to the tissue causing the arrhythmia.

Heart failure is a major problem in elderly patients (see also Chapter 80). Although pharmacologic treatment of heart failure has improved, outcome generally remains poor. New pacing technologies may be used to treat selected patients with heart failure. For many years, permanent pacing has been used to treat symptomatic bradycardia, and pacing may alleviate heart failure when associated with heart block. Several studies have examined the use of conventional dual-chamber atrioventricular–right ventricular pacing for treatment of heart failure in the absence of symptomatic bradycardia or heart block.[3,11] Biventricular pacing aims to restore synchronous cardiac contraction. When ventricular dyssynchrony is reduced, the heart is able to contract more efficiently and increase left ventricular ejection fraction and cardiac output, while working less and consuming less oxygen.[12] In addition, reestablishment of left ventricular synchrony can increase left ventricular filling times, decrease pulmonary capillary wedge pressure, and reduce mitral regurgitation.

NORMAL CARDIAC RHYTHM

In the normal heart, the dominant impulse arises in the sinus node with a rate of 60 to 100 beats/minute (Fig. 68-1). During sleep, the rate may decrease to 30 to 50 beats/minute.[13] Episodes of sinus pauses up to 3 seconds, sinoatrial block, junctional rhythms, and first-degree and second-degree atrioventricular nodal block that occur quite often (especially in trained athletes) are considered to be normal variants.[8]

The impulses generated from the sinoatrial node propagate along three intraatrial conduction pathways: the anterior, middle, and posterior internodal tracts. These tracts are not discrete pathways, but groups of cells that conduct slightly faster than the atrial myocardium.[14] The internodal tracts give rise to interatrial fibers. The electric impulse, whether propagated in the atrial myocardium or along the internodal tracts, converges on the atrioventricular junction. The atrioventricular node located in the atrioventricular junction ultimately receives the impulses generated from the sinoatrial node. The impulses are delayed in the atrioventricular node before they are finally distributed to the ventricular myocardium via the His-Purkinje system.

Normally, the heart rate increases with exercise to at least 85% of the age-predicted maximum of 220 minus age in years; failure to do so is termed chronotropic incompetence. Sinus arrhythmia is defined as sinus rhythm with P-to-P variations of more than 10% (Fig. 68-2). Sinus arrhythmia is due to cyclic variations in vagal tone commonly related to respiration (the rate is faster with inspiration and slower with expiration).[15] Sinus arrhythmia disappears with exercise, breath-holding, and atropine, and is more likely to be seen in individuals who do not have heart disease.[16]

CARDIAC ARRHYTHMIAS

Cardiac arrhythmia is caused by a disorder of impulse generation, impulse conduction, or a combination of both. Cardiac arrhythmia may be life-threatening because of a reduction in cardiac output, reduction in myocardial blood flow, or precipitation of a more serious arrhythmia.[17] Arrhythmias may be described based on (1) rate (bradycardia or tachycardia), (2) rhythm (regular or irregular), (3) origin of impulse (supraventricular, ventricular, or artificial pacemaker), (4) impulse conduction (atrioventricular, ventriculoatrial, or block), (5) ventricular rate, or (6) special phenomena (e.g., preexcitation).

Reentry is a common electrophysiologic mechanism that predisposes to most ventricular arrhythmias and to most supraventricular tachyarrhythmias. The most common mechanism of reentry is based on the model originally proposed by Erlanger and Schmitt and later modified by Wit.[1] This model postulates the presence of a ring or loop of cardiac tissue that is functionally separate from neighboring tissue and the presence of transient or permanent unidirectional block in a portion of the loop. Unidirectional block may be anatomic in origin (e.g., bundle branches, fibrosis, dual pathways, atrioventricular node plus accessory pathway) or functional (e.g., ischemia, drug effect).

Atrial flutter is a macro-reentrant arrhythmia identified by flutter waves, often best seen in the inferior leads at 250 to 350 beats/minute (Fig. 68-3). Patients often present with a 2:1 atrioventricular conduction with a ventricular rate of 150 beats/minute, although the atrioventricular conduction ratio can change abruptly. Atrial fibrillation is a narrow-complex tachyarrhythmia and is the most common in the general population (Fig. 68-4). It is associated with significant morbidity. The prevalence of atrial fibrillation in the general population increases exponentially with age, from 0.9% in individuals 40 years of age to 5.9% in individuals older than age 65 years (see also Chapter 80). The most important risk factors for development of atrial fibrillation in the general population are structural heart disease, valvular heart disease, and left ventricular hypertrophy.[18] Atrial fibrillation is a significant contributor to the development of angina and stroke, with an estimated stroke risk in untreated individuals of 3% to 5%.[19]

Ventricular tachyarrhythmia is defined as three or more consecutive ectopic beats at a rate more rapid than 100 beats/minute (Fig. 68-5).[20] Ventricular tachyarrhythmia is traditionally classified as nonsustained or sustained. Sustained ventricular tachyarrhythmia is defined as ventricular tachyarrhythmia lasting more than 30 seconds. Nonsustained ventricular tachyarrhythmia is defined as ventricular tachyarrhythmia that terminates spontaneously within 30 seconds. Sustained ventricular tachyarrhythmia also is traditionally classified as monomorphic (one site of origin) or polymorphic (two or more sites of origin).[20] Monomorphic ventricular tachyarrhythmia usually results from reentry, and the site of reentry depends in part on the type of heart disease. In patients with coronary artery disease, the reentry circuit is usually located in ventricular myocardium, whereas in dilated cardiomyopathy with left bundle branch block, bundle branch reentry is common.[21] Monomorphic ventricular tachyarrhythmia may occur in individuals with an otherwise normal heart, whereas polymorphic ventricular tachyarrhythmia may occur in acquired states that produce a marked prolongation of the Q-T interval. Nonsustained ventricular tachyarrhythmia is frequently asymptomatic, but may produce palpitations, weakness, and presyncope.[21]

Torsade de pointes is a French term translated as "twisting of the points." It is a syndrome composed of polymorphic ventricular tachyarrhythmia (Fig. 68-6). It may be due to various medications or electrolyte imbalances. Torsade de pointes is usually paroxysmal, but is frequently symptomatic and often produces loss of consciousness. It occasionally degenerates to ventricular fibrillation. Ventricular fibrillation accounts for 80% to 85% of sudden cardiac deaths.[21]

Ventricular fibrillation is usually preceded by ventricular tachyarrhythmia, but also may occur as a primary arrhythmia (Fig. 68-7). More recent studies suggest that ventricular fibrillation results from multiple wavelengths that disperse randomly, using the leading circle form of reentry.[21] The most common cause of ventricular fibrillation is acute myocardial infarction. It also is observed in patients with chronic ischemic heart disease, hypoxia resulting from any cause, acidosis, hypokalemia, and massive hemorrhage.

INDICATIONS FOR CORRECTION OF CARDIAC ARRHYTHMIAS

Intracardiac electrophysiologic studies can give valuable information about normal and abnormal electrophysiology of intracardiac structures (see also Chapters 47, 48, and 108). These studies are used to confirm the mechanism of an arrhythmia, to delineate its anatomic

substrate, and to ablate it. The electric stability of the ventricles also can be assessed, as can the effects of an antiarrhythmic regimen.

In addition, pacing technologies have been developed to treat heart failure with promising results, leading to improvement in morbidity and mortality in patients with heart failure. Hemodynamic responses to biventricular pacing include an increase in the rate of elevation of left ventricular pressure and increases in pulse pressure, left ventricular stroke work, cardiac index, and wedge pressure.[22] Cardiac resynchronization therapy improves ventricular function without increasing myocardial energy consumption, in contrast to the effect of inotropic agents, such as dobutamine.[12] In addition, cardiac resynchronization therapy may reverse left ventricular remodeling over time.[23]

PERMANENT PACING

Indications for pacemaker therapy have increased in recent years and now include the treatment of bradyarrhythmias and heart failure according to the American College of Cardiology and American Heart Association guidelines.[24] These guidelines discuss indications for pacing in patients with sinus node dysfunction, acquired atrioventricular block, chronic bifascicular and trifascicular block, hypersensitive carotid sinus, and neurally mediated syndromes. The guidelines direct the treating physician in selecting patients who would benefit from device therapy.

A Swedish team led by Sennings and Elmqvist implanted the first pacemaker in 1958.[25] A thoracotomy was required, and pacing was done through electrodes sutured to the epicardium. In these early systems, significant problems with changes in pacing threshold, lead infection, and lead breakage were common. Transvenous lead implantation subsequently developed by Furman and colleagues[26] would resolve many of these issues. In 1958, Furman successfully paced an elderly patient with a catheter electrode inserted transvenously. Other investigators took on the challenge of solving various technical problems, such as device miniaturization; longer life batteries; and stable, reliable lead material.[27] As the indication for implantation expanded from atrioventricular conduction disturbances to management of sinus node dysfunction, the need for implantable pacemakers grew in proportion.[27] Technology evolved rapidly with the development of lithium-iodide batteries that had greater longevity. Electronic advances then led to major miniaturization using integrated circuits as opposed to discrete components. Lead materials used in today's pacemaker rely on silicone and polyurethane, which are more biocompatible and reliable than earlier materials. With these technical refinements, present-day pacemakers are small and can pace reliably for 8 to 10 years before generator replacement is needed. The primary functional challenge for contemporary pacemakers is to maintain the heart rate based on circulatory needs, pacing in a manner that mimics the natural physiology of excitation and conduction. In a healthy heart, the sinus node is modulated by the autonomic nervous system, and its rate is determined by a multiplicity of factors, such as physical activity, emotion, and blood pressure. Not only the rate, but also the activation sequence and atrioventricular conduction time vary with demand; these requirements also must be

considered. Rate is controlled by pacemaker discharge, and the excitation and conduction sequence depends on the placement of pacing electrodes. Approximately 120,000 pacemakers are implanted each year in the United States. Indication for implantation for most of these cases is sick sinus syndrome. Other indications include atrioventricular block, carotid sinus hypersensitivity, malignant vasodepressor syndrome, and hypertrophic cardiomyopathy.[28] The primary purpose of implantable pacemakers is to treat symptomatic bradycardia. With the extraordinary developments that have occurred in pacemaker therapy for the traditional indication—bradycardia—new uses are now beginning to be explored. Pacemakers have progressed from large, fixed-rate, single-chamber devices to multiprogrammable, multichamber devices with the ability to respond to changing hemodynamic demands. As technology advances, other possible uses are likely to be conceived.

RESYNCHRONIZATION THERAPY

Cardiac resynchronization is a pacing therapy aimed at improving coordination of atria and both ventricles. This therapy has been demonstrated to be effective for patients with heart failure who have conduction delay and left ventricular systolic dysfunction.[29] In addition, this therapy can reduce hospital readmission rates and improve quality of life in patients with heart failure.[30]

Cardiac resynchronization therapy improves heart failure symptoms, quality of life, exercise capacity, hospitalization, and echocardiographic variables.[31] It is indicated in patients with drug-refractory, symptomatic New York Heart Association functional class III and IV heart failure of either ischemic or nonischemic origin.[30] In addition, these patients are protected from associated risk for sudden cardiac death when combined with an ICD system.[29]

The development of an automatic internal defibrillator, or ICD, began in the 1960s. External cardiac defibrillation was increasingly being used in coronary care units for the treatment of ventricular fibrillation and sudden cardiac death. Although the idea of automatic external defibrillation had been discussed initially by Zycoto, Mirowski and colleagues[32] were the first to champion and begin practical development of an automatic internal device. In 1969, Mirowski and Mower developed the prototype of today's automatic internal defibrillator.[33]

The primary goal of all defibrillators is to terminate ventricular tachyarrhythmias by delivering high-voltage shocks to the ventricle. As with implantable pacemakers, defibrillating devices need to be small and reliable and have adequate longevity. ICDs have evolved not only to perform this function but also to take on additional tasks, such as antitachycardia pacing of the ventricle, dual-chamber pacing, and termination of atrial tachyarrhythmias.

A key difference between pacing and defibrillation of the heart is that for pacing only a very small mass of myocardium needs to be stimulated, whereas for defibrillation, most, if not all, of the myocardium must be stimulated. Because the myocardium is easily excitable throughout diastole, a small wave of depolarization during pacing can readily propagate throughout the whole heart. In contrast, during ventricular fibrillation, multiple reentrant wavefronts usually occur that are continuously changing in location and size and must be quelled. To defibrillate successfully, most of these wavefronts must be interrupted simultaneously; to achieve this, it is necessary to capture most of the tissue that is in a state of relative refractoriness.[34] One unique property of defibrillation success is that it is probabilistic.[35] The same energy that can defibrillate the heart on one occasion may be unsuccessful at another time.

The main purpose of ICD placement is to prevent death from hemodynamically unstable ventricular tachyarrhythmias. Although advances in technology have made these devices much more flexible in terms of arrhythmia detection and electric therapy potions, their main purpose is to reduce sudden cardiac death, which claims approximately 300,000 lives in the United States annually. Secondary prevention of sudden cardiac death in patients who have survived cardiac arrest is another major indication for ICD placement. In such patients and especially in patients of this group for whom no reversible or curable cause can be found, ICD implantation has been repeatedly documented to provide a major mortality benefit.[36] Interest in managing atrial tachyarrhythmias also has grown significantly in recent years. It is now recognized that approximately 30% of patients with ventricular tachyarrhythmia also have atrial tachyarrhythmias.[37] Such atrially initiated tachyarrhythmias can worsen patient symptoms, can result in inappropriate ventricular shocks, and may be responsible for initiating ventricular tachyarrhythmias that can exacerbate other pathologic processes, such as heart failure. New strategies for treatment and prevention of atrial tachyarrhythmias are incorporated into devices that are capable of defibrillation and antitachycardia pacing in the atrium and ventricle, in addition to combined dual-chamber pacing.[38]

The relative ease of ICD implantation and longevity of current defibrillators have made them a valuable tool in primary prevention. Patients no longer must survive cardiac arrest to justify the risk in ICD implantation.

PREOPERATIVE EVALUATION

Most patients who require pacemaker or ICD placement have significant cardiovascular disease. In addition, correction of cardiac arrhythmia may require radiofrequency catheter ablation. Radiofrequency catheter ablation has proved highly effective in the treatment of atrioventricular nodal reentrant and accessory pathway tachycardias. Indications for pacemaker and ICD placement continue to evolve as the utility of these devices continues to increase. Although most pacemaker placement is done with local anesthetic infiltration, ICD placement may require monitored anesthesia care or in some cases general anesthesia. The modern ICD unit is capable of delivering the full spectrum of therapy for ventricular tachyarrhythmias and for bradycardia therapy with dual-chamber pacing or sensing, rate modulation, and mode-switching features.

As mentioned earlier, ICD placement has two common indications. One is continued ventricular tachyarrhythmias despite adequate drug therapy, and the other is

history of sudden cardiac arrest that is not associated with myocardial infarction. Preoperative evaluation processes necessary for placement of an ICD should be complete by the time the decision is made to place the device (see also Chapters 38 and 39). These patients need a thorough preoperative evaluation. This evaluation includes electrophysiologic testing to determine the inducibility of ventricular tachycardia and electrophysiologically guided drug therapy. Preoperative pulmonary function tests may be necessary in patients on amiodarone to evaluate possible toxicity of this drug, which can result in chronic obstructive pulmonary disease or interstitial lung disease. In some instances, the underlying pathophysiology of malignant ventricular arrhythmias is related to ischemic or idiopathic cardiomyopathy.[39] These patients often present with poor left ventricular function and more frequent incidence of congestive heart failure. Patients with a history of congestive heart failure should be in optimal condition before surgery.

Generally, all patients who present for correction of cardiac arrhythmia require preoperative evaluations including electrocardiogram (ECG), chest radiograph, hemoglobin value, and electrolyte levels. Patients should receive nothing by mouth (NPO) for at least 8 hours before the procedure. In addition, patients who require device and lead extractions because of malfunction or infection may require blood product transfusions during the procedure. Consequently, type and crossmatch of blood products is frequently necessary for these procedures (also see Chapter 61).

ANESTHETIC CONSIDERATIONS

Pacemakers

Permanent implantable pacemakers have been the standard modality of treatment for patients with all types of bradyarrhythmias. A significant number of these patients present with sick sinus syndrome and are older. Consequently, devices are placed under general anesthesia in these patients. As a result of more recent advances in pacemaker technology, these devices now can be placed as a therapeutic modality to alter hemodynamic states. Surgeons used to be primarily responsible for device insertion. Now the task falls under the services of cardiologists. Device placement is commonly performed in the cardiac catheterization suite under local anesthesia on an outpatient basis. Patients at high risk who have complicated disease now present for pacemaker insertion, however, in addition to those with indications more recently identified by the American College of Cardiology and American Heart Association for these devices. In light of these increased indications, the expertise of anesthesiologists is needed for monitoring and perioperative care of these patients.

Monitored Anesthesia Care

Currently, most pacemaker insertions are performed by cardiologists. Most of these cases are performed under local anesthesia with sedation. Depending on the level of training, administration of sedatives and analgesics can be provided by nurses.

In instances that require deeper sedation for a patient's comfort or for critically ill patients with hemodynamic instability, monitored anesthesia care by an anesthesiologist may be required (see also Chapter 89). Adequate monitoring and resuscitation equipment are required in such situations. The goal of monitored anesthesia care is to provide analgesia, sedation, and anxiolysis, while ensuring rapid recovery with minimal or no side effects. Any sedative-hypnotic medication may be used during monitored anesthesia care with a wide variety of delivery systems.[40] Subanesthetic concentrations of inhaled agents also have been used to supplement local anesthetics. Newer drugs, such as centrally mediated α_2-agonists, have been shown to produce anxiolysis, sedation, and reduced requirements for supplemental analgesic medications during monitored anesthesia care.

General Anesthesia

Patients requiring pacemaker placement rarely require general anesthesia for placement. If general anesthesia is required, it should be directed toward underlying cardiac pathophysiology, indications, complications, and hemodynamic goals. Immediate access to life-support equipment, such as a cardiac defibrillator and a transcutaneous pacemaker, is necessary if the device is being placed under general anesthesia.

IMPLANTABLE CARDIOVERTER-DEFIBRILLATOR

Since the 1980s, indications for use and implantation of ICDs have steadily increased. Over the past 2 decades, ICDs have undergone a significant evolution. In the 1970s and 1980s, ICD placement usually required thoracotomy for placement of epicardial patches.

PREOPERATIVE EVALUATION

As mentioned earlier, common indications for ICD implantation include continued ventricular tachyarrhythmias unresponsive to adequate pharmacotherapy and history of sudden cardiac arrest unassociated with myocardial infarction. Newer indications include patients with various forms of the congenital long QT syndrome.[41] Patients with long QT syndrome who have survived an episode of cardiac arrest or documented polymorphic ventricular tachyarrhythmia, especially if on pharmacotherapy at the time, are increasingly being evaluated as ICD candidates. In addition, patients with hypertrophic cardiomyopathies and without a history of sudden death are usually evaluated for ICD placement.[42] In these patients, sustained ventricular arrhythmias, nonexertional syncope, or a strong family history of sudden death with early age of presentation strongly indicates ICD implantation.

In all instances, the evaluation that is necessary for ICD implantation is completed by the time the decision is made to place the device (see also Chapters 38 and 39). Electrophysiologic studies may have been done to determine the forms of arrhythmias present. When the pathophysiology of ventricular arrhythmias is related to

idiopathic or ischemic cardiomyopathy,[43] these patients may present with poor left ventricular function and a high incidence of congestive heart failure. Consequently, they should be optimized as much as possible preoperatively.

ANESTHETIC CONSIDERATIONS

In the 1980s, ICD implantation was done with epicardial leads via thoracotomy under general anesthesia with one-lung ventilation. The technologic development of implantable ICDs with transvenous lead systems has simplified their implantation. Consequently, it was reasoned that ICDs can be placed under deep sedation with little or no intervention by the anesthesiologist analogous to what is needed for pacemaker placement.[44] Placement of an ICD under general anesthesia may be safer and more comfortable for the patient, however. Patients who present for ICD placement are often critically ill with cardiopulmonary comorbidity. These patients often present with ejection fractions of less than 30% and require vasopressors to support hemodynamics during the procedure. In addition, some form of general anesthesia is necessary for intraoperative testing of defibrillating thresholds.

Monitored Anesthesia Care

Small, new-generation devices and transvenous lead systems lend themselves to the use of local anesthesia and intravenous sedation for ICD implantation. Midazolam and fentanyl are usually the drugs of choice when an ICD is placed under monitored anesthesia care (see also Chapter 89). Monitoring includes pulse oximetry, five-lead ECG, and noninvasive blood pressure. Depth of anesthesia is monitored clinically. One of the major aspects of ICD placement is testing the device. Testing the device may require deep sedation or general anesthesia because the shocks associated with this procedure can be very painful. The presence of an anesthesiology team may be necessary for ICD placement under monitored anesthesia care.

General Anesthesia

Most patients who present for ICD placement typically have comorbidities such as ventricular tachycardia, congestive heart failure with ejection fraction less than 30%, coronary artery disease, pulmonary hypertension, chronic renal insufficiency, or valvular heart disease. These patients may be unable to lie flat for the prolonged period necessary for placement of the ICD. In addition, they may require close hemodynamic monitoring during testing of the device. General anesthesia should be considered in these patients. When general anesthesia is chosen, in addition to standard monitoring, an arterial line may be added. External cardioverter-defibrillator pads are required for all ICD placements. These are employed in cases in which an implanted defibrillator fails. General anesthesia also may be requested for anxious and extremely nervous patients. Because pacemakers and ICDs are placed percutaneously, anesthesiologists must be vigilant for possible complications, such as myocardial infarction, stroke, possible cardiac injury (perforation or tamponade), and pneumothorax from subclavian vascular access.

EXTRACTION OF DEVICES

As a result of continued growth and expanding indications for pacemakers and ICD placement, leads may require extraction because of mechanical dysfunction, the need to upgrade to more complex devices, or local or systemic infection. Lead extractions are probably one of the most challenging procedures that a cardiac electrophysiologist faces today.

Indications for lead extractions can be divided into two categories—patient-related and lead-related. Patient-related indications include infection, ineffective therapy (high defibrillation threshold), perforation, migration, embolization, induction of arrhythmias, venous thrombosis, unrelenting pain, device interactions, and device upgrades.[45] Lead-related indications include lead recalls, lead failure, and lead interactions.[46] Lead extraction is performed via powered sheaths through which energy is delivered to the tip in the form of excimer laser light or electrocautery. These systems burn through scar tissue adherent to the wall of the lead throughout its course. The potential for life-threatening complications, such as lead fracture, venous or myocardial rupture, and tamponade, makes general anesthesia with invasive monitors a prudent choice for lead extractions.

POSTOPERATIVE CARE

Postoperative care of patients with pacemaker or ICD implantation depends on various factors surrounding the implantation of the device (see also Chapter 96). As mentioned earlier, most of these patients are quite ill with significant comorbidities. It is not unusual for patients to have congestive heart failure with an ejection fraction less than 30% as a result of poor left ventricular function. Consequently, it is imperative to have these patients monitored in the postanesthesia care unit, especially if the device is placed or extracted under general anesthesia. The spectrum of recovery sites after these procedures may vary from postprocedure units to a coronary intensive care unit. Most of these procedures are done on an outpatient basis, and anesthesia is tailored to ensure rapid recovery after implantation.

CORRECTION OF CARDIAC ARRHYTHMIAS WITH ABLATION THERAPY

Catheter ablation is a safe and curative option for most cardiac arrhythmias, with 85% to 98% cure rates among the arrhythmias treated most frequently.[47] The rate of major complications is less than 3%.[47] Cardiac ablation therapy involves the delivery of energy through a catheter that is usually placed in the endocardial position in the heart, destroying myocardial tissue that is responsible for the tachyarrhythmia (Fig. 68-8). Multiple electrodes are inserted to locate the arrhythmia and ablate it. Usually the diagnostic portions of the ablation study are done during the same procedure.[48] The efficacy of catheter ablation depends on accurate identification of the site of origin of the arrhythmia. When the site is identified, the electrode catheter is positioned in direct contact with

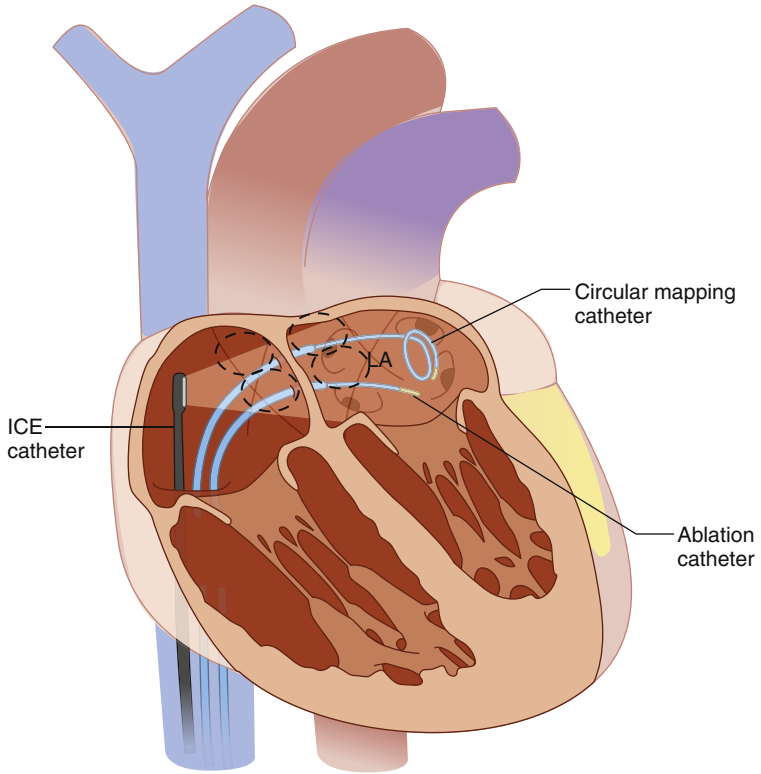

Figure 68-8. Catheter placement during ablation procedures. Mapping and ablation catheters were placed under the guidance of intracardiac echocardiography. *ICE,* Intracardiac echocardiography. *(Courtesy O. Wazni, MD, Cleveland Clinic, Cleveland, OH.)*

the site of the arrhythmia, and radiofrequency energy is delivered through the catheter to destroy it.

The current generated by radiofrequency is alternating current and is delivered at cycle lengths of 300 to 750 kHz when used for catheter ablation.[49] It causes resistive heating of the tissue in contact with the electrode. The degree of tissue heating is inversely proportional to the radius to the fourth power.[50] Consequently, the lesions created by radiofrequency energy are small. Although electric injury may be a contributing factor, the primary mechanism of tissue destruction by radiofrequency current is thermal injury. Acute lesions created by a radiofrequency current consist of a central zone of coagulation necrosis surrounded by a zone of hemorrhage and inflammation.[51] Cardiac arrhythmias that can be treated with radiofrequency ablation include paroxysmal supraventricular tachycardia, Wolff-Parkinson-White syndrome, atrial flutter, atrial fibrillation, and idiopathic ventricular tachycardia. Most cardiac arrhythmias treated with radiofrequency ablation are not life-threatening but have a significant impact on a patient's quality of life.[52] Advantages of radiofrequency ablation of cardiac arrhythmias include relief of symptoms, improvement in functional capacity and quality of life, and elimination of the need for lifelong antiarrhythmic drug therapy. The principal disadvantage is the risk for complications, which varies depending on the type of ablation procedure and skill of the operator.

ANESTHETIC CONSIDERATIONS

Catheter ablation was introduced into clinical practice in 1982. Initially, ablation was performed with direct electric shocks.[53] As a result of several advantages over direct current, radiofrequency ablation has replaced direct current ablation. These advantages include the absence of skeletal and cardiac muscle stimulation, minimal discomfort during delivery of energy, the possibility of performing the procedure in conscious patients, and the discrete nature of resulting lesions.[51]

Most cardiac ablation therapy for correction of arrhythmias can be performed under moderate sedation or monitored anesthesia care. In some of these cases, deep sedation may be required as the case progresses. In a few cases, general anesthesia may be required if the patient is anxious or cannot tolerate lying in the supine position for an extended period. General anesthesia may be implemented for these patients with standard American Society of Anesthesiologists monitors with adequate vascular access. Catheter ablation is the first-choice treatment for most cardiac arrhythmias. It is a safe treatment and is usually effective as a single procedure. Because it is curative in many patients, it is offered to all patients who would otherwise be committed to long-term drug therapy.

FUTURE TRENDS

Correction of cardiac tachyarrhythmias has improved dramatically in the past 2 decades. Emphasis has shifted from pharmacologic therapy to nonpharmacologic therapy of tachyarrhythmias; this has led to a significant increase in the numbers of radiofrequency catheter ablations and defibrillator implantations. These developments were triggered by technologic advances that showed superiority of

these procedures over the use of antiarrhythmic drugs.[54] As a result, treatment of supraventricular tachycardias and tachycardias involving accessory atrioventricular pathways will probably remain the domain of catheter ablation. The cure rate of patients treated with catheter ablation is very high. In addition, treatment of life-threatening ventricular tachyarrhythmia will remain in the domain of ICDs for the foreseeable future. The role of ICD therapy has been clearly defined with respect to prolongation of life and has been expanded to include primary prophylaxis of sudden death in high-risk populations.[55]

The demand for perioperative care in the electrophysiology suite, especially for those undergoing ablation procedures, has resurrected the use of high-frequency jet ventilation (HFJV) in recent years.[56] Although the use of HFJV in the electrophysiology suite is relatively new, studies have demonstrated improved outcomes and decreases in procedure time.[57] HFJV has been demonstrated to provide a more stable environment, especially in the posterior wall of the atrium. As a consequence, in the future HFJV use will increase and provide an attractive alternative to the conventional mode of ventilation during catheter ablation.[19,58] The anesthetic implications of this modality in the electrophysiology suite has recently been reviewed.[59]

As a result of these developments, the presence of an anesthesiology team will continue to increase in cardiology suites. Patients who are being cared for in these areas are sicker with significant comorbidities. The role of conscious sedation will continue to diminish in the performance of these procedures. These patients will require full monitoring and care under the direction of an anesthesiologist.

Chapter 69

Anesthesia for Vascular Surgery

EDWARD J. NORRIS

Key Points

- Perioperative management of patients undergoing vascular surgery requires an understanding of the underlying pathophysiology of the specific vascular lesion.
- Major vascular surgery is particularly challenging to the anesthesiologist because these are high-risk operations in a patient population with a high prevalence of either overt or occult coronary artery disease, which is the leading cause of perioperative and long-term mortality after vascular surgery.
- Accurate clinical assessment of the pretest probability of significant coronary artery disease is necessary for prudent use and rational interpretation of preoperative cardiac testing.
- Guidelines on perioperative cardiovascular evaluation and care suggest that coronary intervention is rarely necessary to simply decrease the risk for surgery unless such intervention is indicated, irrespective of the preoperative context. Prophylactic coronary revascularization has not been shown to reduce perioperative or long-term morbidity after major vascular surgery. Medical therapy is the cornerstone for the management of coronary artery disease.
- Patients should take their usual cardiovascular medications throughout the perioperative period. Antiplatelet therapy requires special consideration and must be individualized to each patient.
- Prevention and treatment of perioperative myocardial ischemia require careful control of the determinants of myocardial oxygen supply and demand. ST-segment monitoring, particularly with computerized ST-segment analysis, should be used to detect myocardial ischemia during the perioperative period.
- Initiation of perioperative β-adrenergic blocker therapy has potential benefits and risks.
- All patients who require statin therapy on an ongoing basis should also receive statins in the perioperative period.
- The clinical usefulness of any intraoperative monitoring technique ultimately depends on patient selection, accurate interpretation of data, and appropriate therapeutic intervention.
- Maintenance of vital organ perfusion and function by the provision of stable perioperative hemodynamics is more important to overall outcome after aortic surgery than is the choice of anesthetic drug or technique.
- The pathophysiology of aortic cross-clamping and unclamping is complex and depends on many factors, including the level of the cross-clamp, the extent of coronary artery disease and myocardial dysfunction, intravascular blood volume and distribution, activation of the sympathetic nervous system, and the anesthetic drugs and techniques.
- The degree of preoperative renal insufficiency is the strongest predictor of postoperative renal dysfunction.
- Endovascular aortic surgery has become an established less invasive alternative to conventional open aortic repair. Endoleak, or the inability to obtain or maintain complete exclusion of the aneurysm sac from arterial blood flow, is a complication specific to endovascular aortic repair.
- The primary clinical utility of cerebral monitoring during carotid endarterectomy is to identify patients in need of carotid artery shunting; second, such monitoring is used to identify patients who may benefit from an increase in arterial blood pressure or change in surgical technique.
- Postoperative hypothermia is associated with many undesirable physiologic effects and may contribute to adverse cardiac outcome.

The perioperative management of patients undergoing vascular surgery is one of the most challenging and controversial areas in the field of anesthesiology. Given the frequent occurrence of coexisting disease in elderly patients (see also Chapter 80), the hemodynamic and metabolic stress associated with arterial cross-clamping and unclamping, and the ischemic insults to vital organs, including the brain, heart, kidneys, and spinal cord, perioperative morbidity and mortality are more frequent with vascular surgery than with most other surgical procedures. Anesthesia care must focus on preservation of vital organ function, with a strong emphasis on the heart, which is the single most important cause of morbidity after vascular surgery. The clinical controversies associated with vascular surgery are diverse and involve aspects of preoperative, surgical, anesthetic, and postoperative management. The controversy associated with routine preoperative screening for coronary artery disease (CAD), as well as appropriate treatment if detected, has particular importance (see also Chapters 38 and 39). A specific anesthetic technique has not been established because vascular procedures often lend themselves to local, regional, general, or combined techniques.

In the 1970s, vascular surgery was recognized as a risk factor for perioperative cardiac morbidity. In the 1980s, the focus shifted to risk stratification in an effort to identify patients who were at the most frequent risk for morbid outcomes. In the 1990s, intensive clinical investigation involving anesthetic technique, sympatholytic drugs, hemodynamic control, and analgesic technique was undertaken and provided important insight into the prevention, treatment, and mechanisms of cardiac and other morbidity. During this time, a guideline-based approach to health care was initiated, primarily in the United States (see also Chapter 102). Over the last decade, a paradigm shift occurred away from routine preoperative screening for CAD with a focus on risk stratification and invasive treatment of CAD to an intensive strategy of perioperative cardiac risk reduction using medications and risk factor modification (see also Chapters 38 and 39). Additionally, over the last decade the multidisciplinary field of endovascular surgery has provided less invasive approaches or alternatives to conventional vascular reconstruction. These less invasive procedures, initially offered to patients traditionally considered unfit for open surgery, are being widely applied to the larger cohort of patients undergoing vascular surgery.

The goal of this chapter is to review issues related to the perioperative care of patients undergoing vascular surgery and to address the underlying controversies. For simplicity, the five major categories of vascular surgical procedures are discussed separately: abdominal aortic surgery, thoracoabdominal aortic surgery, endovascular aortic surgery, lower extremity vascular surgery, and carotid surgery.

ATHEROSCLEROSIS

Cardiovascular diseases place an enormous burden on health care systems worldwide and are the leading cause of death and disability in the United States. Their underlying pathologic process is atherosclerosis, a slowly progressing chronic disorder of the arterial wall that compromises the blood supply to any or all of the vital organs or the extremities and leads to the clinical manifestations of myocardial infarction (MI), stroke, and gangrene. The lesions of atherosclerosis occur primarily in large and medium-sized arteries and tend to form at sites with disturbed laminar flow, such as branch points. The most common sites are the coronary arteries, carotid bifurcation, abdominal aorta, and iliac and femoral arteries (Fig. 69-1). Although atherosclerotic lesions result from a variety of complex pathogenetic processes, progression of atherosclerosis occurs in several stages. The initial lesion of atherosclerosis, the fatty streak, starts in early childhood and is initiated by intimal accumulation of low-density lipoprotein (LDL) particles. The fatty streak lesion consists largely of T cells and lipid-laden macrophages called foam cells. With the progressive accumulation of apoptotic and degenerated foam cells, cell debris, and cholesterol crystals, the fatty streak progresses to an atheromatous plaque with a necrotic lipid core. A more complex lesion develops with the formation of a fibrous cap of variable thickness composed of collagen and proliferated smooth muscle cells. The advanced lesions of atherosclerosis represent a progression of the fibroatheromatous plaque, with an expanded lipid-rich core, accumulation of calcium, and disruption of endothelial integrity. Physical disruption of the plaque's fibrous cap permits contact between flowing blood elements, including platelets and coagulation proteins, and the highly thrombogenic material located in the lesion's lipid core, such as collagen and tissue factor, which results in thrombus formation (i.e., atherothrombosis) or, in the case of intraplaque hemorrhage, plaque progression. Atherothrombosis may lead to complete vascular occlusion at the site of plaque rupture or detach to become an embolus that can block blood flow distal to its origin.

The American Heart Association Committee on Vascular Lesions has provided a numerical classification of histologically defined atherosclerotic lesion types.[1] Figure 69-2 outlines the most updated classification.[2] Lesion types I, II, and III are always small and clinically silent. With the development of type IV lesions, the pathways to clinical disease vary (see Fig. 69-2). Although lesions IV through VI may progress such that they obstruct the lumen of a medium-size or large artery and produce a clinical event (i.e., MI, ischemic stroke, or extremity ischemia), the clinical manifestations of atherosclerotic disease are most often associated with type VI lesions. The criteria for type VI histology are often interrelated and include one or more of the following: surface defect, hematoma, and thrombosis. Regression of lipid from lesion types IV, V, and VI may result in lesion morphology similar to that of type VII and VIII lesions.

Established risk factors for atherosclerosis-related cardiovascular disease are male gender, age, family history of premature cardiovascular disease, high levels of LDL cholesterol, low levels of high-density lipoprotein (HDL) cholesterol, diabetes, obesity, hypertension, and smoking. Newer and emerging risk factors include homocysteine, fibrinogen, lipoprotein(a), apolipoproteins B and A-I, and high-sensitivity C-reactive protein (hsCRP). Atherosclerosis usually has no early warning signs, making primary prevention difficult and often delaying risk modification until the

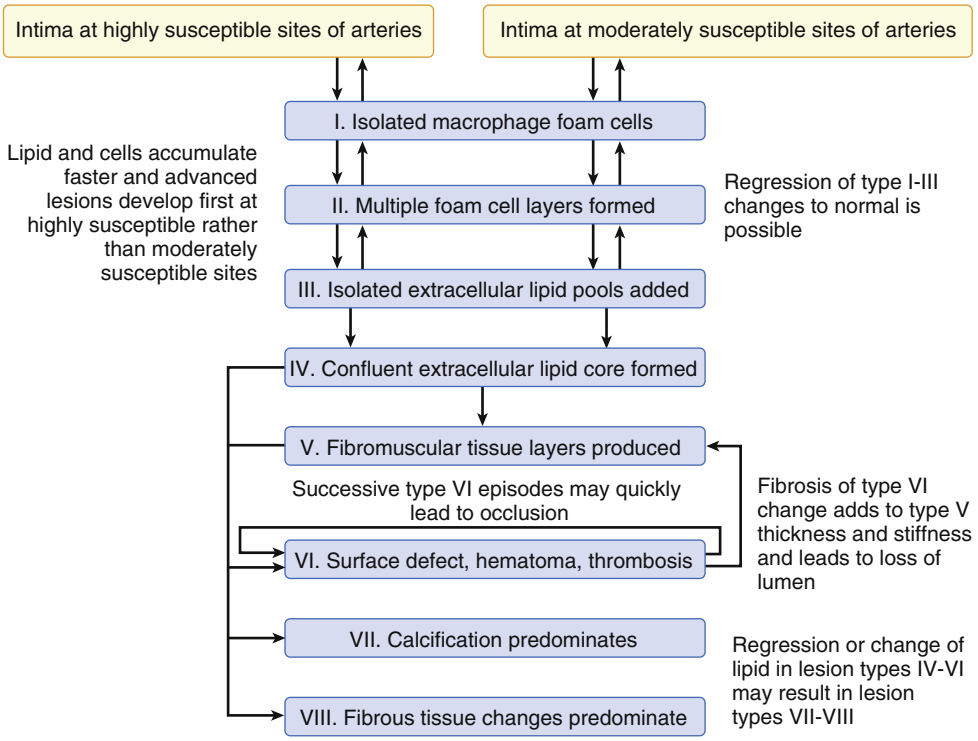

Figure 69-1. Outline of the sequence in the evolution of atherosclerotic lesions from type I to type IV and of the various possible subsequent pathways of progression to lesion types beyond type IV. The diagram lists the main histologic characteristics of each sequential step (lesion type). *Thick or* differentiate between the relative ease with which lesions develop at specific sites, or they indicate the relative frequency and importance of a pathway section. (From Stary HC: Natural history and histological classification of atherosclerotic lesions: an update, *Arterioscler Thromb Vasc Biol* 20:1177-1178, 2000.)

disease has progressed to an advanced stage. Established pharmacologic strategies against atherosclerosis are largely limited to treating hypertension and hyperlipidemia and controlling hemostasis to prevent thrombotic complications. Inhibitors of hydroxymethylglutaryl coenzyme A (i.e., statins) are the lipid-modifying drugs of choice and their efficacy in lowering LDL cholesterol and the risk for cardiovascular events is well established in large outcome-based clinical trials.[3] Antiplatelet drugs, including aspirin and thienopyridines such as clopidogrel, are widely used to prevent vascular events in patients with cardiovascular disease.

Inflammation in the arterial wall plays a fundamental role in both atherogenesis and atheroprogression.[4] Serum markers of inflammation, such as hsCPR, are being used in cardiovascular risk stratification. hsCPR levels are correlated with risk for death and MI and with the development of peripheral vascular disease. As a result of this new understanding, inflammation has become a therapeutic target in the prevention and treatment of atherosclerosis and its complications. Statins have important antiinflammatory modes of action that are independent of LDL cholesterol lowering. For example, treatment with statins decreases hsCRP in patients with atherosclerosis by 13% to 50% in contrast to placebo, and decreased levels of hsCRP while receiving statins is associated with improved clinical outcome.

PREOPERATIVE EVALUATION

COEXISTING DISEASE

Patients undergoing vascular surgery have a frequent incidence of coexisting disease, including diabetes mellitus, hypertension, renal impairment, and pulmonary disease, all of which should be assessed and, if possible, optimized before surgery (see also Chapters 38 and 39). Because of the systemic nature of atherosclerotic disease, patients with vascular disease frequently have arterial disease affecting multiple vascular territories. CAD is the leading cause of perioperative mortality at the time of vascular surgery, and long-term survival after vascular procedures is significantly limited by the frequent occurrence of morbid cardiac events.[5] Less than 10% of patients who undergo vascular surgery have normal coronary arteries, and more than 50% have advanced or severe CAD. Unrecognized MI (determined by wall motion abnormalities at rest in the absence of a history of MI) and silent myocardial ischemia (determined by stress-induced wall motion abnormalities in the absence of angina) often occur in vascular surgery patients (23% and 28%, respectively) and are associated with increased long-term mortality and adverse cardiac events.[6] Left ventricular systolic dysfunction is five times more common in patients with vascular disease than in matched controls.[7] It is not clear whether any specific category of vascular disease is associated with a greater likelihood of coexisting CAD. Some investigators have shown a similar incidence and severity of CAD in patients with aortic, lower extremity, and carotid disease. Others have shown that patients with lower extremity vascular disease are more likely to have significant CAD and to experience perioperative morbidity. Medical therapy is the cornerstone of the management of CAD.

PERIOPERATIVE AND LONG-TERM CARDIAC OUTCOMES

Preoperatively, the potential for MI and death in patients undergoing vascular surgery must be considered (Table 69-1). Nonfatal and fatal MIs are the most important and specific outcomes that determine perioperative cardiac morbidity. When multiple recent studies are pooled, the

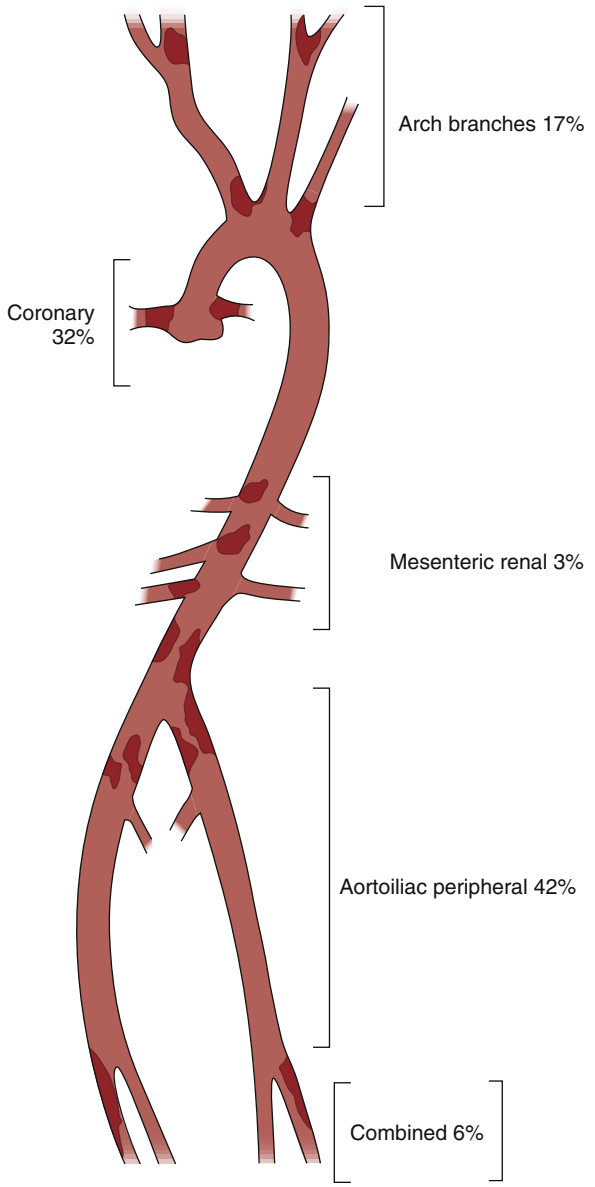

Figure 69-2. Distribution of atherosclerotic lesions. Plaques occur at the origins of large vessels and at bifurcations. Distribution and relative severity differ based on risk factors. MI, *Myocardial infarction.*

*For short-term follow-up, outcomes are reported for the duration of the hospital stay or 30 days, and death from MI was classified as both MI and death. For long-term follow-up, MI was not included as a subset of death because the cause of death was often unknown. The incidence of MI is underestimated in the long-term part of the table.

overall prevalence of perioperative MI and death is 4.9% and 2.4%, respectively. When outcomes are assessed over the long term (2 to 5 years), the prevalence of MI and death is 8.9% and 11.2%, respectively. This perioperative and long-term morbidity and mortality persist despite aggressive medical and surgical therapy.[8]

GUIDELINE-BASED APPROACH

A guideline-based approach to health care is relatively new and originated primarily in the United States. The American College of Cardiology (ACC) Foundation and the American Heart Association (AHA) jointly produced guidelines in the area of cardiovascular disease for more than 2 decades. The ACC/AHA Task Force on Practice Guidelines published "Guidelines on Perioperative Cardiovascular Evaluation for Noncardiac Surgery" in 1996. This evidence-based approach to perioperative evaluation and management was updated in 2002 and 2007,[9,10] and in 2009.[11] New guidelines will be published in 2014. A stepwise approach (simplified from the 2007 guidelines) to perioperative cardiac evaluation and care for noncardiac surgery is provided in Chapter 38. The authors emphasize that the purpose of the preoperative evaluation is not to give medical clearance but rather to perform an evaluation of the patient's current medical status; make recommendations concerning the evaluation, management, and risk for cardiac problems; and provide a clinical risk profile that the patient and caregivers can use in making treatment decisions that may influence perioperative and longer term cardiac outcomes. The overriding theme of the perioperative guidelines is that intervention is rarely

necessary to simply lower the risk associated with surgery unless such intervention is indicated irrespective of the preoperative context. Thus, preoperative testing should not be performed unless it is likely to influence patient care. The particular challenge that the vascular surgery patient presents is emphasized throughout the document. Aspects of the updated guidelines and their evidence-based approach will be discussed throughout this chapter.

CARDIAC RISK ASSESSMENT

The preoperative cardiac assessment presents an opportunity to initiate and optimize pharmacologic management, perform appropriate diagnostic and therapeutic interventions, and adjust overall care to decrease not only perioperative risk but also long-term risks from cardiovascular events. The challenge for clinicians is to accurately assess risk for cardiac morbidity while maintaining a cost-effective, clinically relevant, and evidence-based strategy. The ACC/AHA stepwise approach considers vascular surgery distinct from other noncardiac surgical procedures and is reviewed in detail in Chapter 38. Only issues specific to vascular surgery are reviewed in this chapter.

After assessment of cardiac risk, the additional challenge exists of modifying perioperative management to reduce risk by adjusting or adding cardiac medications (e.g., β-adrenergic blocker), direct coronary intervention (e.g., percutaneous coronary intervention [PCI] or coronary artery bypass grafting [CABG]), modifying or intensifying perioperative management (e.g., invasive hemodynamic monitoring), or changing preoperative plans (e.g., performing endovascular aortic repair rather than open aortic repair). Coordination is essential among surgeons, anesthesiologists, and cardiologists, each of whom may have different criteria for risk assessment and different objectives for risk modification.

Clinical Risk Indices

Assessing cardiac risk in patients before vascular surgery is a controversial and difficult task (see also Chapters 37 and 38). Although risk indices are a cost-effective screening method for determining which patients may require further cardiac evaluation (i.e., additional risk stratification with noninvasive technologies), the high pretest probability of CAD in vascular surgery patients makes the risk index somewhat less useful. Vascular surgery–specific indices have been recently developed to optimize the prediction of perioperative mortality[12] and cardiac morbidity[13] in patients undergoing elective and urgent vascular surgery. Risk indices do not provide specific risk prediction for individuals, but rather place patients in general risk categories, most commonly designated as low (cardiac risk generally < 1%), intermediate (cardiac risk of 1% to 5%), or high (cardiac risk often > 5%). Clinical risk variables identified by logistic regression in vascular surgery cohorts can be used along with noninvasive cardiac testing to optimize preoperative assessment of cardiac risk before vascular surgery. From the registry of the Coronary Artery Revascularization Prophylaxis (CARP) trial, the absence of multiple preoperative cardiac risk variables identifies patients with the best long-term survival after elective vascular surgery.[14]

Previous Myocardial Infarction

In patients undergoing cardiac evaluation before vascular surgery, unrecognized MI (determined by rest wall motion abnormalities and no history of MI) is highly prevalent (23%) and associated with increased long-term cardiac risk.[6] Diabetes and heart failure are important predictors of unrecognized MI. Current guidelines recommend waiting 4 to 6 weeks after an uncomplicated MI before proceeding with elective surgery[11] and risk stratification with stress testing and assessment of ventricular function during this period.[15] Vascular surgery is often not elective, and urgent or emergent surgery may be required for patients with symptomatic aortic aneurysm, crescendo transient ischemic attacks from carotid disease, or limb-threatening ischemia from iliac or femoral occlusive disease. In these instances, the patient must proceed to surgery with careful perioperative medical management and surveillance.

Previous Coronary Artery Bypass Surgery

Patients who have undergone prior (<5 years) CABG and are without current symptoms of angina or heart failure appear to have a relatively infrequent incidence of cardiac morbidity after noncardiac surgery. However, previous coronary revascularization may not provide the same level of protection against MI and death after major vascular surgery. Results from the randomized, prospective CARP trial demonstrated that an aggressive strategy of prophylactic coronary artery revascularization before vascular surgery in patients with stable cardiac symptoms does not improve short-term outcome or long-term survival.[8] At 2.7 years after randomization, mortality was 22% and 23% in patients with and without revascularization, respectively. Postoperative MI, defined by increased troponin levels, occurred in 12% and 14% of patients with and without revascularization, respectively. Among those randomized to revascularization, patients undergoing CABG had fewer perioperative (6.6% versus 16.8%) and late postoperative (9.9% versus 23.7%) MIs than did patients undergoing PCI despite more diseased vessels in the CABG group (3.0 versus 2.2).[16] Completeness of the revascularization procedure (CABG > PCI) was the predominant variable accounting for this difference. The Dutch Echocardiographic Cardiac Risk Evaluation Applying Stress Echocardiography (DECREASE)-V Pilot Study investigated in a randomized fashion the role of prophylactic coronary revascularization in high-risk (three or more clinical risk variables and extensive stress-induced ischemia on noninvasive cardiac testing) patients undergoing major vascular surgery, although concern has been raised about the integrity of investigations from the Poldermans group at Erasmus University.[17-19] Preoperative coronary revascularization was not associated with improved short-term or long-term outcome compared with best medical treatment.[17] No significant difference was found in the composite end point of all-cause death or nonfatal MI at 30 days (43% versus 33%) or during 1-year follow-up (49% versus 44%) between patients randomized to revascularization or no revascularization. Unlike the CARP trial, no difference was observed in the incidence of perioperative cardiac events between patients treated with CABG or PCI. The results of these

two randomized trials are congruent with the current ACC/AHA guidelines on perioperative management[11] and CABG.[20] Specifically, preoperative revascularization should be reserved for patients with unstable cardiac conditions or advanced coronary disease, for whom a survival benefit with CABG has been established. Periprocedural complications after CABG are substantially more frequent in patients with peripheral arterial disease than in those without such disease.[21] These complications may preclude or alter the timing of subsequent vascular surgery.

Previous Percutaneous Coronary Intervention

The role of prophylactic percutaneous coronary revascularization in the preoperative management of vascular surgery patients is controversial.[8,17] PCI probably should be limited to patients with unstable active CAD.[11] Patients with peripheral vascular disease are often not ideal candidates for PCI. These interventions require placement of a large-diameter introducer sheath in the femoral artery, which predisposes to pseudoaneurysm and compromised blood flow to the lower extremities.[22] PCI can be performed through the brachial artery, but it is technically difficult. PCI in patients with peripheral arterial disease, as opposed to those without peripheral arterial disease, is associated with less frequent procedural success, more frequent in-hospital cardiovascular complications, and mortality.[23] Current guidelines indicate that PCI before noncardiac surgery, including vascular surgery, is of no value in preventing perioperative cardiac events, except in patients in whom PCI is independently indicated for unstable active cardiac conditions.[11]

The optimal interval between PCI and subsequent vascular surgery is unknown (see also Chapters 37 and 38). Current perioperative guidelines provide a comprehensive review of this topic and offer recommendations based on clinical data and expert opinion.[11] The type of coronary intervention, the need for dual antiplatelet therapy, the risk for bleeding from surgery, the risk in terminating antiplatelet therapy, and the urgency of the surgery all must be carefully considered.

Noninvasive Diagnostic Cardiac Testing

Accurate clinical assessment of the pretest probability of significant CAD is extremely important. In general, noninvasive cardiac testing before vascular surgery is best directed at patients considered to be at intermediate clinical risk. Such testing should not be undertaken if it is unlikely to alter patient management and should not be considered as a preliminary step leading to coronary revascularization. A revascularization procedure is rarely needed solely for the purpose of getting a patient through the perioperative period. Extensive cardiac evaluation before vascular operations can result in morbidity, delays, and patient refusal to undergo vascular surgery. A complete review of this subject is found in Chapter 38.

Cardiac Catheterization and Prophylactic Revascularization

The largest series on outcome in vascular surgery patients is that of Hertzer and colleagues[24] from the Cleveland Clinic. These investigators performed cardiac catheterization in 1000 consecutive patients scheduled to undergo peripheral vascular surgery (aortic aneurysm resection, carotid endarterectomy, and lower extremity revascularization). The incidence and severity of CAD were assessed according to the following classification: normal coronary arteries; mild-to-moderate CAD with no lesion exceeding 70% stenosis; advanced, compensated CAD with one or more lesions exceeding 70% stenosis but with adequate collateral circulation; severe, correctable CAD with more than 70% stenosis in one or more coronary arteries; and severe inoperable CAD with greater than 70% stenosis in one or more coronary arteries and severe distal disease or poor ventricular function. The most remarkable findings were that only 8.5% of patients had normal coronary arteries and 60% had advanced or severe coronary lesions (>70% stenosis). Even when CAD was not suspected by the clinical history, more than a third of patients had advanced or severe coronary lesions (Table 69-2).

In the Hertzer series, patients with severe correctable CAD were offered CABG before their vascular surgery, patients with normal or mild-to-moderate CAD went directly to vascular surgery, and those with severe inoperable CAD were treated on an individual basis. Combined mortality rates over the immediate- and long-term (4.6-year follow-up) postoperative period are shown in Table 69-3.[25] Of the 216 patients who underwent coronary revascularization (CABG), 12 (5.5%) died after this surgery. This mortality rate is more frequent than that reported for patients undergoing CABG surgery without peripheral vascular disease (1% to 2%). Perhaps the risks associated with CABG should be seriously considered as part of the preoperative evaluation of these patients. When overall early and late mortality (>5 years) is considered, death occurred in 12% versus 26% of patients who did or did not undergo CABG. Although these data

appear to support the beneficial effect of CABG on outcome, the mortality from CABG itself (5.5%) reduces its apparent benefits.

Two randomized clinical trials have been performed to determine the impact of prophylactic coronary artery revascularization on outcome after open aortic and lower extremity arterial vascular surgery.[8,17] Of the 5859 patients screened in the CARP trial,[8] 1190 underwent coronary angiography based on a combination of clinical risk factors and noninvasive stress imaging data.[26] The incidence and severity of CAD on these angiograms were 43% of patients had one or more major coronary arteries with at least a 70% stenosis suitable for revascularization (and were randomized to either revascularization or no revascularization before vascular surgery); 31% had nonobstructed coronary arteries; 18% had coronary stenosis considered unsuitable for revascularization; and 5% had left main coronary artery stenosis of 50% or more. The CARP trial showed that prophylactic revascularization (by CABG or PCI) was generally safe but did not improve long-term outcome after vascular surgery. Long-term mortality (2.7 years) was 22% in the revascularization group and 23% in the group considered inappropriate for revascularization (Fig. 69-3). Although the trial was not designed to test the short-term benefit of prophylactic revascularization, perioperative outcomes were not decreased, including death (3.1% versus 3.4%) and MI (12% versus 14%). The CARP trial results can be applied to most of the vascular surgery patients; however, they cannot be extrapolated to patients with unstable cardiac symptoms, left main coronary artery disease, aortic stenosis, or severe left ventricular dysfunction because these conditions excluded patients from study participation. The DECREASE-V trial[17] screened 1880 vascular surgery patients, 430 of whom with three or more clinical risk factors underwent noninvasive stress testing using stress-echo or perfusion imaging. Patients with extensive stress-induced ischemia (26%) were randomly assigned to

Data from Hertzer NR, Young JR, Beven EG, et al: Late results of coronary bypass in patients with peripheral vascular disease. II. Five-year survival according to sex, hypertension, and diabetes, *Cleve Clin J Med* 54:15-23, 1987.

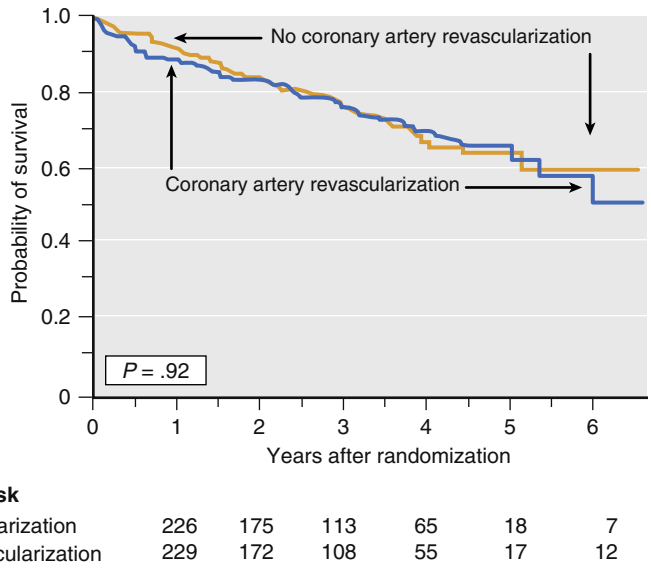

Figure 69-3. Long-term survival in patients randomized to undergo coronary artery revascularization or no coronary artery revascularization before elective major vascular surgery (Coronary Artery Revascularization Prophylaxix trial). Kaplan-Meier estimates were used to generate survival curves from the time of randomization for all patients. (From McFalls EO, Ward HB, Moritz TE, et al: Coronary-artery revascularization before elective major vascular surgery, *N Engl J Med* 351:2796-2804, 2004.)

revascularization or no revascularization. Coronary angiography showed two-vessel disease in 24%, three-vessel disease in 67%, and left main coronary artery disease in 8%. Prophylactic coronary revascularization (CABG or PCI) did not improve perioperative or long-term outcome (Table 69-4). The incidence of all-cause death or nonfatal MI at 30 days in patients who underwent revascularization or who did not was 43% versus 33%, respectively. The incidence of the composite end point at 1 year was similar, 49% versus 44%, respectively. As noted previously, this trial has come under scrutiny based on concerns of unfortunate scientific misconduct by the principal investigator.

The lack of benefit of prophylactic coronary revascularization in the CARP and DECREASE-V trials is difficult to reconcile with the more favorable data from Hertzer and co-workers[24] and other studies (Coronary Artery Surgery Study [CASS][27] and Bypass Angioplasty Revascularization Investigation [BARI][28]), but is consistent with current guideline recommendations.[11] Clearly, issues are involved that go beyond critical coronary lesions; perhaps the current understanding of the pathophysiology of perioperative MI is incomplete. For example, perioperative MI may be caused by culprit lesions (i.e., vulnerable plaques with high likelihood of thrombotic complications) often located in coronary vessels *without* critical stenosis.[29] For this type of MI (atherothrombotic), perioperative strategies aimed at reducing potential triggers of coronary plaque destabilization and rupture may be more appropriate than those leading to coronary revascularization. Demand ischemia is likely the predominant cause of perioperative MI, which has been confirmed by a recent angiographic study.[30]

ASSESSMENT OF PULMONARY FUNCTION

Postoperative pulmonary complications are potentially serious in patients undergoing vascular surgery, with the most significant morbidity seen in patients undergoing open aortic procedures (see also Chapters 67 and 103). The most important pulmonary complications are atelectasis, pneumonia, respiratory failure, and exacerbation of underlying chronic disease. Given the prevalence of cigarette smoking in this population, chronic obstructive pulmonary disease (COPD) and chronic bronchitis are common and, when present, place the patient at increased risk for postoperative pulmonary complications. When clinical assessment suggests severe pulmonary compromise, pulmonary function tests may be useful in evaluating and optimizing respiratory function (see also Chapters 39 and 51). Preoperative analysis of arterial blood gases should be used to establish a baseline for postoperative comparison. Baseline hypercapnia (partial pressure of arterial carbon dioxide > 45 mm Hg) indicates a more frequent risk for postoperative morbidity. Bronchodilator therapy may be indicated on the basis of results of pulmonary function tests, although the risk for β-adrenergic agonist–induced arrhythmia or myocardial ischemia also must be considered. Preoperative treatment with a short course of glucocorticoids (prednisone 40 mg/day for 2 days) may be helpful for patients with significant COPD or asthma. Evidence of pulmonary infection should be treated with appropriate antibiotics. Although improved pulmonary outcome with regional anesthesia is not clear, patients with significant pulmonary disease may benefit from epidural techniques. Use of these techniques in the postoperative period helps avoid respiratory depression from systemic opiates (see also Chapter 98). Pulmonary complications in the postoperative period are difficult to avoid. Incentive spirometry and continuous positive airway pressure do provide benefit.[31] Given proper pulmonary care, even patients with severe pulmonary insufficiency, however, may undergo aortic surgery with acceptable morbidity and mortality outcomes.[32]

Assessment of Renal Function

Chronic renal disease is common in vascular surgery patients and is associated with an increased risk for death and cardiovascular disease (see also Chapters 37 and 52).[33] Chronic renal disease strongly predicts long-term

mortality in patients with symptomatic lower extremity arterial occlusive disease irrespective of disease severity, cardiovascular risk, and concomitant treatment.[34] Cardiovascular disease is independently associated with a decline in renal function and the development of kidney disease.[35] Serum creatinine and creatinine clearance are used to assess renal function perioperatively. A preoperative serum creatinine level more than 2 mg/dL is an independent risk factor for cardiac complications after major noncardiac surgery.[36] Preoperative creatinine clearance less than 60 mL/minute is an independent predictor of both short-term and long-term mortality after elective vascular surgery.[37] Perioperative β-adrenergic blocker[38] and statin[37] administration decrease risk for death in vascular surgery patients with renal impairment. Atherosclerotic disease in the abdominal aorta or renal arteries may compromise renal blood flow and renal function. Conversely, renal artery stenosis causes hypertension through renin-induced and angiotensin-induced vasoconstriction. Hypertension itself may cause renal insufficiency or failure. Diabetic nephropathy is also common (see also Chapter 39). Superimposed on baseline abnormalities in renal function are the preoperatively and intraoperatively administered angiographic dyes, which are directly nephrotoxic. Renal ischemia occurs with interruption of renal blood flow from aortic cross-clamping. Even with infrarenal aortic cross-clamps, renal blood flow may decrease despite normal systemic arterial blood pressure and cardiac output. Embolic plaque can be showered into the renal arteries, especially when suprarenal aortic cross-clamps are applied and released. Fluctuations in intravascular volume and cardiac output can compromise renal perfusion during the intraoperative and postoperative periods. In one series of more than 500 patients, the prevalence of acute renal failure was 7% after abdominal aortic reconstruction.

PERIOPERATIVE MYOCARDIAL ISCHEMIA

ETIOLOGY AND PREVENTION

Ischemic cardiac morbidity is the most common cause of perioperative death in the United States[5] (see also Chapter 39). Myocardial ischemia in the perioperative period is a strong predictor of adverse cardiac events after vascular surgery. Myocardial ischemia results from an imbalance between myocardial oxygen supply and demand, for which many causes exist during the perioperative period. Virtually every determinant of myocardial O_2 supply and demand can be altered by factors common with vascular surgery, including intravascular fluid shifts, blood loss, pain, increased release of catecholamines, hypothermia, altered coagulability, and ventilatory insufficiency. Tachycardia, intravascular hypervolemia, and anemia are particularly detrimental because they simultaneously decrease O_2 supply and increase O_2 demand. The prevention and treatment of perioperative myocardial ischemia require careful control of these and other determinants of myocardial O_2 supply and demand, as well as other physiologic changes that can precipitate ischemia.

Table 69-5 summarizes eight studies showing the relative incidence of preoperative, intraoperative, and postoperative myocardial ischemia. The two studies with the most infrequent rates of intraoperative myocardial ischemia followed a protocol that included rigorously controlled intraoperative heart rate and arterial blood pressure.[39,40] Norris and associates[40] continued this "tight" hemodynamic control into the postoperative period and reported a lower rate (15%) of postoperative myocardial ischemia. Excellent control of perioperative hemodynamics, especially heart rate (<85 beats/minute), likely decreases the incidence of myocardial ischemia. An even slower heart rate control (<70 beats/minute) may reduce myocardial ischemia after vascular surgery[41]; some added risk exists with this approach.[42] The heart rate should clearly be controlled, but also the underlying cause should be determined. The common recommendation is to maintain arterial blood pressure within 20% of baseline. However, a more rational approach that appropriately addresses patients with hypertension or hypotension is described in Figure 69-4. Perioperative statin therapy also reduces the incidence of myocardial ischemia after vascular surgery.[43]

The optimal hematocrit value for vascular surgery patients is not clear. An increased incidence of myocardial ischemia and cardiac morbidity occurs in vascular surgery patients if hemoglobin concentrations are less than 9.0 g/dL in the early postoperative period. Therefore, hemoglobin concentrations should be maintained at

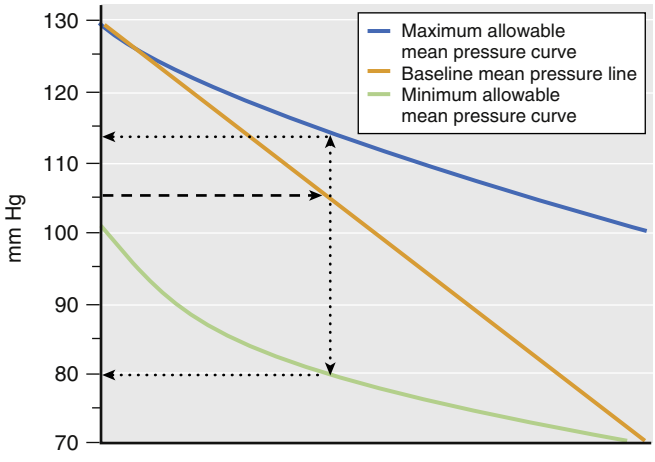

Figure 69-4. Nomogram used to determine minimum and maximum mean blood pressure limits. The nomogram is used by reading the baseline mean arterial pressure (MAP) from the left-hand axis horizontally onto the diagonal baseline mean pressure line. The point of intersection on this line is then extended vertically to intersect with the minimum and maximum allowable mean pressure curves. A patient with a baseline MAP of 105 mm Hg, shown in the figure, would have an allowable MAP range of 80 to 114 mm Hg. (From Norris EJ, Beattie C, Perler BA, et al: Double-masked randomized trial comparing alternate combinations of intraoperative anesthesia and postoperative analgesia in abdominal aortic surgery, *Anesthesiology* 95:1054-1067, 2001.)

greater than 9.0 g/dL in vascular patients, especially those at significant risk for ischemic cardiac morbidity. Accordingly, a "liberal" transfusion trigger should be considered (see also Chapter 61).

MONITORING FOR MYOCARDIAL ISCHEMIA

Three methods are used to detect myocardial ischemia during the perioperative period: surface electrocardiogram (ECG), transesophageal echocardiography (TEE), and pulmonary artery catheterization (see also Chapters 45 to 47). The sensitivity and specificity for detection of ischemia, the level of training required, and the cost of these methods differ and are important considerations. Monitoring for ischemia is important during and after vascular surgery. Ischemia may lead to infarction, especially when the ischemia is sustained over time (>2 hours).[44] Accordingly, the clinical determinants of myocardial O_2 supply and demand should be optimal in an attempt to resolve the ischemic condition.

Serial measurement of cardiac-specific biomarkers in the postoperative period is used to monitor for myocardial injury after vascular surgery. Measurement of cardiac troponin T or I facilitates the detection of myocardial damage over less specific biomarkers and allows the detection of very small injury. Data from the CARP and Ventavis Inhalation With Sildenafil to Improve and Optimize Pulmonary Arterial Hypertension (VISION) trials support the use of perioperative cardiac troponin as a means of stratifying high-risk patients after vascular surgery.[45,46] Although not supported by current guidelines, routine surveillance of cardiac troponin after vascular surgery probably should be used for the detection of cardiac events and postoperative risk stratification.[47]

PERIOPERATIVE β-ADRENERGIC BLOCKER THERAPY

Perioperative β-adrenergic blocker therapy is an important and controversial topic, particularly in patients undergoing vascular surgery, and is reviewed more fully in Chapters 38 and 39. Patients receiving chronic β-adrenergic blocker therapy should continue taking β-adrenergic blockers throughout the perioperative period. However, β-adrenergic blockers should not be used as the initial or primary treatment of tachycardia caused by perioperative events, such as hypovolemia, anemia, pain, or infection, because these conditions require prompt treatment of the underlying cause. Treatment of tachycardia caused by the sympathetic stimulation associated with surgical stress should be considered in high-risk patients, particularly those with known ischemic potential (i.e., ischemia on preoperative testing). Hypotension and bradycardia should be avoided. Acute initiation of large-dose β-adrenergic blockade in the perioperative period should be avoided. If a decision is made to initiate β-blocker treatment in the perioperative period in an effort to reduce cardiac risk, the safest approach may be to initiate therapy with a small dose and titrate to effect over a 7- to 10-day period before the planned surgery. Perioperative β-adrenergic blocker therapy can decrease the number of patients referred for preoperative cardiac testing. However, such testing should not be eliminated, and its risk-to-benefit ratio should be carefully assessed.

PERIOPERATIVE STATIN THERAPY

In addition to their lipid-lowering properties, statins have beneficial antiinflammatory, plaque-stabilizing, and antioxidant effects (see also Chapter 39). Over the last decade, statin use has emerged as a promising strategy for the prevention of perioperative cardiovascular complications in patients undergoing vascular surgery.[48] This approach is supported by the double-blind, placebo-controlled DECREASE-III trial. Unfortunately, controversy exists regarding this trial because of scientific misconduct identified by a recent investigation by Erasmus University.[19] Statin use can help preserve renal function after aortic surgery and improve graft patency after lower extremity bypass surgery.

Although current guidelines recommend the use of statins in all patients with peripheral arterial disease, the optimal timing and dosing of statins for perioperative use has not been established. Because no intravenous (IV) preparations are available, statins should be given that have a prolonged half-life or a slow-release formula.[49] Interruption of statin therapy after aortic surgery can increase cardiac risk.[49,50] Data from the DECREASE III trial suggest that this risk may be avoided if the interruption is brief (2 days) and an extended-release statin is used.[42] Current ACC/AHA guidelines should guide overall use. Because side effects can occur and are difficult to assess clinically in the perioperative period, serial measurements of creatine kinase and liver function are advisable until safety has been established.

HEMODYNAMIC MONITORING

The appropriate level of invasive hemodynamic monitoring (see also Chapter 45) in patients undergoing vascular surgery is a controversial issue. Multiple considerations determine the need for monitoring and are often not the same for all vascular patients. Given the frequency of coexisting disease, the potential for fluid shifts and blood loss, and the physiologic changes associated with cross-clamping and unclamping, virtually all patients undergoing major vascular surgery should be monitored with an intraarterial catheter. This allows beat-to-beat blood pressure monitoring, accurate determination of diastolic pressure, and sampling of arterial blood for diagnostic purposes. The radial artery is most commonly selected for cannulation because of its superficial location and the presence of collateral circulation. The need to verify collateral blood flow is questionable. The Allen test can be used to assess collateral flow in the palmar arch, but evidence suggests that ischemic injury can occur in patients with a normal Allen test result and that no injury occurs in patients with an abnormal Allen test result when the radial artery is cannulated. When the radial artery is difficult to cannulate, the ulnar or axillary arteries are alternative sites. The axillary artery can be cannulated by the Seldinger technique, but extreme care should be taken to avoid injecting air when flushing an axillary catheter because the tip may lie close to or inside the aortic arch and thus allow air to enter the cerebral circulation. Whenever possible, the femoral arteries should be avoided in patients with peripheral vascular disease.

Vascular surgery patients often have a large discrepancy in arterial blood pressure between the right and left arms as a result of atherosclerotic lesions in the subclavian or axillary arteries; such discrepancy results in a falsely low arterial blood pressure in the ipsilateral arm.[51] Patients scheduled for carotid surgery have a frequent incidence of right and left arm arterial blood pressure differences. To avoid pseudohypotension, arterial blood pressure should be verified in both arms, and the arm with the higher pressure should be used for monitoring during surgery. Both arms may have falsely low arterial blood pressure as a result of bilateral disease. In this case, the femoral artery may be the best option for monitoring.

The utility of central venous and pulmonary artery catheters for hemodynamic monitoring of patients during vascular surgery is controversial. The surgical procedure often determines the degree of fluid shifting and blood loss and thus the usefulness of invasive monitoring. The patient's underlying cardiac, pulmonary, and renal status also need to be considered. Although cardiovascular function is highly dependent on adequate ventricular filling (i.e., the heart cannot pump out more blood than it receives), values of central venous pressure and pulmonary artery occlusion pressure do not correlate with values of measured circulating blood volume.[52] Additional information, such as stroke volume and cardiac output, are often important when extreme stress is placed on an already impaired heart. The indications for central venous pressure and pulmonary artery catheter monitoring are discussed in further detail in the subsequent sections.

The role of TEE (see also Chapter 46) in the perioperative period has expanded rapidly over the last decade. TEE is useful in identifying anatomic and functional cardiac abnormalities and is a sensitive monitor for detection of myocardial ischemia. During complex aortic reconstruction, TEE provides important real-time information on cardiac filling and function and is particularly useful when unexplained hemodynamic instability is encountered.

ABDOMINAL AORTIC RECONSTRUCTION

Anesthesia for conventional abdominal aortic reconstruction requires an understanding of the pathophysiology, extensive knowledge of the surgical procedure, the ability to interpret sophisticated hemodynamic data, and skillful pharmacologic control and manipulation of hemodynamics. Preoperative and intraoperative communication with the surgical team is essential. All open operative procedures on the abdominal aorta and its major branches require large incisions and extensive dissection, clamping and unclamping of the aorta or its major branches, varying duration of organ ischemia-reperfusion, significant fluid shifts and temperature fluctuations, and activation of neurohumoral and inflammatory responses. The major objectives of surgical treatment of the aorta are to relieve symptoms, reduce the frequency of associated complications, and in the case of aortic aneurysm, prevent rupture. Over the last two decades, the growth and development of catheter-based technology for the treatment of peripheral arterial disease have generated tremendous interest for less invasive methods to treat aortic disease. Endovascular aortic aneurysm repair (discussed later) has become an established less invasive alternative to conventional open repair, and its use has expanded to more than 75% of elective repairs and 30% of rupture repairs.[53] The endovascular field continues to evolve rapidly with new devices, innovations, and indications for aortic disease.

NATURAL HISTORY AND SURGICAL MORTALITY

Abdominal Aortic Aneurysm

Abdominal aortic aneurysms (AAAs) occur frequently in elderly men, with an incidence approaching 8% (see also Chapter 80). Increasing age, smoking, family history of AAA, and atherosclerotic disease are established risk factors. Although the prevalence is less frequent in women, the risk factors for AAA are similar to those in men. More than 30,000 deaths result from rupture of AAAs each year in the United States.[54] The number of hospital discharges each year with the first diagnosis of aortic aneurysm is nearly 70,000. Approximately 40,000 patients undergo repair of AAA each year in the United States, at a cost likely to exceed a billion dollars. The incidence of AAA appears to be increasing and is age and gender dependent.

AAA is a multifactorial disease associated with aortic aging and atherosclerosis. Although no unified concept of pathogenesis exists, genetic, biochemical, metabolic, infectious, mechanical, and hemodynamic factors may

contribute to the development of AAA disease. Adventitial elastin degradation (elastolysis), a hallmark of AAA formation, may be the primary event. Chronic inflammation plays a fundamental role in the destruction of connective tissue in the aortic wall. Concomitant aortoiliac occlusive disease is present in approximately 20% to 25% of patients with AAA. Approximately 5% of patients undergoing abdominal aortic resection have inflammatory aneurysms. Rare causes of AAA disease include trauma, mycotic infection, syphilis, and Marfan syndrome.

Most AAAs are detected incidentally when imaging is performed for other reasons or through screening programs. The natural history of AAA disease is progressive enlargement and ultimate rupture and death. The diameter and rate of expansion of asymptomatic AAAs are the best predictors of the risk for rupture. Current guidelines emphasize that it is not possible to recommend a single threshold diameter for operative intervention that can be generalized to all patients. Yet, elective repair should be undertaken in all patients with AAA 6 cm or larger in diameter. Although some controversy exists regarding elective AAA repair when its diameter is in the 5.5- to 5.9-cm range, the risk for rupture of a 5.5-cm aneurysm (per year) is equal to or greater than the risk for perioperative mortality, and thus surgical repair is indicated. The 1-year incidence of probable rupture in patients refusing or unfit for elective repair is 9.4%, 10.2%, and 32.5% for aneurysms 5.5 to 5.9 cm, 6.0 to 6.9 cm, and 7.0 cm or greater, respectively.[55]

Over 90% of AAAs are less than the current threshold (5.5 cm) for surgical repair at the time of detection. Randomized controlled trials in patients with AAAs 4.0 to 5.5 cm in diameter have provided important insight into the natural history of small asymptomatic aortic aneurysms.[56] Four trials have demonstrated that surveillance of small aneurysms (4.0 to 5.5 cm) is a safe management option and that early repair (open or endovascular surgery) did not result in any long-term survival benefit. Surgical repair is often considered if small aneurysms become symptomatic or expand more than 0.5 cm in a 6-month period. Although significant interest exists in medical treatment (e.g., antibiotics, β-adrenergic blockers, statins) to delay or reverse expansion of small aneurysms, evidence for a protective effect is limited.[57] Aneurysms less than 4.0 cm in diameter are thought to be relatively benign in terms of rupture and expansion.

Perioperative mortality from elective resection of infrarenal AAAs has progressively declined from 18% to 20% during the 1950s, 6% to 8% in the mid-1960s, 5% to 6% in the early 1970s, and 2% to 4% in the 1980s, at which time it plateaued. A publication of data from 1000 consecutive elective open infrarenal abdominal aneurysm repairs over a 15-year period reported a perioperative mortality rate of 2.4%.[58] Hertzer and co-workers[59] reported a mortality rate of 1.2% for 1135 consecutive elective open infrarenal abdominal aortic repairs at the Cleveland Clinic. This single-center mortality rate is considerably less than the mortality rates of 5.6% to 8.4% reported from large national data sets. These more frequent mortality rates on the national level suggest that all of the technologic and treatment advances over the last 2 decades have not had an impact on outcomes of patients requiring open AAA repair. Regionalization of patient care and endovascular treatments currently hold the most promise for improvement in operative mortality.

For ruptured AAAs, perioperative mortality has not changed significantly over the last 4 decades and remains nearly 50%, with few exceptions. Including patients with rupture who die before reaching a hospital, the overall mortality rate after rupture may very well exceed 90%.

The long-term durability of open infrarenal AAA repair is excellent and well established. The incidence of late graft complications is infrequent (0.4% to 2.3%). Postoperative survival rates after repair of nonruptured AAA are 92% at 1 year and 67% at 5 years.

Aortoiliac Occlusive Disease

The infrarenal aorta and the iliac arteries are two of the most common sites of chronic atherosclerosis. Because of the diffuse and progressive nature of aortoiliac atherosclerosis, plaque enlargement may reduce blood flow to the lower extremities below a critical level and result in symptoms of ischemia. Unlike patients with aortic aneurysmal disease, patients undergo surgery for aortoiliac occlusive disease only if they are symptomatic. Surgical intervention is indicated for disabling intermittent claudication and limb-threatening ischemia. Intervention is directed toward restoring peripheral pulsatile circulation to relieve claudication and toward preventing amputation. Patients with localized aortoiliac occlusive disease typically have claudication because collateral circulation adequate to prevent critical lower extremity ischemia usually exists. Perioperative mortality is lower in patients undergoing aortoiliac reconstruction than in those undergoing abdominal aortic surgery.

Therapeutic options for managing aortoiliac occlusive disease include anatomic or direct reconstruction (i.e., aortobifemoral bypass), extraanatomic or indirect bypass grafts (i.e., axillofemoral bypass), and catheter-based endoluminal techniques (i.e., percutaneous transluminal angioplasty with or without stent insertion). Aortobifemoral bypass is viewed as the gold standard in treating aortoiliac occlusive disease. Extraanatomic bypass grafts are generally reserved for specific indications, usually patients with infection, failure of previous reconstruction, or prohibitive risk. Reduced long-term patency and inferior functional results are frequently the trade-off for lower perioperative morbidity and mortality. Catheter-based endoluminal techniques, such as percutaneous transluminal angioplasty, are used for relatively localized disease and may be reasonable alternatives to aortobifemoral bypass in 10% to 15% of patients with aortoiliac occlusive disease.

Renal and Visceral Arterial Insufficiency

Atherosclerosis is the most common cause of renal artery stenosis. Occlusive lesions are located almost exclusively in the proximal segment and orifice of the renal artery and are usually an extension of aortic atherosclerosis. Fibromuscular dysplasia is an important, but less common, cause of renal artery stenosis and most frequently involves the distal two thirds of the renal arteries. Hemodynamically significant renal artery stenosis may cause hypertension by activation of the renin-angiotensin-aldosterone system, and bilateral involvement may result in renal failure. Patients with renovascular hypertension

frequently have poorly controlled hypertension despite maximal medical therapy. These patients often have severe bilateral renal artery stenosis and may have recurrent congestive heart failure or flash pulmonary edema. Indications for intervention include control of hypertension and salvage of renal function. Operative interventions include aortorenal bypass, extraanatomic bypass (hepatorenal or splenorenal bypass), or transaortic endarterectomy. Suprarenal or supraceliac aortic cross-clamping is frequently required for open operative interventions. Percutaneous transluminal angioplasty with stenting of the renal artery is used as the first-line treatment in selected patients.

Stenosis at the origin of the celiac and mesenteric arteries occurs as a result of extension of aortic atherosclerosis. The inferior mesenteric artery is by far the most commonly involved, followed by the superior mesenteric artery and the celiac artery. Occlusion of a single vessel rarely causes ischemic symptoms because of the extensive nature of visceral collateralization. However, occlusion or significant stenosis of any two vessels may compromise collateral flow sufficiently to give rise to chronic visceral ischemia. Operative repair of visceral artery stenosis is reserved for symptomatic patients. Operative interventions include transaortic endarterectomy and bypass grafts, which frequently require supraceliac aortic cross-clamping. Mortality rates for such procedures range from 7% to 18%. To avoid the high mortality associated with open repair, percutaneous transluminal angioplasty with stenting has increasingly been applied in patients with chronic visceral ischemia. Acute visceral artery occlusion can be caused by an embolus or, less commonly, by thrombosis. To avoid the extremely high mortality associated with acute visceral ischemia, diagnosis and surgical intervention must occur before gangrene of the bowel develops.

AORTIC CROSS-CLAMPING

The pathophysiology of aortic cross-clamping is complex and depends on many factors, including level of the cross-clamp, status of the left ventricle, degree of periaortic collateralization, intravascular blood volume and distribution, activation of the sympathetic nervous system, and anesthetic drugs and techniques. Most abdominal aortic reconstructions require clamping at the infrarenal level. However, clamping at the suprarenal and supraceliac levels is required for suprarenal aneurysms and renal or visceral reconstructions and is frequently necessary for juxtarenal aneurysms, inflammatory aneurysms, and aortoiliac occlusive disease with proximal extension. These higher levels of aortic occlusion have a significant impact on the cardiovascular system, as well as on other vital organs rendered ischemic or hypoperfused. Ischemic complications may result in renal failure, hepatic ischemia and coagulopathy, bowel infarction, and paraplegia. With endovascular aortic repair now common, an increasing proportion of patients undergoing open repair have anatomically complex aneurysms, many of which require suprarenal cross-clamping.[60]

Hemodynamic and Metabolic Changes

The hemodynamic and metabolic changes associated with aortic cross-clamping are summarized in Box 69-1.

BOX 69-1 ***Physiologic Changes With Aortic Cross-Clamping* and Therapeutic Interventions***

HEMODYNAMIC CHANGES

↑ Arterial blood pressure above the clamp
↓ Arterial blood pressure below the clamp
↑ Segmental wall motion abnormalities
↑ Left ventricular wall tension
↓ Ejection fraction
↓ Cardiac output†
↓ Renal blood flow
↑ Pulmonary occlusion pressure
↑ Central venous pressure
↑ Coronary blood flow

METABOLIC CHANGES

↓ Total body oxygen consumption
↓ Total body carbon dioxide production
↑ Mixed venous oxygen saturation
↓ Total body oxygen extraction
↑ Epinephrine and norepinephrine
- Respiratory alkalosis‡
- Metabolic acidosis

THERAPEUTIC INTERVENTIONS

Afterload reduction
  Sodium nitroprusside
  Inhalational anesthetics
  Amrinone
  Shunts and aorta-to-femoral bypass
Preload reduction
  Nitroglycerine
  Controlled phlebotomy
  Atrial-to-femoral bypass
Renal protection
  Fluid administration
  Distal aortic perfusion techniques
  Selective renal artery perfusion
  Mannitol
  Drugs to augment renal perfusion
Other
  Hypothermia
  ↓ Minute ventilation
  Sodium bicarbonate

*These changes are of greater significance with longer duration of cross-clamping and with more proximal cross-clamping.
†Cardiac output may increase with thoracic cross-clamping.
‡When ventilatory settings are unchanged from preclamp levels.

The magnitude and direction of these changes are complex, dynamic, and vary among experimental and clinical studies. However, several important factors must be considered (Box 69-2). The systemic cardiovascular consequences of aortic cross-clamping can be dramatic, depending primarily on the level at which the cross-clamp is applied. Arterial hypertension above the clamp and arterial hypotension below the clamp are the most consistent components of the hemodynamic response to aortic cross-clamping at any level. The increase in arterial blood pressure above the clamp is primarily due to the sudden increase in impedance to aortic blood flow and the resultant increase in systolic ventricular wall tension or afterload. However, factors such as myocardial contractility, preload, blood volume, and activation of the

Duration of aortic cross-clamp
Body temperature

sympathetic nervous system also may be important.[61] Cross-clamping of the aorta at or above the diaphragm results in the most profound increases in arterial blood pressure unless diverting circulatory support or IV vasodilators are used.

Changes in cardiac output and filling pressure with aortic cross-clamping are not consistent and require an integrated approach in understanding the direction and magnitude of such changes (Fig. 69-5). Cross-clamping of the proximal descending thoracic aorta increases mean arterial, central venous, mean pulmonary arterial, and pulmonary capillary wedge pressure by 35%, 56%, 43%, and 90%, respectively, and decreases the cardiac index by 29%.[62] Heart rate and left ventricular stroke work are not significantly changed. Supraceliac aortic cross-clamping increases mean arterial pressure by 54% and pulmonary capillary wedge pressure by 38%.[63] Ejection fraction, as determined by two-dimensional echocardiography, decreases by 38%. Despite normalization of systemic and pulmonary capillary wedge pressure with anesthetic agents and vasodilator therapy, supraceliac aortic cross-clamping causes significant increases in left ventricular end-systolic and end-diastolic area (69% and 28%, respectively), as well as wall motion abnormalities indicative of ischemia in 11 of 12 patients (Table 69-6). Aortic cross-clamping at the suprarenal level causes similar but smaller cardiovascular changes, and clamping at the infrarenal level is associated with only minimal changes and no wall motion abnormalities.

The marked increases in ventricular filling pressure (preload) reported with high aortic cross-clamping have been attributed to increased afterload and redistribution of blood volume, which is of prime importance during thoracic aortic cross-clamping. The splanchnic circulation, an important source of functional blood volume reserve, is central to this hypothesis. The splanchnic organs contain nearly 25% of the total blood volume, nearly two thirds (>800 mL) of which can be autotransfused from the highly compliant venous vasculature into the systemic circulation within seconds.[64] Primarily because of smaller splanchnic venous capacitance, blood volume is redistributed from vascular beds distal to the clamp to the relatively noncompliant vascular beds proximal to the clamp (see Fig. 69-5). Both passive and active mechanisms lower splanchnic venous capacitance with thoracic aortic cross-clamping. Cross-clamping the aorta above the splanchnic system dramatically reduces splanchnic arterial flow, which produces a significant reduction in pressure within the splanchnic capacitance

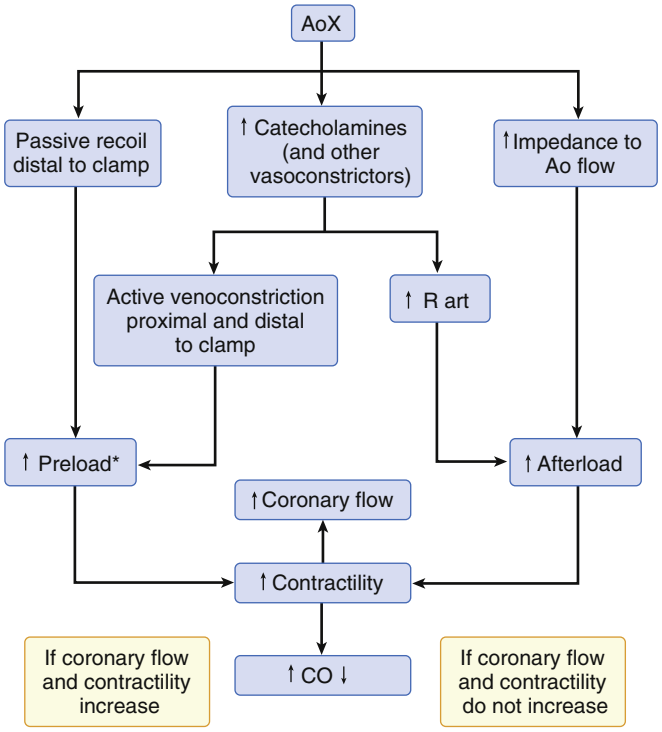

Figure 69-5. Systemic hemodynamic response to aortic cross-clamping. Preload (*asterisk*) does not necessarily increase with infrarenal clamping. Depending on splanchnic vascular tone, blood volume can be shifted into the splanchnic circulation and preload will not increase. *Ao,* Aortic; *AoX,* aortic cross-clamping; *CO,* cardiac output; R art, arterial resistance. vessels.[52] This decreased pressure allows the splanchnic veins to passively recoil and increase venous return to the heart and blood volume proximal to the clamp. Thoracic aortic cross-clamping also results in significant increases in plasma epinephrine and norepinephrine, which may enhance venomotor tone both above and below the clamp. The splanchnic veins are highly sensitive to adrenergic stimulation. The major effect of catecholamines on the splanchnic capacitance vessels is venoconstriction, which actively forces out splanchnic blood, reduces splanchnic venous capacitance, and increases venous return to the heart.[52]

Several animal studies support the blood volume redistribution hypothesis. Cross-clamping the thoracic aorta in dogs results in marked increases in mean arterial pressure and end-diastolic left ventricular pressure (84% and 188%, respectively) and no significant change in stroke volume.[65] In this same experimental model, simultaneous cross-clamping of the thoracic aorta and the inferior vena cava resulted in no significant change in mean arterial pressure or preload (Fig. 69-6). Stroke volume was reduced by 74%. By transfusing blood (above the clamps) during this period of simultaneous clamping, the authors reproduced the hemodynamic effect of thoracic aortic cross-clamping alone. This study also demonstrated that thoracic aortic cross-clamping is associated with a significant and dramatic increase (155%) in blood flow above the level of the clamp whereas no change in blood flow occurred with simultaneous aortic and inferior vena cava clamping. In other animal models, the proximal aortic hypertension and increased central venous pressure occurring after thoracic aortic cross-clamping were completely reversed by phlebotomy.[66] Aortic cross-clamping at the thoracic and suprarenal levels in dogs both resulted in proximal aortic hypertension, but only occlusion at the thoracic level increased central venous pressure.[67] In this study, thoracic aortic occlusion increased blood volume in organs and tissues proximal to the clamp whereas no such increase occurred with suprarenal aortic cross-clamping. These experimental data strongly support the hypothesis of blood volume redistribution during aortic cross-clamping and help explain the marked differences in hemodynamic responses observed after aortic cross-clamping at different levels.[63]

Afterload-dependent increases in preload also occur with aortic cross-clamping, usually in the setting of impaired myocardial contractility and reduced coronary reserve. The impaired left ventricle may respond to increased afterload with an increase in end-systolic volume and a concomitant reduction in stroke volume (afterload mismatch). The reduction in stroke volume may be due to limited preload reserve, myocardial ischemia, or inability of the heart to generate a pressure-induced increase in contractility (the Anrep effect). If right ventricular function remains normal, the preclamp right ventricular stroke volume added to the increased left ventricular end-systolic volume results in left ventricular dilation and elevated end-diastolic volume. If corrective measures are not undertaken, overt left ventricular overload may result, with severe peripheral organ dysfunction and pulmonary edema.

Most clinical studies indicate that cardiac output decreases with thoracic aortic cross-clamping (without vasodilator therapy or diverting circulatory support), whereas most animal studies show no significant change or an increase in cardiac output. However, the status of the left ventricle clearly plays a major role. Whereas a normal intact heart can withstand large increases in volume without significant ventricular distention or dysfunction, an impaired heart with reduced myocardial

contractility and coronary reserve may respond to such increase in volume conditions with marked ventricular distention as a result of acute left ventricular dysfunction and myocardial ischemia. Although impaired myocardial contractility and reduced coronary reserve are rare in animal experiments, such disorders are frequent in the elderly population undergoing aortic reconstruction. The increase in ventricular loading conditions seen with thoracic and supraceliac cross-clamping[62,63] in the clinical setting may increase left ventricular wall stress (afterload), with resultant acute deterioration of left ventricular function and myocardial ischemia. Impaired subendocardial perfusion caused by high intramyocardial pressure may be the cause of wall motion abnormalities and changes in ejection fraction. Reflex mechanisms causing immediate feedback inhibition may also explain the reduction in cardiac output with aortic cross-clamping. For example, baroreceptor activation resulting from increased aortic pressure should depress the heart rate, contractility, and vascular tone. Thoracic aortic cross-clamping with the use of vasodilator therapy to normalize ventricular loading conditions maintains or increases cardiac output.[68]

The metabolic effects of aortic cross-clamping are summarized in Box 69-1. Cross-clamping of the thoracic aorta decreases total-body O_2 consumption by approximately 50%. For reasons that are unclear, O_2 consumption decreases in tissues above the clamp. In clinical studies, increased mixed venous O_2 saturation occurs with aortic cross-clamping above the celiac axis. This increase in mixed venous O_2 saturation may be explained by a reduction in O_2 consumption that exceeds the reduction in cardiac output, thus decreasing total body O_2 extraction. Central hypervolemia and increased arteriovenous shunting in tissues proximal to the aortic clamp may play a role in reducing total body O_2 extraction.

Arterial blood pressure, blood flow, and O_2 consumption distal to a thoracic aortic cross-clamp decrease by 78% to 88%, 79% to 88%, and 62%, respectively, from baseline values before clamping. Blood flow through tissues and organs below the level of aortic occlusion is dependent on perfusion pressure and is independent of cardiac output. Administration of sodium nitroprusside to maintain proximal aortic pressure above the cross-clamp at preclamp levels has been shown to further reduce arterial pressure distal to the clamp by 53%. As discussed later, these data have significant implications regarding vital organ protection during aortic cross-clamping.

The cardiovascular response to infrarenal aortic cross-clamping is less significant than with high aortic cross-clamping (see Table 69-6). Although several clinical reports have noted no significant hemodynamic response to infrarenal cross-clamping, the hemodynamic response generally consists of increases in arterial pressure (7% to 10%) and systemic vascular resistance (20% to 32%), with no significant change in heart rate. Cardiac output is most consistently decreased by 9% to 33%. Reported changes in ventricular filling pressure have been inconsistent. Blood volume redistribution may affect preload with infrarenal aortic cross-clamping (see Fig. 69-5). In this situation, blood volume below the clamp shifts to the compliant venous segments of the splanchnic circulation above the clamp, thereby dampening the expected increase in preload. The preload changes with infrarenal aortic cross-clamping also may depend on the status of the coronary circulation. Patients with severe ischemic heart disease responded to infrarenal aortic cross-clamping with significantly increased central venous (35%) and pulmonary capillary (50%) pressure, whereas patients without CAD had decreased filling pressure. Echocardiographically detected segmental wall motion abnormalities occur in up to 30% of patients during infrarenal aortic reconstruction, with over 60% occurring at the time of aortic cross-clamping. Patients with aortoiliac occlusive disease may have less hemodynamic response to infrarenal aortic cross-clamping than do patients with AAA disease, perhaps as a result of more extensive periaortic collateral vascularization.

Renal Function and Protection

Preservation of renal function is of significant importance during aortic reconstructive surgery. Acute renal failure occurs in approximately 3% of patients undergoing elective infrarenal aortic reconstruction, and mortality resulting from postoperative acute renal failure is more frequent than 40%. Despite significant improvements in the perioperative care of these patients, the frequent incidence of morbidity and mortality resulting from acute renal failure has remained largely unchanged over the last several decades. Most of the morbidity associated with significant postoperative renal dysfunction is nonrenal.

The adequacy of renal perfusion "cannot" be assumed by urine output. Although urine output is closely monitored and often augmented during aortic surgery, intraoperative urine output does not predict postoperative renal function. Procedures requiring aortic cross-clamping above the renal arteries dramatically reduce renal blood flow. Experimental studies report an 83% to 90% reduction in renal blood flow during thoracic aortic cross-clamping. Infrarenal aortic cross-clamping in humans is associated with a 75% increase in renal vascular resistance, a 38% decrease in renal blood flow, and a redistribution of intrarenal blood flow toward the renal cortex. These rather profound alterations in renal hemodynamics occurred despite no significant change in systemic hemodynamics, and they persisted after unclamping. The sustained deterioration in renal perfusion and function during and after infrarenal aortic cross-clamping has been attributed to renal vasoconstriction, but the specific pathophysiologic process remains unknown. Renal sympathetic blockade with epidural anesthesia to a T6 level does not prevent or modify the severe impairment in renal perfusion and function that occurs during and after infrarenal aortic cross-clamping. Although plasma renin activity is increased during aortic cross-clamping, pretreatment with converting enzyme inhibitors before infrarenal aortic cross-clamping does not attenuate the decreased renal blood flow and glomerular filtration rate. Other mediators, such as plasma endothelin, myoglobin, and prostaglandins, may contribute to the decreased renal perfusion and function after aortic cross-clamping.

Acute tubular necrosis accounts for nearly all the renal dysfunction and failure after aortic reconstruction. The degree of preoperative renal insufficiency remains the strongest predictor of postoperative renal dysfunction. In

addition to aortic cross-clamping–induced reductions in renal blood flow, ischemic reperfusion injury, intravascular volume depletion, embolization of atherosclerotic debris to the kidneys, and surgical trauma to the renal arteries all contribute to renal dysfunction.

Mannitol, loop diuretics, and dopamine are used clinically in an attempt to preserve renal function during aortic surgery. Significant controversy exists regarding the use of these drugs, as well as the mechanisms by which they may offer a protective effect. Although not proved, pharmacologic "protection" before aortic cross-clamping is believed to be beneficial, and is therefore given. The use of mannitol 12.5 g/70 kg to induce osmotic diuresis before aortic cross-clamping is ubiquitous in clinical practice. Mannitol improves renal cortical blood flow during infrarenal aortic cross-clamping and reduces ischemia-induced renal vascular endothelial cell edema and vascular congestion. Other mechanisms by which mannitol may be beneficial include acting as a scavenger of free radicals, decreasing renin secretion, and increasing renal prostaglandin synthesis.

Loop diuretics and low-dose dopamine (1 to 3 μg/kg/minute) are used to protect the kidneys from aortic cross-clamp–induced injury by increasing renal blood flow and urine output intraoperatively. Routine use of these drugs is common for patients with preoperative renal insufficiency and for procedures requiring suprarenal aortic cross-clamping. Intraoperative use of these drugs requires increased surveillance of intravascular volume and electrolytes during the postoperative period. Therapy with these drugs could actually be harmful because of hypovolemia and resultant renal hypoperfusion. In addition, dopamine's positive inotropic and chronotropic activity may cause tachycardia and increase myocardial O_2 consumption in patients with limited coronary reserve. Although I have virtually abandoned the prophylactic use of dopamine, diuretics are often given to patients with low urine output after aortic unclamping, particularly those maintained on chronic diuretic therapy.

Fenoldopam mesylate, a selective dopamine type 1 agonist that preferentially dilates the renal and splanchnic vascular beds, has shown some promise as a renoprotective drug. However, its role in the prevention of renal dysfunction after aortic surgery is not known. Statin use is associated with preserved renal function after aortic surgery requiring suprarenal aortic cross-clamping.[69] Remote ischemic preconditioning reduces the incidence of renal impairment after open aortic surgery.[70]

Optimal systemic hemodynamics, including maintenance of intravascular volume, is generally considered the most effective means of renal protection during and after aortic cross-clamping. The goal is to achieve a preload adequate to allow the left ventricle to cope with cross-clamping–induced changes in contractility and afterload while maintaining cardiac output. However, in providing such therapy, excessive intravascular volume should be avoided, because it may lead to inappropriate increases in preload or pulmonary edema in patients with decreased myocardial reserve.

Therapeutic Strategies

Patients with preexisting impaired ventricular function and reduced coronary reserve are most vulnerable to the stress imposed on the cardiovascular system by aortic cross-clamping. Rational therapeutic strategies to prevent the deleterious effect of aortic cross-clamping primarily include measures to reduce afterload and maintain a normal preload and cardiac output. Vasodilators, positive and negative inotropic drugs, and controlled intravascular volume depletion (i.e., phlebotomy) may be used selectively.

Patients with impaired ventricular function requiring supraceliac aortic cross-clamping are the most challenging. Myocardial ischemia, reflecting an unfavorable balance between myocardial O_2 supply and demand, may result from the hemodynamic consequences of aortic cross-clamping. Controlled (i.e., slow clamp application) supraceliac aortic cross-clamping is important to avoid abrupt and extreme stress on the heart. Both afterload and preload reduction are often required. Afterload reduction, most commonly accomplished with the use of sodium nitroprusside (predominantly an arteriolar dilator), is necessary to unload the heart and reduce ventricular wall tension. In a large series of patients requiring cross-clamping of the descending thoracic aorta, stable left ventricular function was maintained with sodium nitroprusside during cross-clamping. Sodium nitroprusside most likely allowed adequate intravascular volume before unclamping, which resulted in stable unclamping hemodynamics. Although isoflurane can provide hemodynamics comparable to those provided by sodium nitroprusside during thoracic aortic cross-clamping, I do not advocate its use to control proximal hypertension in patients with significantly impaired ventricular function. Though not widely used, amrinone provides hemodynamic control equivalent to that of sodium nitroprusside during abdominal aortic surgery. A normal preload is equally important and involves careful IV fluid titration and vasodilator administration. Nitroglycerin is commonly used because it increases venous capacity more than does sodium nitroprusside.

In patients without evidence of left ventricular decompensation or myocardial ischemia during supraceliac aortic cross-clamping, a proximal aortic mean arterial pressure of up to 120 mm Hg is acceptable. The surgeon may request lower proximal arterial pressure if friable aortic tissue is encountered. Blood flow below the aortic clamp depends on pressure and decreases further during therapy with vasodilators. In this setting, vital organs and tissues distal to the clamp are exposed to reduced perfusion pressure and blood flow. Though infrequent, maintenance of adequate cardiac output may require active intervention with inotropic drugs.

AORTIC UNCLAMPING

The hemodynamic and metabolic effects of aortic unclamping are listed in Box 69-3. The hemodynamic response to unclamping depends on many factors, including the level of aortic occlusion, total occlusion time, use of diverting support, and intravascular volume. Hypotension, the most consistent hemodynamic response to aortic unclamping, can be profound, particularly after removal of a supraceliac cross-clamp (Fig. 69-7). Reactive hyperemia in tissues and organs distal to the clamp and the resultant relative central hypovolemia are the

dominant mechanisms of the hypotension. Washout of vasoactive and cardiodepressant mediators from ischemic tissues, as well as humoral factors, may also contribute to the hemodynamic responses after unclamping the aorta. These humoral factors and mediators, which may also play a role in organ dysfunction after aortic occlusion, include lactic acid, renin-angiotensin, O_2 free radicals, prostaglandins, neutrophils, activated complement, cytokines, and myocardial-depressant factors.[61]

Avoidance of significant hypotension with unclamping requires close communication with the surgical team, awareness of the technical aspect of the surgical procedure, and appropriate administration of fluids and vasoactive drugs. It is essential that correction of preoperative fluid deficits, maintenance of intraoperative fluid requirements, and replacement of blood loss be accomplished before unclamping. Vasodilators, if used, should be gradually reduced and discontinued before unclamping. The inspired concentrations of volatile anesthetics should be decreased. Moderate augmenting of intravascular volume by administration of fluids (~500 mL) during the immediate prerelease period is indicated for infrarenal unclamping. More aggressive intravascular fluid administration is required in the period immediately preceding supraceliac unclamping. Maintaining increased central venous or pulmonary capillary wedge pressure during the cross-clamp period is not indicated and may result in significant overtransfusion of fluids and blood products. If significant hypotension results, gradual release of the aortic clamp and reapplication or digital compression are important measures in maintaining hemodynamic stability during unclamping. Although vasopressor requirements are minimal after release of the infrarenal clamp, significant support is often needed after the removal of supraceliac clamps. Caution must be observed when vasopressor support is used in this setting because profound proximal hypertension may occur if reapplication of the cross-clamp is required above the celiac axis. In addition, hypertension should be avoided to prevent damage to or bleeding from the vascular anastomoses.

ANESTHETIC MANAGEMENT

Intraoperative Monitoring

The potential for significant and rapid blood loss cannot be underestimated. The author most commonly uses one 8.5-Fr internal jugular catheter and one or two large-bore peripheral catheters. A hemostatic valve with a side port is placed on the 8.5-Fr catheter to accept either a central venous or a pulmonary artery catheter. Placement of an arterial catheter should be routine in all patients undergoing aortic reconstruction. As with other vascular procedures, the radial artery is most commonly selected for cannulation because of its superficial location, easy accessibility, and low complication rate. A noninvasive blood pressure cuff should be placed on the arm contralateral to the arterial catheter in the event of catheter malfunction.

A central venous catheter should be used for all open aortic procedures. It allows monitoring of CVP and administration of drugs directly into the central circulation. The routine, nonselective use of pulmonary artery catheter monitoring is not recommended for patients undergoing infrarenal abdominal aortic reconstruction. For these procedures, pulmonary artery catheters should be considered for patients with significant left ventricular dysfunction (ejection fraction < 30%), a history of congestive heart failure, significant renal impairment (preoperative creatinine > 2.0 mg/dL), or cor pulmonale. In patients with good left ventricular and pulmonary function, CVP correlates well with left ventricular filling pressure. I routinely insert a pulmonary artery catheter for all patients requiring supraceliac aortic cross-clamping. The invasive monitoring catheters can be placed before or after induction of general anesthesia. The advantage of preinduction catheter placement is assessment of the patient's awake (i.e., baseline) cardiovascular status, which allows correction of significant abnormalities in cardiac filling and function before induction.

With selective use, accurate interpretation of data, and rational treatment strategies, pulmonary artery catheter monitoring may be beneficial in high-risk patients undergoing complex aortic reconstruction. Yet, the clinical value of pulmonary artery catheter monitoring in high-risk patients has not been established.[71] Clinical studies over the last 2 decades have yielded quite conflicting and variable results, including both increases and decreases in mortality. The National Heart, Lung and Blood Institute and the Food and Drug Administration (FDA)[72] sponsored a large prospective, randomized trial that compared goal-directed therapy guided by a pulmonary artery catheter with standard care without the use of a pulmonary artery catheter in high-risk surgical patients. The result found no benefit in treatment guided by a pulmonary

artery catheter.[73] Yet this study did not find an increase in mortality with insertion and use of a pulmonary artery catheter.

Two-dimensional TEE has been used intraoperatively to assess global ventricular function, guide intravascular fluid therapy, and monitor for myocardial ischemia. Continuous monitoring of ventricular function is commonly obtained with a single short-axis view at the level of the midpapillary muscle. Using this same view, visualization of the left ventricle at end-diastole allows rapid assessment of ventricular filling (preload). Ejection fraction area can be calculated by use of the left ventricular end-diastolic and end-systolic area. In patients undergoing abdominal aortic reconstruction, echocardiographic short-axis left ventricular end-diastolic area, end-systolic area, and ejection fraction area correlate closely with changes in corresponding left ventricular volume and ejection fraction obtained by radionuclide angiography. Patients requiring supraceliac aortic cross-clamping have significant increases in end-diastolic area and significant decreases in ejection fraction on echocardiography that are not completely normalized with vasodilators and frequently are not detected by pulmonary artery catheter monitoring.[63]

TEE can also reveal abnormalities in left ventricular wall motion and wall thickening. The relationship between these abnormalities and coronary perfusion has been established experimentally and clinically, and such abnormalities may precede ECG evidence of ischemia. The short-axis view at the level of the midpapillary muscles allows assessment of all three major coronary distributions. TEE-detected segmental wall motion abnormalities may occur in up to 37% of patients during infrarenal aortic reconstruction and in more than 90% of patients requiring supraceliac aortic cross-clamping. The natural history of echocardiographic segmental wall motion abnormalities was studied in 156 patients undergoing noncardiac surgery who were at risk for cardiac morbidity. The 24 patients undergoing aortic surgery had the highest incidence of new segmental wall motion abnormalities (38%). Surprisingly, the incidence of new segmental wall motion abnormalities did not differ in patients with known CAD and those with cardiac risk factors only. Ischemic episodes detected by TEE correlated poorly with postoperative cardiac complications. The authors also reported a discordant relationship between new segmental wall motion abnormalities and ischemic changes on the ECG. In a subsequent report, a subset of

285 patients who were at high risk for cardiac complications and were undergoing noncardiac surgery were studied with continuous intraoperative use of a two-lead ECG, 12-lead ECG, and TEE for the detection of ischemia. A lack of concordance was found among the three different ischemia monitors. When compared with preoperative clinical data and intraoperative monitoring in which a two-lead ECG was used, routine monitoring for myocardial ischemia with TEE or a 12-lead ECG during noncardiac surgery had little incremental clinical value in identifying patients at high risk for perioperative ischemic outcomes. Thus, available data are insufficient to define the sensitivity and specificity of segmental wall motion abnormalities as a marker for myocardial ischemia or as a predictor of perioperative ischemic outcomes.

The optimal intraoperative monitoring techniques for patients undergoing abdominal aortic reconstruction have not been established. Existing clinical studies offer insufficient data to conclusively answer the question of whether pulmonary artery catheter or TEE monitoring improves outcome. The clinical usefulness of any monitoring technique ultimately depends on patient selection, accurate interpretation of data, and appropriate therapeutic intervention.

Autologous Blood Procurement

Elective abdominal aortic reconstruction may result in substantial blood loss and warrants the routine crossmatching of 4 to 6 units of packed red blood cells (RBCs). Suprarenal aneurysms and other more complex aortic reconstructions often demand even greater allogeneic blood availability. Over the last 2 decades, concerns regarding the safety, availability, and acceptability of allogeneic blood have led to greater use of autologous blood procurement (see also Chapters 61 and 63). Preoperative autologous donation, intraoperative cell salvage, and acute normovolemic hemodilution have all been used during aortic surgery to reduce or eliminate exposure to allogeneic blood and the associated risks for transfusion-related complications.

Intraoperative cell salvage is the most widely used technique and in some centers is considered routine. The equipment is expensive and requires significant training and expertise. An early, nonrandomized study reported a 75% reduction in the number of allogeneic RBC units transfused during elective aortic surgery with the use of cell salvage. Later randomized studies have reported conflicting results. The routine use of cell salvage during aortic surgery may not be cost-effective ($250 to $350 per case), and thus it may best be reserved for a select group of patients with an expected large blood loss. The equivalent of at least 2 units of washed blood must be recovered for this technique to be cost-effective. A cost-effective option is to use the cell salvage reservoir for blood collection and activate the full salvage process only if large blood loss occurs.

Acute normovolemic hemodilution is often used in conjunction with intraoperative cell salvage during aortic surgery. Two randomized studies reported that the combined use of hemodilution and cell salvage reduced the allogeneic blood requirement in patients undergoing aortic surgery. As with cell salvage alone, this benefit is probably greater with procedures involving higher blood loss. Another randomized study found that the combined use of the two techniques during aortic surgery was cost neutral in comparison to standard allogeneic transfusion. Hemodilution does not worsen myocardial ischemia and may improve hemodynamic tolerance to aortic cross-clamping in patients with CAD.

Anesthetic Drugs and Techniques

A variety of anesthetic techniques, including general anesthesia, regional (epidural) anesthesia, and combined techniques, have been used successfully for abdominal aortic reconstruction. Combined techniques most commonly use a lumbar or low thoracic epidural catheter in addition to a "light" general anesthetic. Local anesthetics, opioids, or, more commonly, a combination of the two may be administered by bolus or continuous epidural infusion. Maintenance of vital organ perfusion and function by the provision of stable perioperative hemodynamics is more important to overall outcome than is the choice of anesthetic drug or technique.[40] Therefore, the specific anesthetic technique for patients undergoing abdominal aortic reconstruction is important insofar as it allows rapid and precise control of hemodynamic parameters. Given the frequent incidence of cardiac morbidity and mortality in patients undergoing aortic reconstruction, factors that influence ventricular work and myocardial perfusion are of prime importance.

Induction of general anesthesia should ensure that stable hemodynamics are maintained during loss of consciousness, laryngoscopy and endotracheal intubation, and the immediate postinduction period. A variety of IV anesthetics (propofol, etomidate, thiopental) are suitable. The addition of a short-acting, potent opioid such as fentanyl 3 to 5 μg/kg) usually provides stable hemodynamics during and after induction of anesthesia. Volatile anesthetics may be administered in low concentrations before endotracheal intubation during assisted ventilation as an adjunct to blunt the hyperdynamic response to laryngoscopy and endotracheal intubation. Esmolol 10 to 25 mg, sodium nitroprusside 5 to 25 μg, nitroglycerin 50 to 100 μg, and phenylephrine 50 to 100 μg should be available for bolus administration during induction if needed to maintain appropriate hemodynamics.

Maintenance of anesthesia may be accomplished with a combination of a potent opioid (fentanyl or sufentanil) and an inhaled anesthetic (sevoflurane, desflurane, or isoflurane) (i.e., balanced anesthesia). Patients with severe left ventricular dysfunction may benefit from a pure opioid technique, but a balanced anesthetic technique allows the clinician to take advantage of the most desirable characteristics of potent opioids and inhaled volatile anesthetics while minimizing their undesirable side effects. Nitrous oxide can be used to supplement either an opioid or an inhaled anesthetic. I typically use low-dose isoflurane in 50% N_2O and fentanyl 12 to 18 μg/kg. Approximately 50% of the opioid dose is administered during induction of anesthesia and before skin incision. When epidural local anesthetics are used, this author uses the same technique and reduces the fentanyl dose to 6 to 8 μg/kg.

Various regional anesthetic and analgesic techniques have been used effectively during and after aortic reconstruction. For over 2 decades, interest has focused on

the use of regional anesthetic and analgesic techniques to reduce the incidence of perioperative morbidity in patients undergoing aortic reconstruction. The benefits of combined general and epidural anesthesia intraoperatively, with or without epidural analgesia continued into the postoperative period, remain controversial.[40,74-78] Moreover, studies that have reported improved outcome do not determine whether the benefit results from the intraoperative anesthetic technique or the postoperative analgesic regimen (or a combination of the two). In a randomized trial using epidural morphine in patients undergoing aortic surgery, Breslow and associates[79] found attenuation of the adrenergic response and a less frequent incidence of hypertension in the postoperative period. A large randomized trial reported no reduction in nonsurgical complications with the use of intrathecal opioid.[80] The effects of the anesthetic or analgesic technique on the incidence of perioperative myocardial ischemia have received considerable attention. Four randomized trials, with nearly 450 combined patients undergoing aortic reconstruction, failed to demonstrate a reduction in the incidence of perioperative,[40,81] intraoperative,[82] or postoperative[77] myocardial ischemia when epidural techniques were used. Additionally, randomized trials have not demonstrated a reduction in the incidence of cardiovascular, pulmonary, or renal complications after aortic surgery with the use of epidural techniques.[40,74,76,77,83]

The duration and intensity of postoperative care after aortic surgery are critically dependent on the physiologic derangements incurred during the perioperative period (i.e., depression of consciousness, hypothermia, excessive intravascular fluids, incisional pain, ileus, and respiratory depression), as well as on the development of certain less common, but more severe postoperative complications (i.e., MI, pneumonia, sepsis, renal failure, and decreased tissue perfusion). Length of hospital stay may therefore be considered the outcome variable most directly proportional to an integrated final negative effect of all significant perioperative morbidity (excluding in-hospital death) and the variable most likely to be altered by the anesthetic or analgesic technique. Randomized trials have not demonstrated any reduction in length of hospital stay after aortic surgery with the use of regional techniques.* Norris and colleagues[40] reported the results of a randomized clinical trial comparing alternative combinations of intraoperative anesthesia (i.e., general or combined epidural and general) and postoperative analgesia (i.e., IV patient-controlled analgesia or epidural patient-controlled analgesia) with respect to length of stay after abdominal aortic surgery. Two unique features of the trial included a factorial design (Fig. 69-8), which allowed the inclusion of all four combinations of intraoperative anesthesia and postoperative analgesia and the ability to separate the influence of time period and technique, and a double-blind design, which helped eliminate investigator and treating physician bias. The study rigorously protocolized perioperative management, standardized postoperative surgical care, and optimized postoperative pain management. Although the overall length of stay was much shorter (median, 7.0 days) than

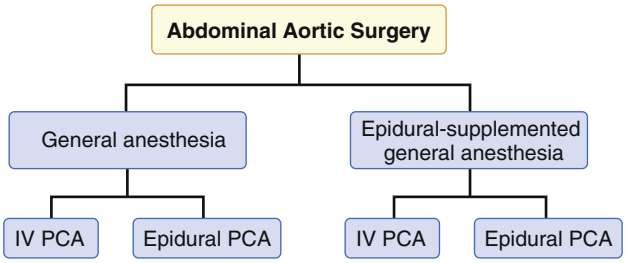

Figure 69-8. Outline of factorial study design. This design allows the inclusion of all four possible combinations on intraoperative anesthesia and postoperative analgesia and the ability to separate the influences of time period and technique. Data analysis by treatment group, intraoperative treatment, postoperative treatment, and any epidural activation, as well as simultaneous consideration of both intraoperative and postoperative treatments in the same model (factorial analysis), is possible and allows improvement in outcome to be attributed to the intraoperative anesthesia, postoperative analgesia, the combination of the two, or to unrelated factors. *IV,* Intravenous; *PCA,* Patient-controlled analgesia. (From Norris EJ, Beattie C, Perler B, et al: Double-masked randomized trial comparing alternate combinations of intraoperative anesthesia and postoperative analgesia in abdominal aortic surgery, *Anesthesiology* 95:1054-1067, 2001.)

that reported in other studies,[74,75,77,83] we were not able to demonstrate a reduction in length of stay or direct medical costs based on anesthetic or analgesic technique (Table 69-7). The overall incidence of postoperative complications in the trial was low and not different based on anesthetic or analgesic technique. Postoperative pain was well controlled overall, with similar pain scores in both analgesic treatment groups. Thus, if perioperative care and pain relief are optimized, epidural anesthetic and analgesic techniques for aortic surgery offer no major advantage or disadvantage over general anesthesia and IV patient-controlled analgesia.

The use of epidural local anesthetics in combination with general anesthesia during aortic reconstruction poses several problems, including hypotension at the time of aortic unclamping and the need for increased intravascular fluid and vasopressor requirements. Supraceliac aortic cross-clamping may significantly exaggerate these disadvantages, and, as a result, some clinicians avoid epidural local anesthetics for such procedures. Epidural opioids without local anesthetics can be used for procedures requiring supraceliac aortic cross-clamping. Epidural local anesthetic can be given later, after aortic unclamping, when hemodynamics and intravascular volume have stabilized. For low thoracic or high lumbar epidural catheters, the initial bolus should be limited to 6 to 8 mL of local anesthetic. Additional local anesthetic is administered by continuous infusion at 4 to 6 mL/hr with adjustments based on hemodynamics and inhaled anesthetic requirements during surgery. Although elective aortic reconstruction via the retroperitoneal approach using straight epidural anesthesia (no general anesthetic) has been reported, this technique is not recommended for routine use.

Emergence from anesthesia should be conducted after restoration of circulation and establishment of adequate organ perfusion. Hemodynamic, metabolic, and temperature homeostasis must be achieved before skin

closure; otherwise, patients should be transported to the intensive care unit (ICU) with their trachea intubated and their ventilation controlled. Early extubation of the trachea is not generally attempted in patients with supraceliac aortic cross-clamp times longer than 30 minutes, patients with poor baseline pulmonary function, or patients requiring large volumes of blood or crystalloid during surgery. At the start of skin closure, inhaled anesthetics are discontinued, N_2O is increased to 70%, and any residual neuromuscular blockade is reversed. I routinely insert a large nasal airway after induction of anesthesia, but before systemic heparinization in all patients for whom extubation is planned in the operating room. Hypertension and tachycardia are aggressively controlled during emergence by the use of short-acting drugs such as esmolol, nitroglycerin, and sodium nitroprusside. Patients are placed in a recumbent, head-up position, and N_2O is discontinued. If spontaneous ventilation is adequate, the trachea is extubated. Some centers advocate extubation of all patients in the ICU after a period of stability has been established. In these cases, mild sedation with a benzodiazepine such as midazolam is appropriate.

Temperature Control

Postoperative hypothermia is associated with many undesirable physiologic effects and may contribute to adverse outcomes (see also Chapter 54). Normothermia should be maintained before skin incision by increasing ambient temperature in the operating room, applying warm cotton blankets, and warming IV fluids. If significant hypothermia occurs early in the procedure, normothermia is extremely difficult to achieve, and emergence and tracheal extubation may be delayed. During surgery, all fluids and blood products should be warmed before administration. A forced-air warming blanket should be applied over the upper part of the body. The lower part of the body should not be warmed because doing so can increase injury to ischemic tissue distal to the cross-clamp by increasing metabolic demands.

THORACOABDOMINAL AORTIC SURGERY

Open repair of the thoracoabdominal aorta is widely regarded as the most challenging surgical procedure in terms of overall anesthetic and perioperative management. Surgical repair is required for a spectrum of disease, including degenerative aneurysm, acute and chronic dissection, intramural hematoma, mycotic aneurysm, pseudoaneurysm, penetrating aortic ulcer, coarctation, and traumatic aortic tear. Since the first thoracoabdominal aortic aneurysm (TAA) repair in 1955, tremendous advances have been made in the field. These advances have led to significant reductions in operative mortality and perioperative complications. However, even in centers where numerous procedures are performed, morbidity and mortality are frequent, especially in patients with dissecting or ruptured aneurysms. To successfully care for these patients, the anesthesiologist must be knowledgeable in the areas of one-lung ventilation; extracorporeal circulatory support, including circulatory arrest; renal and spinal cord protection; induced hypothermia; invasive hemodynamic monitoring, including TEE; massive transfusion; and management of coagulopathy. Intraoperative management requires a team effort with intimate cooperation among surgeons, anesthesiologists, perfusionists, nurses, and electrophysiologic monitoring staff. Endovascular stent-graft repair of lesions that affect the descending thoracic and thoracoabdominal aorta is evolving rapidly. As discussed later, accumulating experience with stent-graft repair of thoracic aortic aneurysm, dissection, and traumatic tear has demonstrated this modality to be an effective alternative to open repair for select patients.

ETIOLOGY AND CLASSIFICATION

Aneurysms of the thoracoabdominal aorta occur primarily because of atherosclerotic degenerative disease (80%) and chronic aortic dissection (17%).[84] The remainder

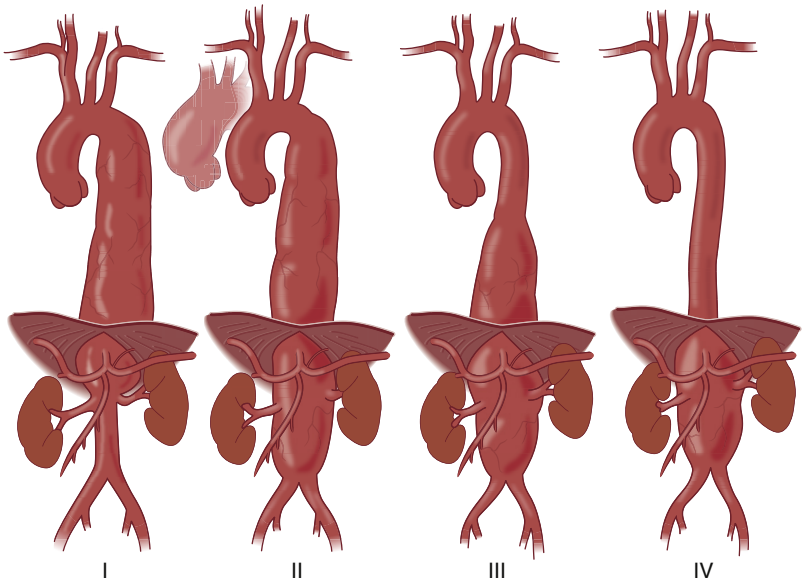

Figure 69-9. The Crawford classification of thoracoabdominal aortic aneurysms is defined by anatomic location and the extent of involvement. Type I aneurysms involve all or most of the descending thoracic aorta and the upper abdominal aorta; type II aneurysms involve all or most of the descending thoracic aorta and all or most of the abdominal aorta; type III aneurysms involve the lower portion of the descending thoracic aorta and most of the abdominal aorta; and type IV aneurysms involve all or most of the abdominal aorta, including the visceral segment. (Modified from Crawford ES: Thoracoabdominal and supra-renal abdominal aortic aneurysm. In Ernst CB, Stanley JC, editors: *Current therapy in vascular surgery*, Philadelphia, Decker, 1987, pp 96-98.)

are caused by either trauma or connective tissue diseases involving the aortic wall from conditions such as Marfan syndrome, cystic medial degeneration, Takayasu arteritis, or syphilitic aortitis.[85] The true incidence of TAA is unknown, but population studies suggest a prevalence much less than that of infrarenal AAA. Degenerative and dissecting TAAs differ in their associated risk factors, extent of aortic involvement, and natural history. Thus, complete characterization of each TAA is required to formulate a comprehensive treatment plan. Development of both degenerative and dissecting TAAs is ultimately related to weakening of the aortic wall. Although the natural history of TAA without surgery is uncertain, enlargement tends to be progressive and nonoperative management is generally associated with a poor prognosis. With progressive enlargement, nutritional blood flow to the aorta is compromised. The increasing diameter is associated with increased wall tension, even when arterial pressure is constant (law of Laplace). The frequent incidence of associated systemic hypertension enhances aneurysm enlargement.

Degenerative and dissecting TAAs are symptomatic at initial evaluation in 57% and 85% of patients, respectively. The most common initial complaint is back pain. Additional symptoms can be caused by compression of organs or structures adjacent to the aneurysm. Aortic rupture, as a manifestation of TAA, occurs with equal frequency (9%) in both degenerative and dissecting aneurysms. Rupture of the thoracic and abdominal segments occurs with equal frequency and primarily in patients with aneurysms larger than 5 cm. Surgical repair is usually recommended when aneurysm diameter exceeds 6 cm, but earlier repair may be offered to patients with Marfan syndrome and those with a strong family history of an aortic aneurysm.

In addition to cause, aneurysms of the thoracoabdominal aorta may be classified according to their anatomic location. In 1986, Crawford and colleagues,[84] recognizing the correlation between aneurysm extent and clinical outcome, proposed a classification based on the extent of aortic involvement (Fig. 69-9). The Crawford classification defines aneurysms as types I, II, III, and IV and is appropriately applied to aneurysms of all causes (degenerative and dissecting). Type I aneurysms involve all or most of the descending thoracic aorta and the upper abdominal aorta. Type II aneurysms involve all or most of the descending thoracic aorta and all or most of the abdominal aorta. Type III aneurysms involve the lower portion of the descending thoracic aorta and most of the abdominal aorta. Type IV aneurysms involve all or most of the abdominal aorta, including the visceral segment. Types II and III are the most difficult to repair because they involve both the thoracic and the abdominal segments of the aorta. Patients with Crawford type II aneurysms are at greatest risk for paraplegia and renal failure from spinal cord and kidney ischemia during cross-clamping. Even with extracorporeal circulatory support, an obligatory period occurs when blood flow to these organs is interrupted because the origin of the blood flow is between the cross-clamps. For this reason, protective measures to prevent ischemic injury are important in reducing morbidity.

Aortic dissection, with or without aneurysm formation, has likewise been classified according to the extent of aortic involvement. The most widely used classification, proposed by DeBakey and colleagues, defines aortic dissection as types I, II, and III (Fig. 69-10). Type I aneurysms begin in the ascending aorta and extend throughout the entire aorta. These lesions are usually repaired via a two-stage approach, with the first procedure on the ascending aorta and aortic arch and the second procedure on the descending thoracic aorta. Type II aneurysms are confined to the ascending aorta. Both types I and II often involve the aortic valve and cause aortic regurgitation, and sometimes they involve the ostia of the coronary arteries. Type III aneurysms begin just distal to the left subclavian artery and extend either to the diaphragm (type IIIA) or to the aortoiliac bifurcation (type IIIb). Another commonly used classification of aortic dissection is the Stanford classification. This more simplified

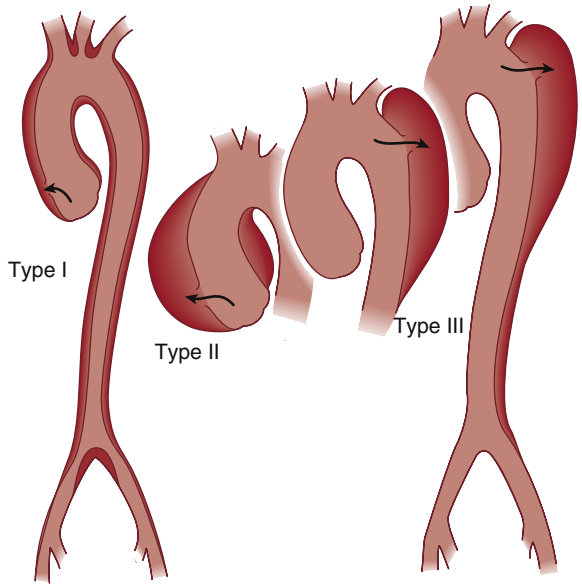

Figure 69-10. The DeBakey classification of dissecting aneurysms of the aorta. Type I has an intimal tear in the ascending aorta with dissection extending down the entire aorta. Type II has an intimal tear in the ascending aorta with dissection limited to the ascending aorta. Type III has an intimal tear in the proximal descending thoracic aorta with dissection either limited to the thoracic aorta (type IIIA) or extending distally to the abdominal aorta or aortoiliac bifurcation (type IIIB). (Adapted from DeBakey ME, Beall AC Jr, Cooley DA, et al: Dissecting aneurysms of the aorta, *Surg Clin North Am* 46:1045-1055, 1966.)

classification divides aortic dissection into those that involve the ascending aorta (Stanford type A) and those that do not involve the ascending aorta (Stanford type B). Aortic dissection is also classified by duration, with those less than 2 weeks classified as acute and those greater than 2 weeks classified as chronic. This classification has very significant mortality implications, with much higher mortality in the acute phase.

Acute aortic dissection involving the ascending aorta (DeBakey types I and II, Stanford type A) is a surgical emergency that requires immediate cardiac surgical repair (see also Chapter 67). Acute dissections involving the descending aorta (DeBakey type III, Stanford type B) are most often treated conservatively (i.e., arterial blood pressure, heart rate, and pain control) because surgical repair has no proved benefit over medical or interventional treatment in stable patients. Early surgical intervention may be required for a variety of reasons, including aneurysmal formation, impending rupture, organ or leg ischemia, and inadequate response to medical therapy. In approximately 20% to 40% of patients with chronic aortic dissection, significant aneurysmal dilatation of the descending thoracic or thoracoabdominal aorta will develop.

MORBIDITY AND MORTALITY

Despite tremendous development in surgical and anesthetic technique, mortality, and complication rates remain frequent for open surgical repair of TAA. Patients who undergo replacement of the entire thoracoabdominal aorta (Crawford extent type II) have the most frequent perioperative risk. Contemporary mortality rates reported from large institutions range from 5% to 14%. Statewide and nationwide mortality rates may be considerably more frequent (~20%). The perioperative mortality rate may significantly underestimate the risk associated with TAA repair. In a large statewide series, the mortality with elective TAA repair was 19% at 30 days and 31% at 365 days.[86]

The incidence of paraplegia or paraparesis in patients undergoing surgical repair of TAA is reported to be 3.8% to 40%, depending on complex factors such as anatomic location, the duration of cross-clamping, the use of protective measures, the degree of dissection, and whether the aneurysm has ruptured. Extensive dissecting TAA repair carries the highest risk for neurologic deficit. A contemporary report of 210 consecutive open TAA repairs reported three patients with paraplegia and two with temporary paraparesis for an overall rate of neurologic deficit of 2.4% (1.4% permanent).[87] Renal failure occurs in 3% to 30% of patients, depending on similar factors noted earlier. Overall, approximately 6% of patients need postoperative dialysis after TAA repair, which is associated with high mortality (30% to 60%). Gastrointestinal complications occur in approximately 7% of patients and are associated with a mortality approaching 40%. Not surprisingly, pulmonary complications are the most common problem associated with TAA repair. The incidence of postoperative pulmonary insufficiency approaches 50%, with 8% to 14% of patients requiring tracheostomy. As with all other vascular surgical procedures, cardiac complications are common and a leading cause of perioperative mortality. In general, perioperative mortality and major complication rates after open isolated descending thoracic aortic replacement are lower than those described for TAA repair.

PREOPERATIVE PREPARATION AND MONITORING

Open surgical TAA repair requires extensive preoperative evaluation and planning. The evaluation and management of coexisting cardiac and pulmonary disease are discussed earlier in this chapter. Before the day of surgery, the anesthesiologist and vascular surgeon should discuss, at a minimum, extent of the aneurysm and technique of surgical repair, plans for distal aortic perfusion, monitoring for spinal cord ischemia, renal and spinal cord protection, hemodynamic monitoring, and ventilation strategy.

Blood loss during TAA repair can be profound, and the need for massive transfusion must not be underestimated. This author routinely has 15 units of packed RBCs and 15 units of thawed fresh frozen plasma immediately available in the operating room, and additional units must be readily obtainable. I use a large cooler to store blood products on ice in the operating room so that they can be returned to the blood bank if not used. Platelets should be readily available as well. A dedicated critical care technician is helpful in assisting with laboratory testing and retrieving products from the blood bank (also see Chapter 61).

Large-bore IV access is obviously important, especially if partial bypass (in contrast to full bypass) is planned,

because it is difficult or impossible for the perfusionist to administer fluid or blood products into the closed partial bypass circuit. This author routinely inserts three 8.5-Fr catheters into the internal jugular and antecubital veins. One of these accepts a pulmonary artery catheter, and the other two are connected to a rapid infuser system that allows the delivery of up to 1500 mL/minute of blood products at a temperature of 37° to 38° C. A right radial arterial catheter is used for aneurysms involving the proximal descending thoracic aorta because occasionally the cross-clamp is placed proximal to the left subclavian artery, thus occluding flow to the left upper extremity. When distal aortic perfusion techniques are used, I monitor arterial blood pressure distal to the cross-clamps. This can be accomplished with the placement of a right femoral arterial catheter, or the surgical team can place a catheter directly into the femoral artery or distal aorta. This catheter monitors perfusion pressure to the kidneys, spinal cord, and mesenteric circulation during the time when the cross-clamps are high on the descending aorta and the lower body region is perfused by a shunt or bypass circuit. Radial and femoral arterial pressure should be simultaneously displayed on the anesthesiologist's monitor and a monitor visible to the surgeons and the perfusionists. TEE is used routinely during TAA repair (see also Chapter 46). When TEE is used by a properly trained individual, assessment of left ventricular end-diastolic volume, myocardial ischemia, and valvular function is possible. It is also possible to determine the size and the extent of the aneurysm.

A double-lumen endobronchial tube should be inserted for the purpose of one-lung ventilation (see also Chapter 66). One-lung ventilation provides optimal visualization of the surgical field and reduces retraction-related trauma to the left lung. A left-sided endobronchial tube is optimal because it is more easily positioned and less likely to become malpositioned. Additionally, risk exists for occluding the right upper lobe bronchus with a right-sided tube. I position all double-lumen tubes under direct vision using a fiberoptic bronchoscope because it facilitates quick and definitive placement and allows direct visualization of the distal trachea and mainstem bronchi. Occasionally, when the left mainstem bronchus is compressed by a large aneurysm, the lumen does not accommodate an endobronchial tube. In this situation, a right-sided endobronchial tube might be necessary. Rarely, the right mainstem bronchus may be compressed by a large aneurysm. The double-lumen tube is usually changed, if possible, to a single-lumen tube at the completion of surgery. This facilitates ICU management of pulmonary hygiene and reduces resistance to breathing during weaning in the postoperative period. The airway is often edematous after surgery, and it may be difficult or impossible to change the double-lumen tube without tube-changing catheters.

Many centers use electrophysiologic monitoring with somatosensory evoked potentials (SSEPs) or motor evoked potentials (MEPs) to monitor for spinal cord ischemia (see also Chapter 49). These monitoring techniques may be helpful in both identifying the important intercostal arteries that perfuse the spinal cord and confirming successful reimplantation into the aortic graft. If spinal cord ischemia is identified, cross-clamps can often be repositioned, upper or lower body blood pressure can be increased to augment perfusion through collateral channels, or other measures may be taken to protect the spinal cord (i.e., cerebrospinal fluid [CSF] drainage, induced hypothermia, or intrathecal pharmacologic agents). These techniques are discussed later. Three general problems exist with SSEP monitoring when used during TAA repair. First, sensory monitoring is more likely to detect lateral and posterior sensory column ischemia and is a poor monitor for the anterior motor column. As a result, paraplegia can occur despite normal SSEP signals. Second, inhaled anesthetics and hypothermia can significantly interfere with SSEP signals. Third, ischemia affects peripheral nerves, and ischemia in the lower extremities delays conduction from the usual stimulation sites (e.g., posterior tibial nerve). To eliminate the peripheral nerves as a confounding factor, spinal stimulation via a lumbar epidural electrode can be used, which may be more specific for ischemic injury than peripheral monitoring alone. Lower extremity and peripheral nerve ischemia can be avoided with the use of distal aortic perfusion techniques. To avoid lower extremity ischemia from occlusion of the left femoral artery at the insertion site of the retrograde perfusion cannula, some surgeons suture a small-caliber graft onto the femoral artery (end to side) for insertion of the cannula, which allows both antegrade and retrograde perfusion. These limitations of SSEP monitoring probably accounted for the lack of improvement in neurologic outcome in a large prospective series of TAA repairs. In this same series, the incidence of false-negative responses was 13% and that of false-positive responses was 67%, thus making identification of critical spinal arteries impossible.

The transcranial MEP technique has been used successfully to monitor the anterior columns of the spinal cord. The technique is relatively simple and can be viewed as a "train-of-four" for the brain and spinal cord. Electrical stimulation over the motor cortex activates α-motor neurons, and evoked electromyographic responses are obtained in lower extremity muscle. Only electromyogenic responses are specific for the status of the motor neurons in the anterior horn gray matter. Bilateral recording needles should be placed in the popliteal fossae (i.e., popliteal nerve) and bilateral surface electrodes over the gastrocnemius and tibialis anterior muscles. Bilateral stimulating needles are routinely placed in the popliteal fossae to monitor direct muscle responses and the level of neuromuscular blockade. During aortic cross-clamping, MEPs are monitored every minute. A reduction in MEP amplitude to less than 25% of baseline is considered an indication of spinal cord ischemia and requires corrective measures. Because signal averaging is not required and the anterior horn cells react with an almost immediate functional loss after the onset of ischemia, the technique can be used to rapidly identify intercostal arteries supplying the spinal cord. Additionally, the technique can be used to evaluate the adequacy of distal aortic perfusion and the patency of reimplanted critical intercostal arteries. Careful titration of a short-acting neuromuscular blocker is required to maintain a stable level of neuromuscular blockade. Complete neuromuscular blockade makes MEP monitoring impossible. I use a continuous infusion

technique to maintain electrical muscle amplitude at approximately 50% of baseline. Isoflurane, desflurane, sevoflurane, and N_2O depress synaptic conduction and significantly decrease the amplitude of myogenic MEPs. Although modifications of the stimulating technique have improved monitoring with inhaled anesthetics somewhat, a total IV anesthetic technique may be optimal. Fentanyl and ketamine have little effect on myogeneic MEPs and have been used successfully as a combined anesthetic in a large series of patients undergoing TAA repair with MEP monitoring.[87] This series of 210 consecutive patients had the lowest rate of neurologic deficit (2.4%) and permanent paraplegia (1.4%) reported.[87]

Body temperature should be monitored at two sites (core and peripheral) to assess cooling and warming when bypass techniques are used. However, an important difference exists between full and partial bypass with regard to temperature monitoring. With full bypass, perfusion is usually into the ascending aorta, and typically the upper body core temperature (i.e., nasopharynx or esophagus) cools and warms fastest, whereas the lower body temperature changes more slowly. With partial bypass, the opposite is true. The blood from bypass is returned into the femoral artery, and the lower part of the body (i.e., rectum or bladder) changes before the upper part changes. This difference is important to recognize to achieve complete cooling and warming because the lagging temperature should be the end point for cooling and warming.

ANESTHETIC MANAGEMENT

Simple Aortic Cross-Clamping

Descending thoracic and thoracoabdominal aortic surgery can be performed without extracorporeal support (i.e., left heart bypass or cardiopulmonary bypass). The "clamp-and-sew" technique has had relatively favorable outcomes, but these cases are from institutions with extensive clinical experience and the shortest cross-clamp times. Advocates of this technique favor its surgical simplicity. However, the benefits of avoiding the complexity and complications of bypass must be weighed against the risk for vital organ ischemia and complications such as renal failure and paraplegia.

Other than the location and extent of the aneurysm, the duration of cross-clamping on the aorta is the single most important determinant of paraplegia and renal failure with the clamp-and-sew technique. Clamp times of less than 20 to 30 minutes are associated with almost no paraplegia. When clamp times are between 30 and 60 minutes (the vulnerable interval), the incidence of paraplegia increases from approximately 10% to 90% as time progresses. Because clamp times are typically in this range or longer, specific adjuncts directed against end-organ ischemic complications are often used. Such adjuncts include epidural cooling for spinal cord protection, regional hypothermia for renal protection, and inline mesenteric shunting to reduce visceral ischemia.

When the simple clamp-and-sew technique is used, application of the aortic cross-clamp results in significant proximal hypertension, which requires active pharmacologic intervention. Management strategies have been discussed previously in the section on abdominal aortic reconstruction. Briefly, both sodium nitroprusside and isoflurane have been used successfully to control the proximal hypertension associated with high aortic cross-clamping. Isoflurane is best reserved for patients with good myocardial function. Vasodilators, such as sodium nitroprusside, must be used with caution because they can result in significant overperfusion of the body proximal to the clamp and very low pressures distally. Nitroglycerin can be used to normalize preload and cardiac filling and thus reduce ventricular wall tension. Although nitroglycerin does not control proximal hypertension well as a single agent, it is very helpful when used in combination with sodium nitroprusside. Management of aortic unclamping has been discussed earlier.

Left Heart Bypass

Maintaining lower body perfusion with the use of retrograde distal aortic perfusion reduces ischemic injury and improves outcome, provided the pressure is high enough to perfuse the organs. The simplest method of providing distal aortic perfusion is a passive conduit or shunt. The heparin-bonded Gott shunt was developed to avoid the need for systemic heparinization and is used to divert flow passively from the left ventricle or proximal descending thoracic aorta to the distal aorta. Some centers place a temporary axillary-to-femoral artery graft to function as a shunt during aortic cross-clamping.

Partial bypass, also referred to as left heart bypass or left atrial-to-femoral bypass, is the most commonly used distal aortic perfusion technique (Fig. 69-11). This technique allows adjustment of blood flow and usually draws blood

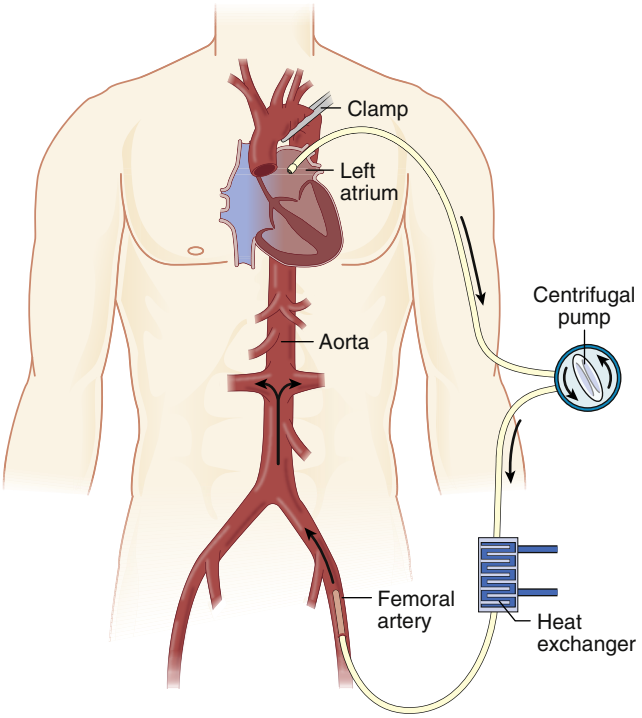

Figure 69-11. Diagram of left atrial-femoral bypass. The left atrium and the left femoral artery are cannulated, and a centrifugal pump is used with heparin-coated tubing. A heat exchanger may be added into the circuit for cooling and rewarming.

from the left atrium and returns blood to the left femoral artery. A centrifugal pump is used (Biomedicus, Eden Prairie, Minn), and full-dose systemic heparin is not needed because the circuit is coated with heparin. The typical heparin dose for partial bypass is 100 units/kg. With this technique, an oxygenator is unnecessary because only the left side of the heart is bypassed. Insertion of a heat exchanger into the circuit allows cooling and warming, which is beneficial but not absolutely essential. Variations of left heart bypass include cannulating the aortic arch or proximal descending thoracic aorta instead of the left atrium. With this circuit, the left ventricle is relieved of the increased afterload during aortic cross-clamping. With left atrial cannulation, the left ventricle is relieved of preload and cardiac output is reduced. Either way, proximal hypertension is controlled, the work of the ventricle is decreased, and perfusion is provided to the distal aorta. My colleagues and I have had even greater success with cannulation of a pulmonary vein instead of the left atrium. This method accomplishes the same effect as with atrial cannulation but is associated with less atrial irritability. When hypothermia (30° C) is combined with atrial cannulation, approximately 15% of patients experience new atrial fibrillation. Although most patients revert to sinus rhythm on rewarming, direct cardioversion may be required.

During left heart bypass, it is essential that arterial blood pressure be monitored above and below the aortic cross-clamps. I simultaneously display radial and femoral artery pressure and aim for a mean arterial pressure of 80 to 100 mm Hg above the cross-clamp and at least 60 mm Hg below the cross-clamp. Careful control of intravascular volume, bypass pump flow, and vasoactive drugs is required to achieve the target blood pressures. Management of left heart bypass requires continuous communication and cooperation between the surgeon, anesthesiologist, and perfusionist. We typically set the initial pump flow to approximately 50% of the patient's cardiac output with application of the proximal aortic clamp. Flow is then adjusted to maintain target proximal and distal pressures. Administration of vasodilators is very infrequently required at this stage. With no vital organ ischemia, the surgeon can complete the proximal anastomoses in an unhurried fashion. With sequential aortic clamping, intercostal arteries can be reimplanted with minimal adjustments of pump flow. Pump flow is eventually reduced significantly during reimplantation of the visceral and renal arteries. At this time, distal perfusion is only to the lower extremities. We routinely use moderate hypothermia (32° C) during bypass to protect the vital organs during obligate periods of ischemia. After completion of the distal anastomoses, pump flow is increased, and the patient is actively warmed to 37° C.

Deep Hypothermic Circulatory Arrest

Complex aneurysms involving the aortic arch often require elective cardiopulmonary bypass with an interval of deep hypothermic (15° C) circulatory arrest (DHCA) because cerebral blood flow is transiently interrupted during surgery (see also Chapter 67). Bypass can be accomplished by cannulation of the femoral artery and the femoral vein (i.e., femoral-femoral bypass). During the interval of DHCA, some centers also use anterograde (i.e., innominate artery) or retrograde (i.e., internal jugular vein) selective cerebral perfusion with cold oxygenated blood to extend the safe maximum duration of circulatory arrest. Without this technique, 45 to 60 minutes is thought to be the safe limit of DHCA, but 90 minutes has been reported with selective cerebral perfusion.

DHCA also may be necessary whenever the location, extent, or severity of aortic disease precludes placement of a proximal aortic clamp during thoracic or thoracoabdominal aortic repair. This is often the case in patients with previous aortic arch repair, in which adhesions and scarring make application of the proximal aortic cross-clamp difficult or impossible during TAA repair. DHCA eliminates the need for proximal aortic clamping and allows a bloodless field for the proximal aortic anastomosis. Some centers advocate the routine use of DHCA during complex aortic reconstruction because deep hypothermia may provide better end-organ and spinal cord function. This potential benefit must be carefully weighed against the risks associated with prolonged cardiopulmonary bypass and circulatory arrest. After completion of the proximal anastomosis and intercostal artery–to-graft anastomoses under DHCA, the aortic graft is cannulated and bypass flow is reestablished to the upper part of the body. During a period of hypothermic low bypass flow, the distal anastomoses are completed and then rewarming is initiated.

Anesthetic Technique

No single anesthetic technique is best for TAA repair. Usually, balanced anesthesia is provided with a combination of an opioid, a low-dose potent volatile anesthetic, a benzodiazepine, and a muscle relaxant. A total IV technique may be optimal if transcranial MEP monitoring is used. Induction of general anesthesia should be slow and controlled. Hypertension should be avoided because acute stress on the aneurysm can cause rupture. The heart rate should be maintained at or below baseline because myocardial ischemia is often related to the heart rate. Extubation should always take place in the ICU and only after a significant period of hemodynamic and metabolic stability. The postoperative analgesic regimen should focus on pain control and stable hemodynamics.

Spinal Cord Ischemia and Protection

Paraplegia is a devastating complication of aortic surgery. The incidence of paraplegia is reported to be 0.5% to 1.5% for coarctation repair, 0% to 10% for thoracic aneurysm repair, 10% to 20% for thoracoabdominal repair, and as high as 40% for extensive dissecting TAA repair.

The spinal cord receives its blood supply from two posterior arteries (≈25%) and one anterior spinal artery (≈75%) (Fig. 69-12). The posterior spinal arteries, which supply the sensory tracts in the spinal cord, receive flow from the posterior and inferior cerebellar arteries, the vertebral arteries, and the posterior radicular arteries. The anterior spinal artery, which supplies the motor tracts in the spinal cord, is formed by two branches of the intracranial portion of the vertebral arteries. The upper cervical segment of the spinal cord receives most of its blood flow from the vertebrals. The thoracic portion of the anterior

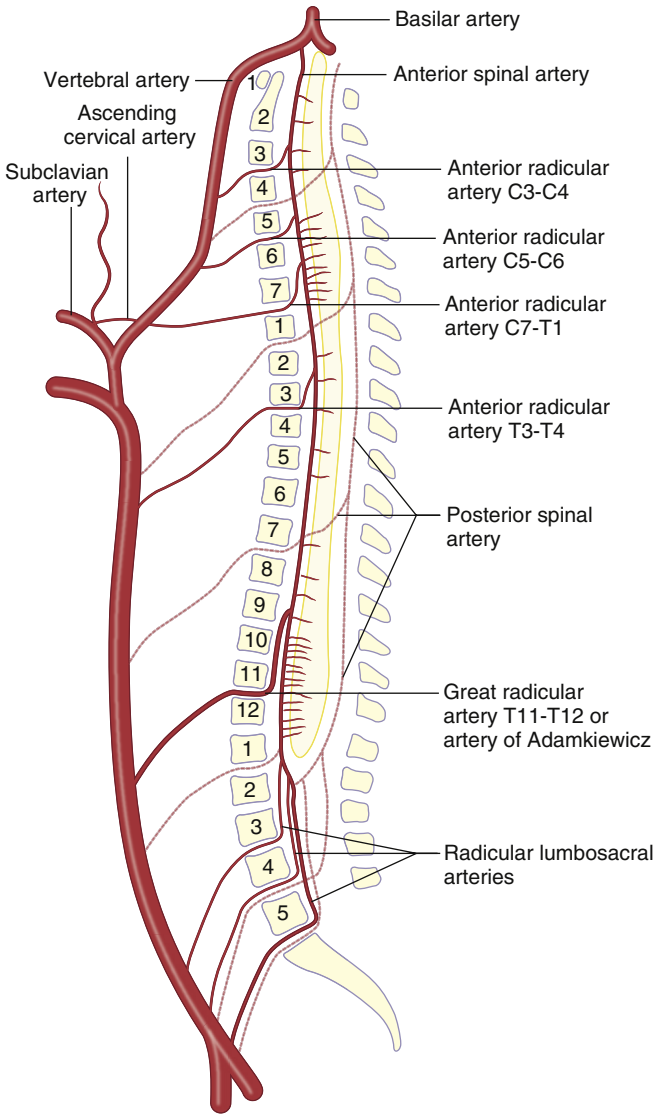

Figure 69-12. Diagram of the blood supply to the spinal cord showing the anterior and posterior radiculomedullary branches seen in a lateral view. The primary blood supply to the thoracolumbar portion of the spinal cord is derived from the artery of Adamkiewicz; its origin varies but usually branches off the aorta in the T9 to T12 region. (From Djindjian R: Arteriography of the spinal cord, *Am J Roentgenol Radium Ther Nucl Med* 107:461-478, 1969.)

spinal artery is supplied by the anterior radicular arteries (one or two cervical, two or three thoracic, and one or two lumbar). The largest of the radicular arteries is called the great radicular artery (GRA) or the artery of Adamkiewicz. The GRA is the major blood supply to the lower two thirds of the spinal cord. The segmental supplier of the GRA is variable (T5-L5) but is located between T9 and T12 in approximately 75% of cases. The variation in origin of the GRA explains why even infrarenal aortic aneurysm repair is associated with a 0.25% incidence of paraplegia. The specific impact of extensive segmental artery sacrifice on spinal cord perfusion during TAA repair is poorly understood.

Various methods can facilitate preventing ischemic injury to the spinal cord. Distal aortic perfusion with extracorporeal support reduces the incidence of paraplegia. Any of the various methods of distal bypass are likely to be beneficial when the anticipated cross-clamp time is longer than 30 minutes, but they are probably not beneficial when cross-clamp time is less than 20 minutes. CSF drainage is frequently used to improve spinal cord perfusion during TAA repair and is often used in combination with distal aortic perfusion. Spinal cord perfusion pressure is defined as distal mean aortic pressure minus CSF pressure or central venous pressure, whichever is greatest. Autoregulation of spinal cord blood flow is similar to cerebral autoregulation, and blood flow is relatively constant over the range of 50 to 125 mm Hg. During hypoxia or hypercapnia, autoregulation is lost, and flow becomes linearly related to perfusion pressure. Thus, significant flow may remain even at very low perfusion pressure. Drainage of CSF is important because CSF pressure often increases (by 10 to 15 mm Hg) with cross-clamping of the descending thoracic aorta. The increase in CSF pressure reduces spinal cord perfusion pressure and increases the likelihood of ischemic spinal cord injury.

Despite evidence from animal studies that CSF drainage protects the spinal cord, clinical use of this technique is controversial. One randomized trial reported a reduced incidence of paraplegia, but another reported no benefit. Most of the evidence in support of CSF drainage comes from nonrandomized historical cohort studies in which the technique is used in combination with other adjuncts, such as intrathecal papaverine and hypothermic partial bypass. Coselli and colleagues[88] offered the strongest evidence supporting the efficacy of CSF drainage. They conducted a prospective, randomized clinical trial to evaluate the impact of CSF drainage on the incidence of spinal cord injury after Crawford type I and II TAA repair. CSF drainage resulted in an 80% reduction in the relative risk for a postoperative deficit. Nine patients in the control group (13%) had paraplegia or paraparesis versus only two patients in the CSF drainage group (2.6%). Left heart bypass, moderate heparinization, permissive mild hypothermia, and reimplantation of patent intercostal and lumbar arteries were performed in both treatment groups. The target CSF pressure was 10 mm Hg. CSF drainage also reverses delayed-onset neurologic deficit after open and endovascular TAA repair.[89]

Although CSF drainage is widely used during TAA repair, it has risks. Potential complications include headache, meningitis, chronic CSF leakage, spinal or epidural hematoma, and subdural hematoma. The possibility of intraspinal pathologic processes should be considered in any patient with a postoperative lower extremity neurologic deficit. A retrospective review of 230 patients who underwent TAA repair with CSF drainage at my institution reported eight subdural hematomas (3.5%).[90] High-volume CSF drainage was identified as a risk factor for its occurrence. Six patients had subdural hematomas detected during hospitalization, with an associated mortality of 67%. Two patients were seen in a delayed fashion, and both required an epidural blood patch to control chronic CSF leakage.

Hypothermia is probably the most reliable method of neuroprotection from ischemic injury. By reducing O_2 requirements by approximately 5% for each degree centigrade, a twofold prolongation of tolerated cross-clamp time is achieved by cooling even to mild hypothermia (34° C). Because the reduction in metabolic rate is linearly related to temperature, moderate or profound hypothermia provides even greater protection. Both systemic and regional spinal cord cooling is beneficial. Systemic hypothermia can been achieved with either full cardiopulmonary bypass (with or without DHCA) or partial bypass. Cooling to 30° to 32° C with left atrial-to-femoral bypass in conjunction with CSF drainage was associated with no permanent neurologic sequelae in a series of 20 patients despite a relatively long average cross-clamp time (≈70 minutes).[91] My colleagues and I have since used this technique in more than 600 patients cooled to 32° C, with a 5% incidence of paraplegia. Although some risk is incurred when a beating heart is subjected to moderate hypothermia, the benefits appear to outweigh the risks. Supraventricular and ventricular dysrhythmias respond well to cardioversion or mild warming to 33° to 34° C. Regional cooling of the spinal cord by cold perfusion of the GRA with blood or crystalloid provides significant protection during spinal ischemia in animal models. Regional cooling is beneficial in humans who received epidural infusions of 4° C saline. Even if active cooling is not used, it is advantageous to allow patients to passively cool to 33° to 34° C during TAA repair. With passive cooling, the challenge is rewarming after the surgical repair. This is most easily accomplished with the use of a forced-air blanket over the upper part of the body. The lower body region should not be actively warmed because warming ischemic tissue increases metabolic requirements, acidosis, and ischemic injury.

Many drugs have been studied in an attempt to reduce the incidence of ischemic spinal cord injury. Barbiturates provide significant protection. Corticosteroids provide protection in dogs but were beneficial in humans only when they were combined with CSF drainage. Calcium channel blockers were not consistently shown to be protective against spinal cord ischemia. *N*-methyl-D-aspartate (NMDA) receptor antagonists have been investigated because ischemic injury appears to be related to increased levels of excitatory amino acids (particularly glutamate), which allow increased permeability to Ca^{2+} ions and high intracellular Ca^{2+} concentrations. Dextrorphan (a noncompetitive NMDA receptor antagonist) shows promise during spinal cord ischemia. Magnesium, another NMDA receptor antagonist, improves recovery from spinal cord ischemia in rat and dog models when administered intrathecally. Naloxone is protective in patients with traumatic spinal cord injuries and in a rabbit model of spinal ischemia. Naloxone also shows promise when combined with CSF drainage in patients undergoing TAA repair. Intrathecal papaverine appears to be protective, especially when combined with CSF drainage. Other agents under investigation include levosimendan, allopurinol, adenosine, ziconotide, activated protein C, and desferrioxamine. Other than the use of corticosteroids and naloxone at a few centers, most of these agents are considered investigational.

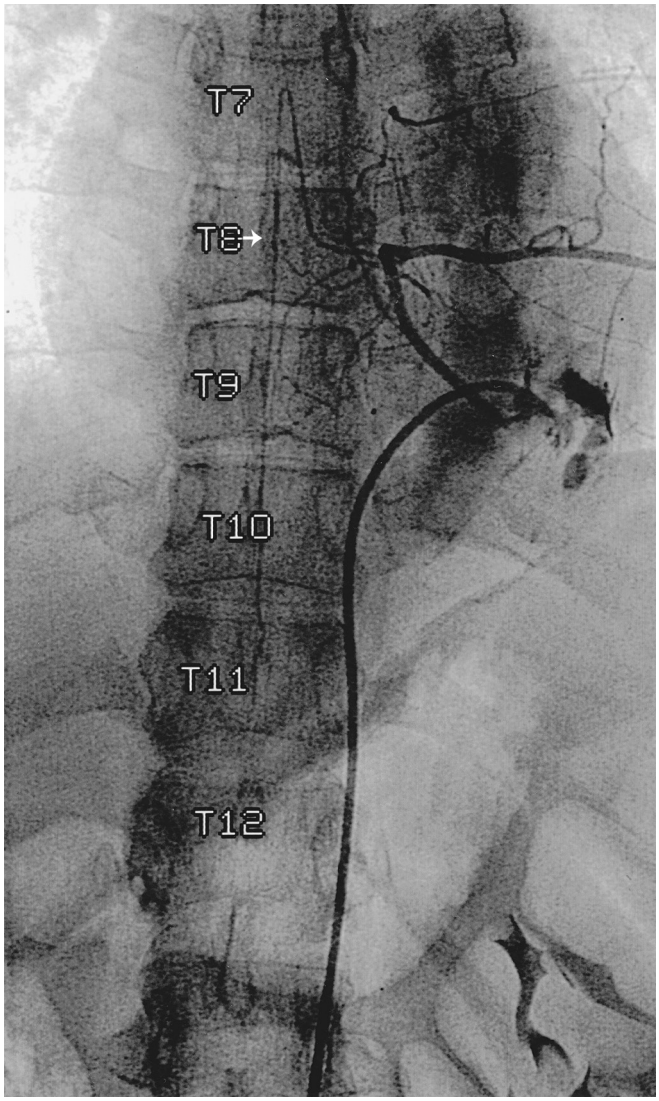

Figure 69-13. Spinal cord angiogram of an extensive degenerative thoracoabdominal aortic aneurysm. Selective injection of the intercostal artery at T8 (*arrow*) demonstrates the great radicular artery and the extensive paravertebral collateralization.

Preoperative spinal cord angiography has been used in patients with TAA. The rationale for this highly invasive angiographic procedure is that precise identification of intercostal arteries giving rise to the GRA will allow focused reimplantation of these vessels during surgical repair and help prevent spinal cord injury. Selective intercostal angiography identifies the GRA when an intercostal branch is found making a cephalad hairpin turn to enter the spinal canal and supply a midline longitudinal artery (i.e., the anterior spinal artery) (Fig. 69-13). The GRA can be identified in 43% to 86% of patients studied with traditional angiography. Higher detection rates for GRA localization have been reported with computed tomographic angiography (CTA) and magnetic resonance angiography (MRA), with the latter achieving rates of nearly 100%.[92]

The importance of reimplanting the intercostal arteries identified as supplying the GRA is not universally accepted. Even in patients with an identified and reimplanted GRA, spinal cord injury is not always prevented. Some investigators have concluded that preoperative localization of the GRA has little impact on neurologic outcome after TAA repair. A report from my institution[93] found no improvement in overall neurologic outcome with preoperative spinal cord angiography, but it offered important insight regarding the type of aneurysm, identification of the GRA, and neurologic outcome. In patients undergoing TAA repair for extensive degenerative aneurysms, spinal cord injury occurred in 0 of 45 patients versus 10 (12%) of 81 patients with and without an identified GRA, respectively. In contrast, identification of the GRA was not helpful in the case of chronic expanding aortic dissection, with 3 (15%) of 20 patients versus 3 (6%) of 49 patients suffering spinal cord injury with and without an identified GRA, respectively. The investigators hypothesized that mural thrombus in degenerative aneurysms results in the occlusion of many intercostal arteries and favors the development of extensive paravertebral collateral channels (see Fig, 69-13). Identification of a GRA allows focused reimplantation with uniform success. In patients with chronic dissection, most intercostal arteries are patent, collateralization is minimal, and reimplantation of one or two intercostal arteries may be insufficient to supply blood flow to the spinal cord. This collateral blood supply concept is further supported by clinical studies demonstrating that clamping the segmental supplier to the GRA during TAA repair does not produce critical spinal cord ischemia in the majority of patients.[94] Sufficient collateral blood supply, independent of the GRA, must therefore exist to maintain spinal cord integrity.

Delayed-onset neurologic deficits are common after TAA repair.[95] In a large series of 2368 TAA repairs, 93 (3.9%) patients had postoperative paraplegia or paraparesis, 34 (37%) of whom initially had intact spinal cord function but a deficit developed later.[96] Preoperative renal dysfunction, acute dissection, and extent type II TAA are significant predictors of delayed neurologic deficit. Postoperative hypotension and CSF drain malfunction may play an important role in the development of these deficits. Neurologic function can frequently be recovered by maintaining an optimal arterial blood pressure and CSF drainage.

Renal Ischemia and Protection

Renal failure after TAA repair results from preexisting renal dysfunction, ischemia during cross-clamping, thrombotic or embolic interruption of renal blood flow, and hypovolemia and hypotension. Approximately 6% of patients require postoperative dialysis, even in centers with the most clinical experience. The associated mortality can be high. The primary predictor of postoperative renal failure is preoperative renal dysfunction. The duration of cross-clamp time is very important with the clamp-and-sew technique.

Retrograde distal aortic perfusion techniques are widely used to preserve renal function during the cross-clamp period. Adequate bypass flow and arterial blood pressure are essential for maintaining renal function. Systemic and regional hypothermia, by reducing O_2 requirements, protects the kidneys during ischemia. Some centers advocate the use of DHCA in the treatment of distal TAAs (i.e., extent type III and IV) to preserve renal function.

The role of pharmacologic protection is somewhat controversial. Mannitol 12.5 to 25 g/70 kg is often given before cross-clamping. Mannitol improves renal cortical blood flow and the glomerular filtration rate in animal models of ischemia. Endothelial cell swelling is decreased, and an osmotic diuresis occurs. Evidence demonstrates free radical scavenging with mannitol and subsequent protection from ischemia in animals. Loop diuretics are sometimes given, but these drugs have been less effective than mannitol in experimental models. In clinical studies, the prophylactic use of loop diuretics has not been shown to improve outcome or reduce the need for dialysis for patients with acute renal failure. Dopamine given in low doses (1 to 3 μg/kg/minute) dilates renal blood vessels and increases renal blood flow and urine output. Despite these beneficial effects, whether dopamine provides renal protection during ischemia is not clear. Fenoldopam mesylate, a selective dopamine type 1 agonist that preferentially dilates the renal and splanchnic vascular beds, has shown some promise as a renoprotective drug.

At the present time, optimal renal protection during TAA surgery should rely on hypothermia, mannitol, and prevention of hypotension and hypoperfusion of the kidneys.

Coagulation and Metabolic Management

Coagulopathy is a frequent complication during TAA repair. A dilutional coagulopathy in which platelets become deficient after approximately one blood volume of replacement develops during massive transfusion (see also Chapters 61 and 62). At between one and two blood volumes of replacement, coagulation factors are diluted to levels low enough to increase bleeding. Other contributing factors are residual heparin; ischemia of the liver, in which most coagulations factors are produced; and persistent hypothermia after weaning from bypass. With the early use of fresh frozen plasma and platelets, severe coagulopathy often can be avoided. The prothrombin time, partial thromboplastin time, fibrinogen level, and platelet count should be measured frequently. Cryoprecipitate may be necessary to correct coagulopathy, especially when the prothrombin time and partial thromboplastin time are prolonged and hypervolemia prevents the administration of significant volumes of fresh frozen plasma. When coagulopathy persists despite these efforts, ε-aminocaproic acid is beneficial as antifibrinolytic therapy, and desmopressin can be given to increase circulating levels of von Willebrand factor and factor VIII. Normothermia should be achieved by complete rewarming before separation from bypass, by increasing ambient temperature after separation from bypass, and by forced-air warming over the upper body skin surface.

Analysis of arterial blood gases and electrolyte levels should be performed frequently. Sodium bicarbonate should be given to treat the metabolic acidosis that occurs during and after cross-clamping. Hyperkalemia should be treated aggressively, especially in oliguric or anuric

patients. Calcium chloride and sodium bicarbonate are the primary acute treatments of hyperkalemia.

ENDOVASCULAR AORTIC REPAIR SURGERY

Endovascular surgery is one of the most exciting developments in the treatment of vascular disease and is revolutionizing current treatment modalities for aortic disease. The endovascular approach was initially developed as a less invasive alternative to elective open AAA repair and to provide a treatment option for patients considered to be poor surgical candidates. Over the last 2 decades, an explosive increase has occurred in the use of endoluminal devices to treat AAA. These devices accounted for nearly 50% of elective repairs of AAA in Medicare beneficiaries during the period 2001 to 2004.[97] Interest in endoluminal aortic grafting has rapidly expanded beyond the abdominal aorta to include disease of the thoracic and thoracoabdominal aorta and, most recently, the ascending aorta and aortic arch. Endovascular grafting has also emerged as a viable alternative to open repair of aortic dissection, rupture, and traumatic injury. As experience with endoluminal techniques increases, along with continued refinement of stent-graft devices, the endovascular approach will be applied to more patients with increasingly complex aortic disease.

EVOLUTION OF STENT-GRAFT DEVICES

The transluminal placement of an endovascular stent-graft to treat arterial disease began experimentally in the late 1960s. The feasibility of this technique for the treatment of AAA was established experimentally some 2 decades later. In 1991, Parodi and colleagues[98] reported the first clinical use of the technique in five patients with infrarenal AAAs. They described the placement of an endoluminal, stent-anchored, Dacron tube graft via retrograde cannulation of the common femoral artery under local or regional anesthesia. Balloon expansion of the stents fixed the ends of the graft to the aortic wall and excluded the aneurysm from the systemic circulation. The technique was satisfactory in three of the five patients.

After nearly a decade of refinements, in 1999 the FDA approved the use of two endovascular stent-graft devices for repair of infrarenal AAAs in the United States. FDA approval of these devices was granted without the usual requirement for a randomized controlled trial. Instead, the FDA allowed a concurrent "matched" group of patients treated by open repair to serve as a control group. Additional stent-graft devices have received regulatory approval in the United States, and several are approved for use by other governments around the world. Since regulatory device approval, a rapid increase in endovascular AAA repair has occurred nationwide. The stent-grafts used for infrarenal AAA repair are usually modular bifurcated devices made of synthetic fabric reinforced by a stainless steel or nitinol (nickel-titanium alloy) framework that can be compressed within a catheter-based delivery and deployment system. The larger main trunk is designed for the infrarenal aorta and the two smaller branches are for the iliac arteries. Proximal external barbs or hooks aid device fixation to the aortic wall. A device with a suprarenal bare stent component is available for transrenal fixation without compromising renal blood flow.

The emergence of endovascular repair of the descending thoracic aorta quickly followed the success achieved with the infrarenal aorta. The initial report of stent-grafts for the treatment of descending thoracic aortic aneurysms was by Dake and co-workers in 1994.[99] Using custom-designed self-expanding stent-grafts, they reported a 100% technical success rate in 13 patients. In 2005, the FDA approved the use of a thoracic stent-graft device for the treatment of descending thoracic aortic aneurysms. Additional devices have received FDA approval, and several are commercially available around the world. Devices are tubular, with one or two components and a variable bare stent configuration. Current generation devices have been used extensively for a spectrum of aortic disease, including aneurysms, dissections, penetrating ulcers, ruptures, and traumatic transections.

Fenestrated stent-grafts have been developed to facilitate the endovascular repair of juxtarenal and pararenal aortic aneurysms. These highly customized devices have openings in the graft fabric that align with arteries branching off the aorta, thereby maintaining end-organ perfusion while excluding the aneurysm. A modular fenestrated device received FDA approval in 2012. Alignment stents can be used to secure the position of the fenestration with the orifice of the aortic branch vessel.

Branched stent-grafts are also used in the endovascular repair of complex aneurysms that span aortic branch vessels. Directional branches off the graft body are custom-designed based on patient-specific anatomy derived from three-dimensional aortic imaging and reconstruction. Endovascular procedures on the thoracoabdominal aorta and aortic arch often require these novel stent-grafts. These devices are currently in use in Europe and await FDA approval in the United States.

ENDOVASCULAR TECHNIQUE

The endovascular approach can be undertaken without the large incisions, extensive dissections, prolonged aortic cross-clamp times, and significant blood loss and fluid shifts associated with open repair. The arterial access site for endovascular stent-graft placement is selected on the basis of vessel size and degree of obstructing atherosclerotic disease. The technique most commonly requires bilateral transverse groin incisions to expose the common femoral arteries. In patients with severely diseased femoral or iliac arteries, balloon angioplasty or local endarterectomy can be performed to allow passage of the delivery system. Adjunctive retroperitoneal procedures may be necessary in up to 20% of patients during endovascular AAA. Indications include small external iliac arteries that limit femoral access and a concomitant iliac artery aneurysm that precludes distal fixation of the stent-graft in the common iliac artery. In these cases, a transverse lower abdominal incision with retroperitoneal dissection exposes the iliac artery, and a synthetic conduit is sutured (end to side or end to end) onto the common iliac

artery. The delivery system is endoluminally placed into the aorta through this iliac conduit. At the termination of the procedure, the conduit can be ligated, attached to the external iliac artery (interposition graft), or attached to the common femoral artery (iliofemoral bypass graft). Although adjunctive retroperitoneal procedures may allow a larger number of patients to undergo endovascular aortic repair, such procedures are associated with an increased risk for complications, greater blood loss, longer procedure time, and longer hospital length of stay than endovascular repair with standard femoral access. Obviously, the advantage of endovascular techniques being less invasive than open repair is reduced when adjunctive procedures are required. Adjunctive procedures may also be needed with endovascular repair of the thoracic aorta. One series involving patients with a spectrum of aortic disease reported that 25% of patients needed open surgical access to the aorta and 21% needed left subclavian–carotid transposition to provide an adequate proximal fixation site.

Although adjunctive surgical procedures may be needed, the technical skill required for endovascular aortic surgery is primarily catheter based. Thus, appropriately trained cardiologists, radiologists, and vascular surgeons can deliver endovascular treatment of aortic disease. A multispecialty approach is commonly used and offers patients the expertise of both surgical and catheter-based specialists. Even though no standard has been set, the requirements for endovascular aortic surgery are the same wherever it is performed. The standard operating room environment is ideal from the surgical and anesthesia standpoint, particularly when conversion to an open repair is required. The operating room must be equipped with endovascular supplies, portable radiologic imaging tools, and an angiographic table. Angiographic suites often have superior radiographic imaging tools and angiographic tables and are better equipped to deal with ionizing radiation. The superior imaging may reduce radiation exposure and decrease contrast dye loads. In an effort to provide an optimized environment for multispecialty endovascular intervention, many centers are constructing sophisticated operative angiographic suites in or adjacent to the operating room.

Endovascular stent-grafting of the aorta requires preprocedural diagnostic imaging to precisely evaluate and delineate the aortic anatomy. CTA and MRA have been established as the gold standard for preprocedural evaluation. For AAAs, length and diameter of the proximal neck, location of important aortic and iliac side branches (accessory renal arteries, inferior mesenteric artery, and hypogastric arteries), and distal fixation site characteristics must be determined. Significant aneurysm neck angulation, short neck length, large neck diameter, and severe aortic calcification currently exclude many patients from endovascular repair.

Endovascular stent-grafts are often custom-made for each patient based on aortic anatomy. Each endovascular stent-graft delivery device has a unique method of deployment, and many individual variations in technique are possible. First-generation endografts were not fully stented and required balloon expansion of the proximal portion at the time of deployment. Metal hooks in the proximal portion were embedded into the aortic wall with balloon inflation, which resulted in complete aortic occlusion, not unlike aortic cross-clamping. These unsupported endografts were prone to complications such as migration and kinking. Distal migration during proximal endograft deployment was particularly troublesome with intrathoracic endograft placement. Induced hypotension, adenosine-induced asystole, and induced ventricular fibrillation have all been used successfully to reduce endograft migration during deployment. Current-generation endografts are fully stented (i.e., stent-grafts) and self-expanding. Balloon expansion is not required at the time of deployment. Stent-graft migration at the time of deployment is largely prevented, and associated complications are reduced. A unique trilobed aortic balloon can be used to expand the stent-graft for aortic apposition after deployment without complete aortic occlusion. Though no longer a requirement, mild induced hypotension (with nitroglycerin or sodium nitroprusside) can be used selectively during stent-graft deployment.

Hybrid procedures (a combination of open surgical and endovascular stenting) have expanded the endovascular approach to include aortic aneurysms involving major branches that originate from the aorta. Type IV TAA repair can be accomplished with open visceral and renal bypass followed by stent-graft implantation over the "debranched" visceral segment. Similar approaches are being used to treat complex aneurysms that involve the aortic arch. Hybrid procedures rarely require aortic cross-clamping. In patients with aneurysmal disease of the entire aortic arch, the traditional "elephant trunk" procedure has been combined with a second-stage stent-graft procedure of the descending thoracic aorta. The distal end of the elephant trunk serves as the proximal attachment site for the stent graft.

ANESTHETIC MANAGEMENT

Local, regional, and general anesthesia techniques have all been described for endovascular aortic repair shortly after its introduction. Several regional techniques have been used, including paravertebral, spinal, continuous spinal, epidural, and combined spinal and epidural. General anesthesia was commonly used with early-generation devices because the surgical procedure times were often long. As centers have gained experience with newer-generation devices, procedure times have been reduced and local and regional techniques are used more often, most commonly with IV sedation. A sedation technique using dexmedetomidine with local anesthesia has been reported.[100] Despite procedural advances and the established feasibility of local and regional anesthesia, these techniques have not become accepted on a large scale. An analysis of anesthesia type based on data from the EUROSTAR registry (5557 endovascular repairs of infrarenal aortic aneurysm) reported the use of local, regional, and general anesthesia in 6%, 25%, and 69% of patients, respectively.[101] The influence of anesthesia type on outcome based on the EUROSTAR data indicates that the use of local or regional anesthesia may reduce ICU admission, hospital length of stay, and early complications.[101] Further analysis of high-risk patients from this registry

suggests that a mortality benefit may exist when local or regional anesthesia is used.[102] A retrospective analysis of 229 endovascular AAA repairs using local anesthesia with IV sedation or general anesthesia reported similar rates of cardiac and pulmonary morbidity.[103] Reduced intraoperative fluid requirements[103,104] and less vasopressor support[104] have been reported with the use of local anesthesia. Given the retrospective nature of these reports and the significant selection bias regarding assignment of anesthetic technique, specific recommendations regarding the use of local, regional, and general anesthesia are premature. As with open aortic repair, maintenance of vital organ perfusion and function by the provision of stable perioperative hemodynamics is probably more important to overall outcome than is the choice of anesthetic technique.

I commonly use a general anesthetic technique for endovascular aortic repair in patients requiring extensive groin dissection or any retroperitoneal dissection and those requiring complex repairs, where conversion to open repair may be more likely. A balanced technique using relatively short-acting agents maximizes management flexibility. Opioid requirements are usually minimal (fentanyl 2 to 4 μg/kg), and postoperative pain is easily managed. Esmolol, sodium nitroprusside, nitroglycerin, and phenylephrine should be available and used to maintain appropriate hemodynamics. Epidural and spinal anesthesia are used selectively based primarily on patient and surgeon preference.

Placement of a radial artery catheter should be routine for all endovascular aortic repairs. It should be placed on the right side because a catheter may be placed percutaneously in the left brachial artery for aortic angiography. Central venous and pulmonary artery catheter monitoring are rarely used. Two large-bore peripheral IV catheters are recommended. Although blood loss and fluid requirements are not usually excessive, the potential for rapid blood loss is real. The possibility of acute aortic rupture necessitates the availability of fluids, blood, and a rapid infusion device. Catheterization of the bladder is required for most procedures. Monitoring of urine output can help guide fluid management, particularly when large volumes of heparinized flush solution and radiographic contrast material are used and when diuretics (i.e., mannitol or furosemide) are administered. Fluid management is directed primarily at maintaining normovolemia. Isotonic HCO_3^- infusion is often used in patients with renal dysfunction to reduce the incidence of contrast-induced nephropathy.[105] Active patient warming is frequently necessary to prevent hypothermia, particularly with longer procedures.

Endovascular repairs involving the descending thoracic aorta require additional preparation and monitoring. These procedures are often performed in the operating room under general anesthesia. Although current-generation devices are much less prone to graft migration during deployment, pharmacologically (i.e., sodium nitroprusside or nitroglycerin) induced hypotension (i.e., systolic blood pressure < 100 mm Hg) is commonly used during deployment. TEE monitoring is frequently used and can be extremely helpful in identifying proximal and distal stent-graft landing zones, entry and exit points of dissections, true and false lumens, and aneurysm exclusion. Paraplegia is a recognized complication after endovascular repair of the descending thoracic aorta and is reported to be as high as 8%.[88] Concomitant or previous abdominal aortic repair and long-segment thoracic aortic exclusion appear to be important risk factors. Postoperative hypotension may play a role as well. CSF drainage reverses delayed-onset neurologic deficit after endovascular TAA repair,[89] prompting some centers to use perioperative CSF drainage in all high-risk patients. Intraoperative spinal evoked potential monitoring plus temporary (15 minutes) balloon occlusion of the thoracic aorta before stent-graft deployment is a means to evaluate the patient's risk for spinal cord ischemia.[106]

COMPLICATIONS

Endoleak

The inability to obtain or maintain complete exclusion of the aneurysm sac from arterial blood flow, termed endoleak, is a complication specific to endovascular aortic repair. The concern is that any pressurization of the aneurysm sac (i.e., endotension) can lead to aneurysm enlargement and rupture. Endoleaks can be detected by arteriography, computed tomographic scanning, magnetic resonance imaging, and duplex ultrasound scanning. A classification system developed for endoleak describes four distinct types.[107] Type I endoleak occurs when the seal between the stent-graft and the aortic wall at the proximal or distal attachment sites is inadequate. Type II endoleak occurs when there is retrograde filling of the aneurysm sac from patent intercostal, lumbar, inferior mesenteric, or testicular arteries. Type III endoleak is due to structural failure of the stent-graft that allows blood to flow directly into the aneurysm sac. The structural failure may be due to tears in the graft fabric or separation of individual components of a modular endograft. Type IV endoleak relates directly to the porosity of the graft material. Type V endoleak refers to persistent pressurization of the aneurysm sac after endovascular repair without an identified leak on imaging studies. Endoleaks are also classified as primary (after deployment) or secondary (after initial seal).

The rate of occurrence of endoleak depends on many factors, including the endograft device, the method of deployment, vascular anatomy, and progression of disease. Management of endoleak after endograft placement is controversial and ranges from observation with periodic imaging surveillance to immediate endovascular or surgical correction. Types I and III endoleaks are associated with an increased risk for rupture and are almost uniformly treated aggressively. Although type II endoleaks do not often require urgent treatment and many spontaneously thrombose, they are associated with aneurysm enlargement. Type IV endoleaks are usually self-limited and rarely require specific treatment. Type V endoleaks require intervention if aneurysm growth is detected. Endovascular extension grafts, coil embolization, and conversion to open repair have been used successfully to repair endoleaks.

Early Complications

In addition to primary endoleaks, early complications include access vessel trauma, inadvertent stent deployment over vital branch vessel, aneurysm rupture, pelvic and lower extremity ischemia, acute renal failure, MI, stroke, paraplegia, and postimplantation syndrome (PIS). PIS is a weakly defined yet relatively common condition associated with features of a systemic inflammatory response such as leukocytosis, fever, and elevation of inflammatory mediators. Although transient and usually well tolerated, PIS is associated with an increased length of hospital stay.

Late Complications

Late complications are most often related to endoleak but also include degeneration of the proximal neck, limb occlusion, device migration or fatigue (kinking or collapse), endograft infection, aneurysm enlargement, open conversion, and rupture. Lifelong surveillance imaging is mandatory for the early detection and management of these complications. Approximately 20% of patients will require catheter-based or limited surgical reintervention after endovascular infrarenal aortic aneurysm repair.

Outcomes

Endovascular repair of AAAs was originally developed to provide a treatment option for patients considered to be poor surgical candidates. Early studies reported better hemodynamic stability, reduced stress response, decreased rate of systemic complications and shorter postoperative length of stay, and improved respiratory function and analgesic control than with open aortic repair. Based on these early reports and without the benefit of long-term outcome data or randomized clinical trials, endovascular aneurysm repair has been applied to a large proportion of patients with AAAs. Large retrospective cohort studies and prospective registries subsequently established the safety and efficacy of endovascular repair. Several prospective randomized controlled trials in Europe and the United States followed to answer several critical questions related to the broad application of endovascular technology in patients fit and unfit for open repair.

A meta-analysis of 163 studies involving 28,862 patients assessed safety and efficacy outcomes after endovascular repair of asymptomatic AAA.[108] The operative mortality was 3.3%. Technical success (complete aneurysm exclusion) rate was 82.7%. The rate for primary conversion to open repair was 3.8%, and for secondary conversion to open repair 3.4% (overall 5.4%). The postoperative rupture rate was 1.3% and was associated with a 44.4% mortality rate. A type I endoleak developed in 10.5% of patients, with an annual rate of 8.4%. A type II, III, or IV endoleak developed in 13.7% of patients, with an annual rate of 10.2%. A definite improvement in outcome was reported over the study period (1992 to 2002). Another meta-analysis involving 19,804 patients undergoing endovascular repair of infrarenal aortic aneurysm between 2000 and 2004 reported a 30-day mortality rate of 1.6% and 2.0% in randomized and nonrandomized trials, respectively.[109] Device deployment was successful in 97.6% of patients. Technical success was achieved in 81.9% at discharge and 88.8% at 30 days. Secondary intervention to treat endoleak or to maintain graft patency was required in 16.2% of patients.

In a study of 45,660 Medicare beneficiaries who underwent either endovascular or open repair of an AAA between 2001 and 2004, perioperative mortality was lower after endovascular repair (1.2% versus 4.8%), and the reduction in mortality increased with age (8.5% difference for those 85 years or older).[97] Conversion from endovascular repair to open repair occurred in 1.6% of patients. Endovascular repair was associated with fewer major complications, shorter length of hospital stay (3.4 days versus 9.3 days), and a greater likelihood of being discharged home (94.5% versus 81.6%). Late survival was similar between cohorts, although the survival curves did not converge until after 3 years. By the fourth year, rupture was more likely to occur after endovascular repair (1.8% versus 0.5%), as was aneurysm-related intervention (9.0% versus 1.7%).

Prospective randomized controlled trials comparing endovascular and open repair of asymptomatic infrarenal AAA (in patients fit for open repair) have been undertaken to determine comparative morbidity and mortality, and the need for reintervention. A recent meta-analysis of all prospective, randomized trials (2899 patients) reported short-term (30-day), intermediate-term (up to 2 years), and long-term (3 years or longer) outcomes.[110] The primary conversion rate for endovascular repair was 0.6%. Length of hospital stay and ICU stay were shorter with endovascular repair. There were no differences in perioperative complications, including stroke, MI, and renal failure. The 30-day all-cause mortality was less with endovascular repair (relative risk [RR]: 0.35, 95% confidence interval [CI]: 0.19 to 0.64). At intermediate follow-up, the all-cause mortality had a nonsignificant difference (RR: 0.78, 95% CI: 0.57 to 1.08), the aneurysm-related mortality was lower (RR: 0.46, 95% CI: 0.28 to 0.74), and the reintervention rate higher (RR: 1.48, 95% CI: 1.06 to 2.08) for endovascular repair compared to open repair. At long-term follow-up, no difference was found in all-cause mortality (RR: 0.99, 95% CI: 0.85 to 1.15) or aneurysm-related mortality (RR: 1.58, 95% CI: 0.20 to 12.74) whereas the difference in reintervention persisted (RR: 2.54, 95% CI: 1.58 to 4.08).

The Endovascular Aneurysm Repair (EVAR)-2 trial was designed to compare endovascular repair versus no intervention in patients deemed unfit for open AAA repair.[111] A total of 338 patients with AAAs greater than 5.5 cm, older than 60 years of age, and deemed unfit for open repair because of comorbid conditions were randomized to undergo endovascular repair or no intervention. All patients received best medical treatment for their comorbid conditions. Operative mortality (30 day) for the endovascular group was 9%. The overall mortality rate at 4 years was 64%, and no difference was found between the endovascular group and the no-intervention group in aneurysm-related mortality or all-cause mortality. Although more deaths from aneurysm rupture occurred in the no-intervention group, the initial high mortality in the endovascular group resulted in no late differences in mortality. The authors concluded that endovascular repair did not improve survival over no intervention, had little effect on health-related quality of life, and was associated with a need for continued monitoring and reintervention,

at substantially increased cost. In-hospital mortality for the highest risk patients undergoing endovascular aortic aneurysm repair in the United States may be lower than that reported in EVAR-2, suggesting that these high-risk patients should not be denied endovascular repair.[112]

LOWER EXTREMITY REVASCULARIZATION

Lower extremity arterial insufficiency, or peripheral arterial disease, is a common condition that affects as many as 10 million people in the United States, and its incidence is increasing annually. Because individuals with lower extremity peripheral arterial disease are most often asymptomatic or have symptoms other than classic intermittent claudication, the true prevalence of the disease is unknown. In a population-based study of individuals 55 years of age and older, the prevalence of peripheral arterial disease was 19.1% (16.9% in men and 20.5% in women). The prevalence of peripheral arterial disease in primary care practices in the United States is frequent (29%), and the condition is often unrecognized (44%). Arterial disease of the upper extremity does occur but is much less common than lower extremity involvement.

Atherosclerosis is the most common cause of peripheral arterial disease. Risk factors for atherosclerosis of the lower extremity are the same as for other vascular areas and include advanced age, male sex, hypertension, smoking, hyperlipidemia, and diabetes. Infrainguinal atherosclerosis may involve the femoral artery, popliteal artery, and any of the infrapopliteal arteries. The superficial femoral artery is the most common site of major atherosclerotic involvement below the inguinal ligament. Nonatherosclerotic causes of peripheral arterial disease include embolism, thromboangiitis obliterans (Buerger disease), immune arteritis, radiation arteritis, giant cell arteritis, adventitial cystic disease, fibromuscular dysplasia, and homocysteinemia.

As previously noted, peripheral arterial disease is a very strong indicator of generalized atherosclerosis and is a risk marker for other vascular conditions, including CAD, cerebrovascular disease, and aneurysmal disease. For example, patients with concomitant CAD and peripheral arterial disease have a higher prevalence of triple-vessel coronary disease than do patients with CAD alone. Additionally, over 20% of patients with peripheral arterial disease have a 70% or greater carotid artery stenosis. It is well documented that patients with peripheral arterial disease are at higher risk for cardiovascular morbidity and mortality than individuals without peripheral arterial disease. The increased cardiovascular risk may not be entirely due to atherosclerosis because these patients may have an enhanced prothrombotic state secondary to platelet activation[113] and a high prevalence of diverse hypercoagulable states.[114] The natural history of atherosclerotic lower extremity peripheral arterial disease is illustrated in Figure 69-14.

ACUTE ARTERIAL OCCLUSION

Acute peripheral arterial occlusion occurs primarily as a result of embolism and thrombosis. Pseudoaneurysm after invasive procedures in which the femoral artery is cannulated is a much less common cause of acute ischemia. The vast majority of emboli to the lower extremity originate in the heart, with intermittent atrial fibrillation and myocardial infarction being the most common causes of emboli. Although rheumatic heart disease is now a rare cause of embolic occlusion, prosthetic heart valves may be a source of emboli. Other causes of embolization include bacterial endocarditis, atrial myxoma, paradoxical venous emboli, and atheromatous debris from proximal aneurysms. Arterial emboli often lodge at vessel bifurcations. Common sites in the lower extremity include the femoral artery bifurcation, iliac artery bifurcation, and popliteal artery.

Thrombotic occlusions probably outnumber embolic occlusions by a ratio as high as 6:1. Acute arterial thrombosis of native vessels almost always occurs in the setting of severe and long-standing atherosclerosis. It can be viewed as the terminal event in the progression of atherosclerosis. Thrombosis of vascular bypass grafts is common and may result in acute ischemia. The high prevalence of diverse hypercoagulable states in patients with peripheral arterial disease may predispose such patients to thrombosis.[114]

The clinical computed tomography manifestation of acute arterial occlusion varies depending on the location of the obstruction and the extent of collateral circulation. In patients with a sudden onset of acute extremity ischemia, the occlusion often occurs abruptly and without the preexisting development of collateral pathways. Although ischemic symptoms are often more severe in patients with embolic occlusion than in patients with thrombotic occlusion, differentiation between embolic and thrombotic occlusion may be difficult. Acute occlusion of a previously patent extremity artery is a dramatic event characterized by pulselessness, pain, pallor, paresthesia, and paralysis (the five Ps). Absence of pulses and pallor are early manifestations. The sudden onset of pain is very common, and it may be intense. Motor weakness and paresthesia are usually late manifestations of severe ischemia.

Acute ischemia needs to be evaluated rapidly because irreversible tissue injury can occur within 4 to 6 hours. Initial management usually involves immediate anticoagulation to prevent propagation of thrombus, stabilization and control of coexisting medical conditions, and arteriography. Immediate surgical revascularization is generally indicated in the profoundly ischemic extremity. Patients with embolization to a nonatherosclerotic extremity are frequently managed with femoral thromboembolectomy under local anesthesia. Management of patients with peripheral arterial disease who are suspected of having thrombotic occlusion requires arteriography to determine the severity and anatomic location of the occlusion. Angioplasty or thrombolytic therapy may be performed in conjunction with arteriography. Intraarterial thrombolysis is often used as an initial intervention in an effort to unmask the culprit lesion responsible for the occlusive event. Patients are frequently scheduled for lower extremity bypass surgery the following day, pending evaluation of lower extremity blood flow. The frequent use of heparin anticoagulation and thrombolytics has significant implications for the anesthesiologist because regional anesthesia is not an option in an anticoagulated patient.

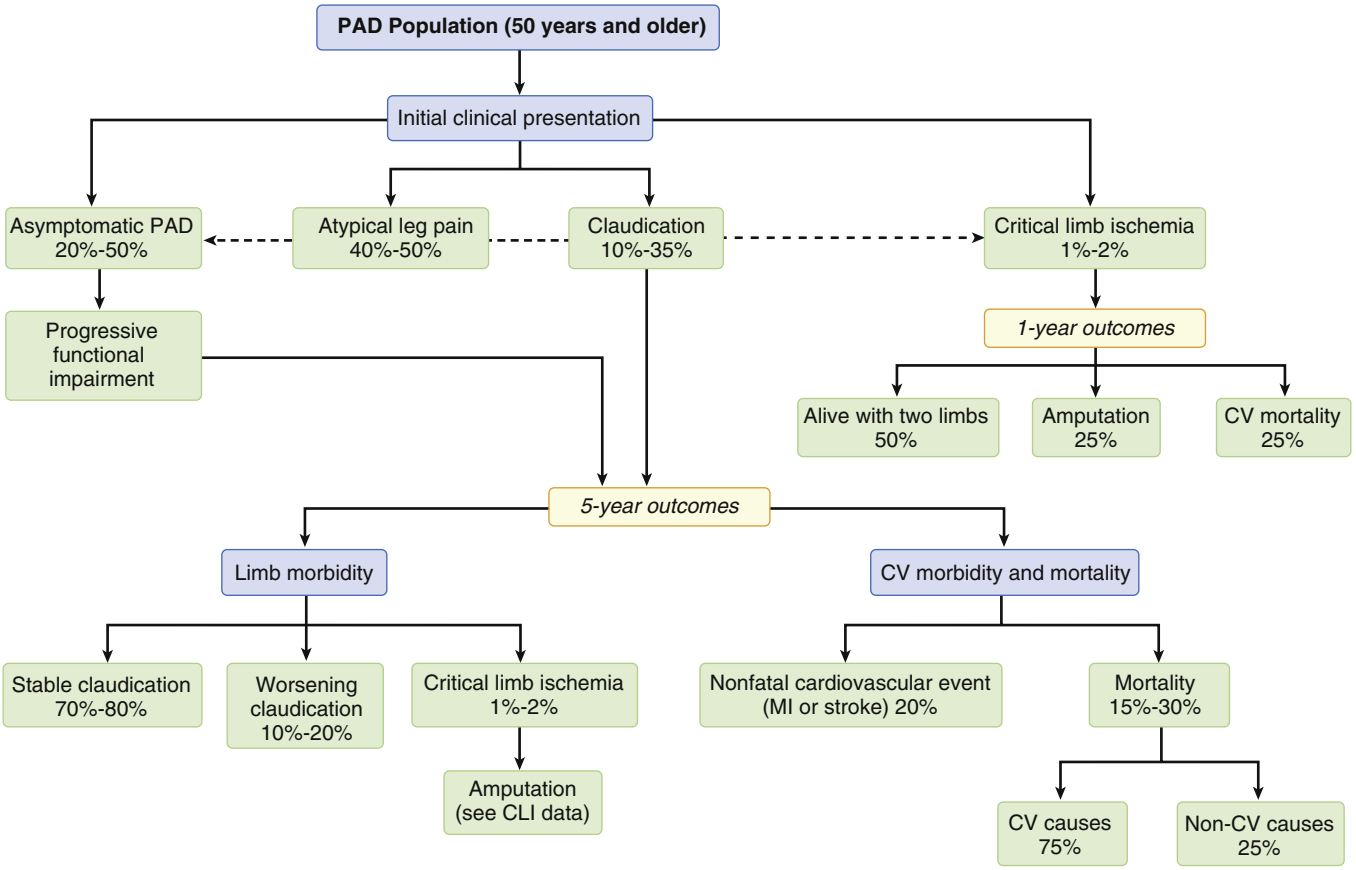

Figure 69-14. The natural history of atherosclerotic lower extremity peripheral arterial disease (*PAD*). Individuals with atherosclerotic lower extremity PAD may be asymptomatic (without identified ischemic leg symptoms, albeit with a functional impairment) or have leg symptoms (classic claudication or typical leg symptoms) or present with critical limb ischemia (*CLI*). All individuals with PAD face a risk for progressive limb ischemic symptoms, as well as a high short-term cardiovascular ischemic event rate and increased mortality. These events rates are most clearly defined for individuals with claudication or CLI and less well-defined for individuals with asymptomatic PAD. *CV,* Cardiovascular; *MI,* myocardial infarction. (From Hirsch AT, Haskal ZJ, Hertzer NR, et al: ACC/AHA 2005 guidelines for the management of patients with peripheral arterial disease (lower extremity, renal, mesenteric, and abdominal aortic): executive summary a collaborative report from the American Association for Vascular Surgery/Society for Vascular Surgery, Society for Cardiovascular Angiography and Interventions, Society for Vascular Medicine and Biology, Society of Interventional Radiology, and the ACC/AHA Task Force on Practice Guidelines (Writing Committee to Develop Guidelines for the Management of Patients With Peripheral Arterial Disease) endorsed by the American Association of Cardiovascular and Pulmonary Rehabilitation; National Heart, Lung, and Blood Institute; Society for Vascular Nursing; TransAtlantic Inter-Society Consensus; and Vascular Disease Foundation, *J Am Coll Cardiol* 47:1239-1312, 2006.)

Morbidity and mortality rates in this patient population are frequent, particularly in patients requiring significant operative intervention.

CHRONIC ARTERIAL OCCLUSION

Chronic arterial insufficiency is most often secondary to long-standing atherosclerosis in which the arterial lumen of the lower extremity becomes progressively stenosed by atherosclerotic plaque. When the stenosis approaches total occlusion, the marked reduction in blood flow leads to thrombotic occlusion. Hemodynamically significant stenosis and total-vessel occlusion commonly exist in the lower extremity with no or very minimal symptoms. The development of collateral vessels around a stenosed or occluded arterial segment often prevents clinical symptoms until multiple occlusions exist in major vessels. Thus, most patients with peripheral arterial disease are asymptomatic. Patients with symptoms most commonly have mild intermittent claudication—pain or fatigue in the muscles of the lower extremity caused by exertion and relieved with rest. The pain usually occurs in the muscle group distal to the site of arterial insufficiency. With disease progression, severe disabling intermittent claudication or rest pain—critical limb ischemia—can develop.

Noninvasive testing with the ankle-brachial index (ABI) is the clinical standard for documenting the presence and severity of peripheral arterial disease. The ABI is determined by dividing ankle systolic pressure by brachial systolic pressure. Normally, the ABI is between 1.0 and 1.1; a value less than 0.9 indicates arterial disease proximal to the point of measurement. The ABI approximates the degree of arterial insufficiency; claudication occurs with indexes ranging from 0.3 to 0.9, disabling claudication or rest pain with indexes less than 0.5, and gangrenous extremities with indexes less than 0.2.

One of the most important aspects of peripheral arterial disease is that it is a very strong marker for early mortality. In patients with peripheral arterial disease the risk for amputation is much less than the risk for death.

A low ABI is a strong predictor for disease progression, but it is also one of the strongest risk factors for all-cause mortality. Claudication is associated with a high rate of mortality but is relatively benign in terms of lower extremity outcome.

SURGICAL MANAGEMENT

Accepted treatments of lower extremity arterial disease include both nonoperative and operative modalities. Nonoperative options include lifestyle and risk factor modification, exercise programs, and pharmacologic therapy. Operative options include percutaneous endovascular modalities and surgical reconstruction. Endovascular techniques include more established therapies such as intraarterial thrombolytic therapy, balloon catheter embolectomy, transluminal balloon angioplasty, and angioplasty and stent placement, as well as new technologies such as novel angioplasty balloons, atherectomy and laser angioplasty systems, cryotherapy, and placement of nitinol and drug-eluting stents. Surgical procedures include endarterectomy, bypass grafting (primary or revision), and amputation.

Lower extremity arterial reconstruction is performed both for severe disabling claudication and critical limb ischemia (limb salvage). The choice of operative approach depends primarily on the location and distribution of arterial occlusions. Several surgical approaches are used in patients with lower extremity arterial insufficiency. For occlusion distal to the inguinal ligament, a femoral-popliteal bypass with an autologous great saphenous vein (reversed) graft is most often the procedure of choice. Graft patency rates with this approach are reported to be 59% at 5 years and 38% at 10 years. The saphenous vein may be used in situ (not reversed), but this technique is more demanding and requires excision of the valves to allow adequate flow. Human umbilical vein and polytetrafluoroethylene grafts can be used when an autologous saphenous vein is unavailable, which is often the case when patients have previously undergone coronary artery bypass or lower extremity bypass. The cephalic and basilic veins from the upper extremities are sometimes used as a graft. Harvesting vein from the upper extremities has obvious implications with regard to IV catheter placement and the use of regional anesthesia.

In patients with aortoiliac disease who are not candidates for aortobifemoral bypass because of coexisting medical diseases, an extraanatomic procedure (axillofemoral or femorofemoral bypass) is an alternative approach that is thought to be a less stressful procedure. Distal arterial reconstruction with a bypass to the tibial, peroneal, or pedal vessels is almost exclusively performed for limb salvage. Prosthetic grafts have very high failure rates, and every attempt is made to harvest adequate autologous vein.

PREOPERATIVE PREPARATION AND MONITORING

Preoperative assessment and optimization of cardiac risk were discussed previously (see also Chapters 38 and 39). It is extremely important that long-term cardiac and respiratory medications be given the morning of surgery. Continuing chronic β-adrenergic blocker therapy is particularly important because acute withdrawal can be associated with significant morbidity. Current, recent, and anticipated use of hemostasis-altering drugs should be established and discussed with the surgical team. In most instances, antiplatelet therapy with aspirin should be continued. Preoperative termination of other antiplatelet therapy, such as thienopyridine derivatives, should be made on an individual basis.

Monitoring for lower extremity arterial revascularization should include an intraarterial catheter that permits continuous blood pressure monitoring to optimize coronary artery and lower extremity graft perfusion, as well as blood sampling for diagnostic laboratory testing. A urinary bladder catheter is usually indicated because the duration of the procedure may be long and urine output may be useful for assessing intravascular volume and cardiac output. Although central venous catheters are not necessarily helpful in routine cases, central venous pressure monitoring should be considered for patients with significant renal dysfunction, in whom intravascular volume should be carefully monitored, and for patients with significantly impaired ventricular dysfunction or congestive heart failure. In these patients, pulmonary artery catheter monitoring may be helpful, but given the relatively low potential for blood loss and third-space fluid loss with lower extremity vascular procedures, the pulmonary artery catheter is usually reserved for patients with active congestive heart failure or unstable angina. Our criteria for using invasive hemodynamic monitoring have been described previously.[39] As discussed earlier, computerized ST-segment monitoring is helpful in monitoring for myocardial ischemia.

REGIONAL VERSUS GENERAL ANESTHESIA

The most appropriate regimen of intraoperative anesthesia and postoperative analgesia for high-risk patients undergoing vascular surgery remains controversial. Competing concerns regarding both the quality and escalating costs of perioperative care have challenged clinicians to establish practice standards that are both safe and efficient. Postoperative complications after vascular surgery are common and have an adverse impact on both clinical outcome and resource use. Improvement in clinical outcome and reduced use of medical resources in patients undergoing vascular surgery may result from the use of one particular regimen of anesthesia and analgesia over another. If such improvement can be achieved, selection of the most appropriate anesthetic and analgesic regimen would then be of great benefit to patients, providers, payers, and society.

The question of whether regional or general anesthesia is preferable for vascular surgery has been debated for years. Early nonrandomized trials were inadequately designed to answer the questions. They were prone to significant bias because many clinicians had the unsupported belief that regional anesthesia was safer for patients with advanced cardiac or pulmonary disease. Even the prospective studies must be interpreted cautiously because many suffer from deficiencies in design and methodology, including nonuniform patient populations,[78,115,116] lack of

standardization or control of perioperative treatments,[†] use of nonequivalent modalities for postoperative pain relief,[74,78,81,115-117] and possible investigator bias.[‡] Many clinical trials have attempted to optimize the delivery and management of anesthetic techniques, which may mask the true risks associated with the anesthetic. An example is the strict hemodynamic control, transfusion thresholds, and postoperative analgesia regimens that have been used in clinical trials.[39,40] The physician must also appreciate that the overall complication rates reported in clinical trials may seem high, but this may be explained by the aggressive surveillance commonly used in clinical trials. In general, it is often best to choose the anesthetic and analgesic techniques that are most familiar to a particular institution—for example, because unfamiliarity and mismanagement of epidural catheters can cause serious complications. I think that overall optimization of perioperative care, rather than anesthetic or analgesic selection, is the most important factor in improving outcome after vascular surgery.

In some situations, one anesthetic technique (regional or general) is preferable to the other. The patient may have a preference for one technique over another based on multiple factors. Regional techniques should be avoided in patients who are uncooperative, demented, or unable to lie flat. Needle or catheter placement can be difficult in patients with severe spine deformity or previous spinal instrumentation. Local infection, neurologic disease affecting the lower part of the body, and hemostasis-altering drugs are all considered, to varying degrees, a contraindication to regional anesthesia. Anticoagulant and antiplatelet therapy is common in the vascular surgery population and often precludes the use of spinal or epidural techniques. Symptomatic bleeding within the neuraxis (spinal or epidural hematoma) is a potentially devastating complication of neuraxial anesthesia that can lead to permanent neurologic injury. I view preoperative anticoagulation with heparin or warfarin and any active thrombolytic therapy as contraindications to the use of spinal and epidural anesthesia. In patients in whom such agents have recently been discontinued, very careful consideration should be given on an individual basis before performing neuraxial techniques. The anesthesiologist must take into consideration the specific drug used, the duration of discontinuance, current coagulation status, and concomitant administration of medications affecting hemostasis. The use of regional techniques during intraoperative systemic heparinization does not appear to represent a significant risk. Although it has been recommended that surgery be canceled when blood is obtained through the neuraxial needle, support for this recommendation is lacking. Much more importantly, it has also been recommended that epidural catheters not be removed until anticoagulants have been discontinued in the postoperative period.[118] The use of and indications for low-molecular-weight heparin (LMWH) continue to increase, and evidence suggests a significant risk for spinal or epidural hematoma when regional techniques are used in conjunction with these drugs. Current recommendations suggest that regional techniques be delayed at least 12 to 24 hours after the last dose of LMWH.[118] The use of antiplatelet agents is a complex topic, and it is important to note the pharmacologic differences among the drugs when regional techniques are desired.[118] Although some centers routinely check a bleeding time in patients who have taken aspirin in the 7 days before a planned regional anesthetic technique, no evidence indicates that bleeding time is useful in this setting. In general, when a regional technique is desired for a patient with any question of a coagulation abnormality, spinal anesthesia with the smallest diameter needle is preferable to epidural anesthesia. A comprehensive consensus report on neuraxial anesthesia and anticoagulation is available and should be read by all clinicians.[118]

Given the relative risks associated with neuraxial anesthesia in patients receiving anticoagulant or antithrombolytic therapy, some clinicians advocate the broader use of peripheral nerve blocks, such as sciatic, femoral, popliteal, and ankle (see also Chapter 57). Continuous catheter techniques can be used to provide both anesthesia and postoperative analgesia. High-resolution ultrasound imaging of neural structures, percutaneous electrode guidance, and the use of stimulating catheters have been introduced into clinical practice. Peripheral nerve blocks are probably associated with fewer systemic and neuraxial side effects, but little clinical information is available in the vascular surgical population. Because of the large volume of local anesthetics frequently used for peripheral nerve blocks, the issue of systemic toxicity must be considered. Caution should be considered with the use of peripheral nerve block in an anticoagulated patient, particularly when the neural structures are deep or located in close proximity to vascular structures.

Because regional anesthesia does not require airway instrumentation, neuromuscular blocking agents, or volatile agents, it has traditionally been a prevailing belief that regional anesthesia is preferable in patients with significant pulmonary disease. Although it is true that instrumentation of the airway may precipitate bronchospasm or increase the risk for nosocomial infection, general anesthesia with endotracheal intubation does allow complete airway and ventilation control, the ability to effectively administer inhaled bronchodilators, and the ability to easily suction airway secretions. A reduction in time to extubation after aortic surgery is a fairly consistent theme with regional anesthesia and analgesia, but this does not appear to have any impact on clinically relevant pulmonary outcomes.[40,74,78,83]

Epidural analgesia has been championed over parenteral opioid analgesia as a means of optimizing postoperative pulmonary function by improving pain control and respiratory muscle function. Although epidural analgesia can provide excellent postoperative pain control and may improve postoperative lung function (i.e., increased tidal volume and vital capacity), clinical studies do not support a consistent finding of improved pulmonary outcomes. Overall, little evidence from well-designed clinical studies exists to demonstrate improved pulmonary outcome with regional anesthesia and analgesia.[119] Because postoperative maneuvers to increase mean lung volumes are of proved benefit in preventing postoperative pulmonary complications, it has been recommended that maneuvers to encourage deep breathing, such as deep-breathing

exercises, incentive spirometry, and chest physiotherapy, should be the focus of preventive efforts.[119]

Cardiac morbidity is the most common cause of death in patients undergoing surgery, and the incidence of perioperative cardiac morbidity is 10 times more frequent in vascular surgery patients than in nonvascular surgery patients.[5] Eleven prospective randomized trials evaluating the effects of regional versus nonregional anesthesia or analgesia in vascular surgical patients have reported on cardiac outcomes and death. Three studies (Bode and associates,[117] Christopherson and co-workers,[39] and Cook and colleagues,[120]) compared pure regional (spinal or epidural) versus general anesthetic techniques in lower extremity vascular patients. Tuman and colleagues[116] compared combined epidural and general versus general anesthetics in aortic and lower extremity surgical patients. Six studies (Baron and co-workers,[74] Bois and co-workers,[80] Boylan and associates,[83] Davies and associates,[76] Garnett and colleagues,[80] and Norris and colleagues[40]) compared epidural and nonepidural anesthetic or analgesic techniques (or both) in aortic surgical patients. Fleron and co-workers[80] compared intrathecal opioid versus IV analgesia in aortic surgical patients. Of note, only the report by Norris and associates[40] had a double-blinded design. The results of these studies, involving more than 1300 patients, are shown in Table 69-8.

In summary, no study demonstrated any difference in outcome with regard to mortality, MI, myocardial ischemia, or congestive heart failure. Only the study by Tuman and colleagues[116] reported a difference in cardiac outcome. Outcome was significantly improved by epidural anesthesia and analgesia, but only when more subtle outcomes (i.e., dysrhythmias) were included. Christopherson and co-workers[39] (i.e., the Perioperative Ischemia Randomized Anesthesia Trial [PIRAT]) and Norris and associates[40] (i.e., PIRAT II) found no difference in cardiac events or myocardial ischemia as detected by continuous Holter monitoring over a 3-day postoperative period. In these studies from my institution, strict intraoperative and postoperative protocols were used to guide and optimize perioperative management and postoperative analgesia. Bode and colleagues[117] described the largest randomized trial, which included a spinal anesthesia group in addition to general and epidural groups. There were no differences in cardiac events in any of the three groups. Of note, a failed spinal or epidural technique in this trial was associated with 9% mortality, as opposed to 2% for all successful general and regional anesthetics.[116]

One of the most interesting and clinically significant findings in these randomized trials is the beneficial effect of regional anesthesia on lower extremity graft patency in the postoperative period. Two of the studies (Tuman and colleagues[116] and Christopherson and co-workers[39]) reported a fivefold greater incidence of graft occlusion after general (relative to regional) anesthesia. Most graft occlusions occurred in the first 1 to 3 days after surgery, after which the established difference in the incidence of graft occlusion between anesthetic techniques was maintained over time (6 weeks and beyond) (Fig. 69-15). This time course suggests that anesthetic technique may have played a role in graft occlusion. Bode's group[121] reported an overall very low incidence of graft occlusion, but differences in hemodynamic management, surgical technique, and the patient population may explain these findings. For example, intraoperative intravascular angioscopy was used to inspect the grafts to confirm patency before completion of surgery, and all patients were cared for in an intensive care setting for 48 hours after surgery. Thus, optimization of care with respect to graft patency may negate any beneficial effect of regional techniques. It is also important to keep in mind that none of these studies were specifically designed to evaluate surgical outcome (i.e., graft patency)

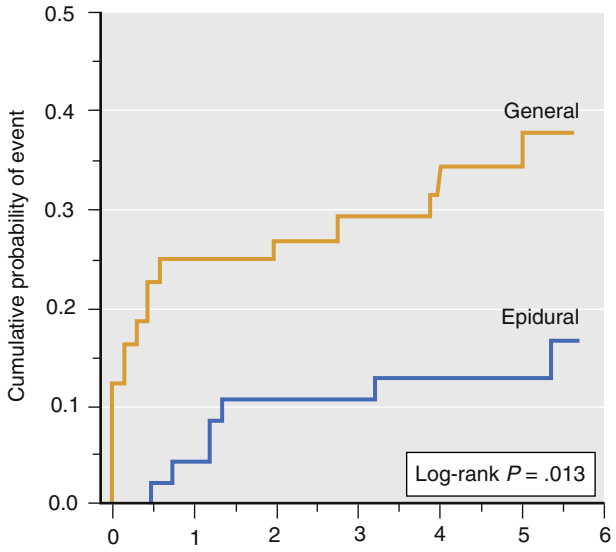

Figure 69-15. Cumulative probability of reoperation for regrafting, thrombectomy, or amputation over a 6-week follow-up period. Reoperation was significantly more frequent after general than after epidural anesthesia. (From Christopherson R, Beattie C, Norris EJ, et al: Perioperative morbidity in patients randomized to epidural or general anesthesia for lower extremity vascular surgery. Perioperative Ischemia Randomized Anesthesia Trial Study Group, *Anesthesiology* 79:422-434, 1993.)

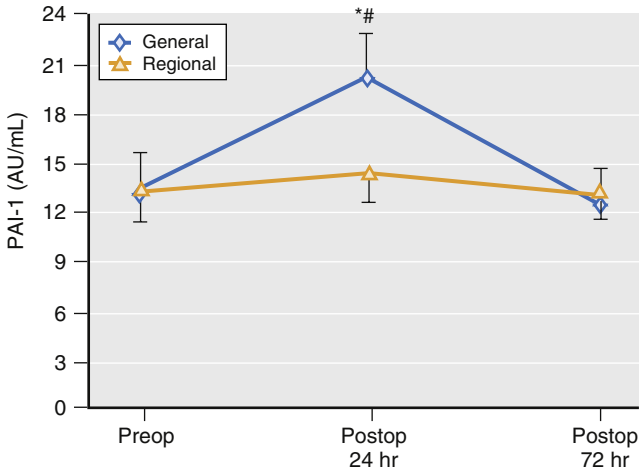

Figure 69-16. Plasminogen activator inhibitor-1 (PAI-1) levels in activity units (AU) per milliliter measured preoperatively and at 24 and 72 hours postoperatively after lower extremity revascularization. PAI-1 levels in the general anesthesia group increased from 13.6 ± 2.1 AU/mL to 20.2 ± 2.6 AU/mL at 24 hours and returned to baseline at 72 hours. In contrast, PAI-1 levels in the RA group remained unchanged over time. (Modified from Rosenfeld BA, Beattie C, Christopherson R, et al: The effects of different anesthetics regimens on fibrinolysis and the development of postoperative arterial thrombosis. Perioperative Ischemia Randomized Anesthesia Trial Study Group, *Anesthesiology* 79:435-443, 1993.)

in a prospective manner. A retrospective review of more than 300 primary femoropopliteal-tibial bypass procedures reported no differences in graft thrombosis rates for epidural (14%) or general anesthesia (9.4%).[122]

The proposed mechanism for the benefit of regional anesthesia is the effect of the anesthetic technique on coagulation. General anesthesia is associated with a hypercoagulable state in the early postoperative period, whereas regional anesthesia attenuates this effect. Tuman and colleagues[116] demonstrated this by thromboelastography and Rosenfeld and co-workers[123] by increased plasminogen activator inhibitor (Fig. 69-16) and fibrinogen levels. Fibrinolysis is decreased after general anesthesia and is normal after regional anesthesia. These findings may be related to attenuation of the surgical stress response with regional anesthesia because a link appears to exist among stress, catecholamines, and acute-phase reactants, such as plasminogen activator inhibitor and fibrinogen.[123-125] Platelet reactivity is also enhanced in the presence of a stress response.[125] Another important mechanism for the increased lower extremity graft patency with regional anesthesia may be the increased lower extremity blood flow associated with sympathectomy.

In the postoperative period, Breslow and associates[126] demonstrated differences in the adrenergic response with general versus regional anesthesia (Fig. 69-17). Epinephrine and norepinephrine are increased after general anesthesia relative to regional anesthesia. The cortisol response after general anesthesia is also greater than after regional anesthesia.[126] This stress response is associated with increased blood pressure and hemodynamic liability during the intraoperative and early postoperative periods after general anesthesia compared with regional anesthesia.[40,127] When the hemodynamic parameters are controlled pharmacologically, however, no difference is found related to anesthetic technique in myocardial ischemia or cardiac morbidity.[39,40,117]

Postoperative pain is recognized as one of the many factors contributing to the surgical stress response. In studies comparing epidural analgesia with parenteral opioid analgesia for control of postoperative pain after major surgery, improved pain control with epidural techniques is often reported. A recent meta-analysis review supports the view that epidural analgesia provides better postoperative analgesia than parenteral opioids.[128] However, the historical studies that form the basis of the meta-analysis review have often neglected to control, specify, and, most importantly, optimize treatment in the nonepidural arms of their studies. Unfortunately, this issue remains a significant limitation in more recent trials.[78,129] Epidural analgesic techniques will probably continue to outperform "suboptimal" nonepidural analgesic techniques. I believe that IV patient-controlled analgesia is the optimal mode of delivery for opioid analgesia and should be used as the nonepidural arm for all postoperative pain studies. Postoperative epidural analgesia does not consistently outperform IV patient-controlled opioid analgesia. Of particular note, patient-controlled epidural analgesia outperforms both intermittent-bolus and continuous-infusion epidural analgesia. Thus, the mode of delivery is an important factor with both epidural and parenteral opioid analgesia. The clinician also needs to keep in mind that the superior pain control reported with epidural techniques is relative, with adequate pain control consistently reported for parenteral analgesia. In the only double-blinded trial in vascular surgery patients, Norris and colleagues[40] reported no difference in postoperative pain scores in patients randomized to either patient-controlled epidural analgesia or

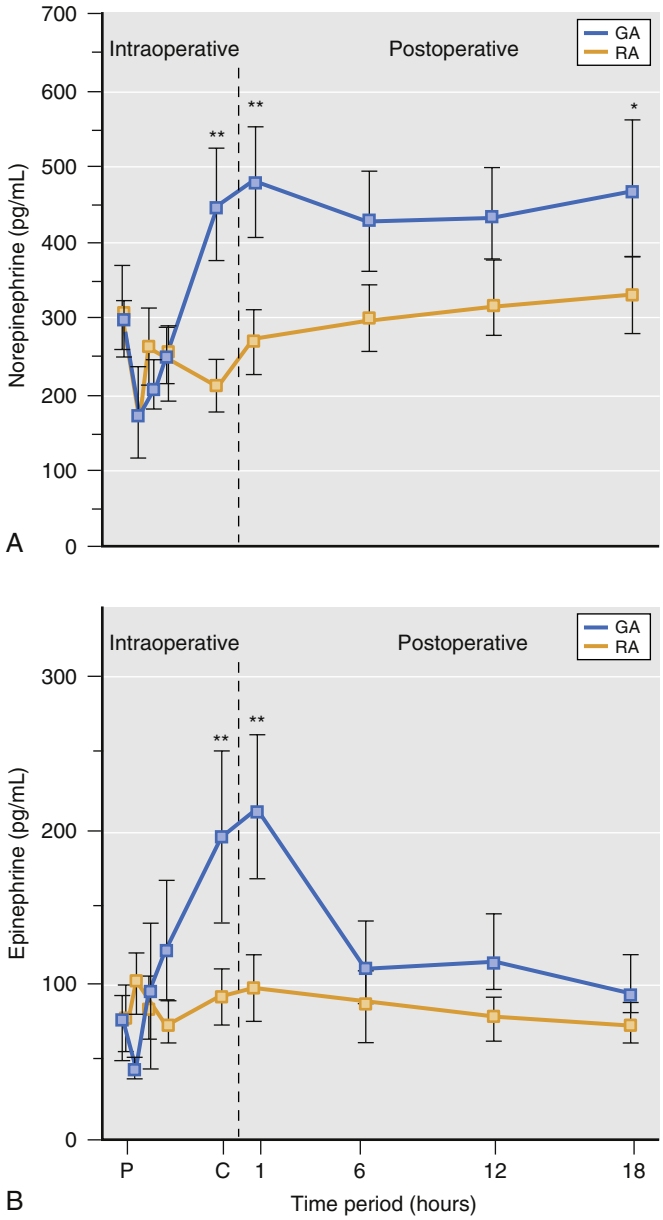

Figure 69-17. Plasma norepinephrine (**A**) and epinephrine (**B**) concentrations before induction of anesthesia (*P*), at skin closure (*C*), and at *1, 6, 12,* and *18* hours after lower extremity revascularization. *GA,* General anesthesia with postoperative parenteral morphine by patient-controlled analgesia; *RA,* regional (epidural) anesthesia with postoperative epidural analgesia by patient-controlled analgesia. patient-controlled IV analgesia after aortic surgery. In this trial, postoperative pain management (i.e., epidural and IV) was optimized, continued for 72 hours, and managed by an acute pain service. Postoperative epidural catheter failure may occur in up to 6% of patients.

ANESTHETIC MANAGEMENT

A variety of anesthesia techniques, including general anesthesia, regional (i.e., epidural or spinal) anesthesia, and combined techniques, are widely used for lower extremity reconstruction. General anesthesia is usually delivered with use of a balanced technique consisting of opioids, volatile inhaled anesthetics, N_2O, and neuromuscular blockade. Induction of anesthesia should proceed in a controlled fashion such that a stable hemodynamic profile is maintained. Maintenance of anesthesia may be accomplished with a low-dose inhaled anesthetic (i.e., isoflurane, desflurane, or sevoflurane) in 50% N_2O and opioid (fentanyl 3 to 5 μg/kg). Because virtually all patients are extubated in the operating room, high doses of opioid are generally avoided. The goal is to maintain stable hemodynamics and prevent myocardial ischemia during the intraoperative and postoperative periods. Judicious use of β-blockers and vasoactive drugs is often necessary.

Regional anesthesia can be accomplished with spinal or epidural techniques. Disadvantages of spinal anesthesia include the limited duration of action in the setting of a surgical procedure that is somewhat unpredictable in length and complexity. The level of sympathetic block is somewhat less controllable than with the epidural technique. Hypotension can occur with either technique and should be treated promptly with judicious use of fluids and vasopressors. An advantage of an epidural technique is the ability to continue drug delivery into the postoperative period for analgesia and attenuation of the stress response. A lumbar epidural catheter is ideal for lower extremity vascular procedures. The dermatomes that need to be anesthetized are innervated at the same level where the catheter is inserted, because the incision is usually in the L1 to L4 region. Small volumes of local anesthetic are recommended because a T10 block is generally sufficient. Usually, 9 to 12 mL (including the test dose) is sufficient for the initial dose, and more drug is given as needed. Because vascular surgery patients are generally advanced in age and thus prone to higher block levels, larger doses may result in high sympathetic blockade with significant hypotension.[130] A high sympathetic block is problematic because of decreased coronary perfusion and excessive fluid and vasopressor requirements. Congestive heart failure may result in the postoperative period when the sympathectomy resolves and the intravascular space contracts. When administering an epidural test dose, careful attention should be directed to both heart rate and blood pressure. Blood pressure may be a more reliable indicator of an intravascular injection because vascular surgery patients may have little or no increase in heart rate as a result of β-blocker therapy and decreased β-adrenergic responsiveness secondary to aging. When hypotension results from sympathectomy, a low-dose phenylephrine infusion is helpful in reducing IV fluid requirements. I think this approach is more physiologic than administration of large fluid volumes.

POSTOPERATIVE CONSIDERATIONS

Pain and anxiety require especially careful attention in the postoperative period because the stress response and myocardial ischemia are of greatest concern at this time. Intravascular volume should be optimized, significant anemia avoided (hemoglobin maintained at > 9.0 g/dL), and heart rate and arterial blood pressure carefully

controlled. Computerized ST-segment analysis is helpful in identifying ischemic changes. Peripheral pulses should be checked frequently to verify lower extremity graft patency. Increasing arterial blood pressure augmentation and anticoagulants may be necessary when peripheral perfusion is limited. Urgent surgery may be required to reopen clotted or stenotic grafts.

Postoperative analgesia can be provided by IV or epidural opioids delivered by patient-controlled analgesia or epidural opioids with local anesthetics delivered by continuous infusion or patient-controlled analgesia. For epidural patient-controlled analgesia, a dilute concentration of local anesthetic should be used to allow neurologic evaluation of the lower extremities to rule out spinal or epidural hematoma. Bupivacaine 0.0625% is ideal in this regard. Fentanyl 5 μg/mL can be added and the solution infused at 2 mL/hr, with an on-demand (patient-controlled analgesia) bolus of 2 to 4 mL and a lockout interval of 10 minutes.

CAROTID ENDARTERECTOMY

The strong association between stroke and carotid artery disease is well known. The principal cause of carotid artery disease is atherosclerosis, which most commonly involves the bifurcation of the common carotid artery with frequent extension into both the internal and external carotid arteries. The clinical manifestations of carotid artery disease represent a spectrum of conditions, with fatal or debilitating stroke secondary to cerebral infarction at one end of the spectrum and ranging successively through nondebilitating stroke, transient ischemic attack, and amaurosis fugax (transient attack of monocular blindness) to an asymptomatic bruit. Cerebrovascular sequelae of carotid atherosclerosis may result either from embolization of thrombus or atheromatous debris or from a reduction in flow (hypoperfusion) secondary to stenosis. The latter probably accounts for less than 10% of the cerebrovascular sequelae of carotid atherosclerosis. Although much is known about the genesis and evolution of atherosclerosis, significantly less is known about the circumstances that lead to plaque instability and rupture. Regardless of the mechanism, the degree of cerebral injury depends on such factors as plaque morphology, characteristics of the embolus, duration of hypoperfusion, cerebrovascular vasoreactivity, integrity of the circle of Willis, and cerebral collateral circulation. A multisociety guideline is available for the management of carotid artery disease.[131]

Stroke is a major public health burden worldwide. It is the fourth leading cause of death and the leading cause of serious, long-term disability in the United States. Stroke is also a major contributor to health care costs. The direct and indirect costs of stroke in the United States in 2008 are estimated at $65.5 billion.[132] Approximately 780,000 people experience a new (≈600,000) or recurrent (≈180,000) stroke each year in the United States.[132] Annually, more than 950,000 hospitalizations and 165,000 deaths occur from stroke. Well-defined risk factors exist in patients with stroke, the most important of which is hypertension. Approximately 83% of strokes are ischemic (i.e., cerebral thrombosis or embolism), and 7.6% of ischemic strokes result in death within 30 days of initial evaluation.[133] Extracranial atherosclerotic disease accounts for up to 20% of all ischemic strokes. Less than 20% of strokes are preceded by a transient ischemic attack. Despite a well-documented decline in stroke mortality, the annual incidence rate of stroke may be increasing. This increase is probably due to growth in high-risk populations. The incidence of perioperative stroke in unselected patients, patients with asymptomatic carotid bruit, and patients with at least 50% carotid stenosis undergoing general anesthesia and surgery is approximately 0.1%, 1.0%, and 3.6%, respectively.

Although treatment options to reverse the effect of acute ischemic stroke are limited, outcomes may be improved with appropriate therapy. The only approved therapy is IV recombinant tissue plasminogen activator. Given the narrow 3- to 4.5-hour treatment window from the onset of symptoms, prompt evaluation and diagnosis of ischemic stroke are critical. With the exception of acute stroke after carotid endarterectomy, surgical treatment of patients with acute ischemic stroke is controversial and not generally recommended because of limited data and perceived high risk. Endovascular treatment of patients with acute ischemic stroke is undergoing intense investigation. Emergency angioplasty and stenting, mechanical disruption of arterial clot, and mechanical extraction of thrombi are interventions currently being evaluated.[134] The AHA and American Stroke Association have guidelines for the early management of patients with ischemic stroke.[135]

INDICATIONS

Endarterectomy of the carotid bifurcation has been used to reduce symptoms and prevent stroke for more than 50 years. Although the efficacy of carotid endarterectomy for prevention of ipsilateral stroke in patients with and without symptoms has been demonstrated in large-scale randomized clinical trials,[136,137] multiple factors including perioperative risk, comorbidities, and life expectancy must be considered in the overall assessment. In centers of excellence, it is a low-risk procedure with excellent long-term durability. Carotid endarterectomy is the most common peripheral vascular surgical procedure performed in the United States, with an estimated 130,000 procedures performed annually. The rate and number of carotid endarterectomies have fluctuated significantly since the early 1970s. With marked growth in the specialty of vascular surgery and an expanding list of surgical indications, the number of carotid endarterectomies performed in nonfederal hospitals increased from 15,000 in 1971 to 107,000 in 1985 and then declined substantially over the next 5 to 6 years. The decline was probably due to publications questioning the indications for the procedures and isolated reports citing excessively frequent rates of operative morbidity and mortality.

In 1992, a marked increase in the number of carotid endarterectomies occurred after the results of two large-scale, prospective randomized trials were published. The North American Symptomatic Carotid Endarterectomy Trial (NASCET) and the European Carotid Surgery Trial both reported definitive results for symptomatic patients with high-grade carotid stenosis (70% to 99%).[136,138] In NASCET, follow-up at 2 years showed a stroke rate for surgical patients of 9% versus 26% for medical patients. This

benefit of carotid endarterectomy has persisted at 8 years of follow-up.[139] In the European Carotid Surgery Trial, the long-term stroke rate was 2.8% for surgical patients, excluding a perioperative stroke and death rate of 7.5%, and 16.8% for medically managed patients.

The efficacy of carotid endarterectomy in asymptomatic patients with carotid stenosis has been evaluated in five randomized trials.[137,140-143] The Carotid Artery Surgery Asymptomatic Narrowing Operation Versus Aspirin trial, the first to publish its results, concluded that carotid endarterectomy was not indicated for asymptomatic patients with 50% to 90% carotid stenosis.[140] Unfortunately, this study was seriously flawed and the results questioned. The Mayo Asymptomatic Carotid Endarterectomy Study was terminated early because of a significantly increased number of MIs and transient cerebral ischemic events in the surgical group.[141] Most of these events were not related to the surgery itself but rather to the absence of aspirin in the surgical group. The Department of Veterans Affairs trial was designed to compare the effects of carotid endarterectomy plus aspirin versus medical treatment (i.e., aspirin) in asymptomatic male patients with 50% or greater carotid stenosis.[142] This trial demonstrated a significant reduction in ipsilateral neurologic events in the surgical group (8%) versus the medical group (20.6%). However, the combined incidence of stroke and death was not different between study groups. The Asymptomatic Carotid Atherosclerosis Study (ACAS) demonstrated that patients with asymptomatic carotid stenosis (≥60%) who were treated with carotid endarterectomy and aspirin have a reduced 5-year risk for ipsilateral stroke compared with patients treated with aspirin alone (5.1% versus 11.0%).[137] These results reflect only a 5.9% absolute risk reduction in 5 years, which is just above 1% per year. Of note, improvement in outcome for patients randomized to undergo endarterectomy in this trial did not reach significance until 3 years after surgery. The European Asymptomatic Carotid Surgery Trial, the largest trial to date, largely replicated the results of ACAS, but in a somewhat more pragmatic setting.[143] This trial demonstrated that patients with asymptomatic carotid stenosis (≈70%) on ultrasound who were treated by immediate carotid endarterectomy plus medical treatment have a reduced 5-year risk for stroke compared with patients treated with medical therapy alone (6.4% versus 11.8%). Of note, half of this 5-year benefit involved disabling or fatal strokes.

Although landmark randomized clinical trials have defined individuals who are likely to benefit from carotid endarterectomy (and set the standard for developing evidence-based practice guidelines throughout the world), it has been suggested that the significant increase in the number of carotid endarterectomies performed over the last decade may be due in part to the extrapolation of trial results to patients and settings not directly supported by the trials. For example, both NASCET and ACAS restricted enrollment to patients younger than 80 years of age, and both trials carefully selected institutions and surgeons to optimize the results of surgery. Additionally, subgroup analysis of ACAS could not demonstrate a significant benefit for women.[137]

With the advent of a second interventional treatment modality, percutaneous carotid angioplasty and stenting (discussed later), and the evolution of intensive medical therapy, this issue has become more complex.

PERIOPERATIVE MORBIDITY AND MORTALITY

Although the randomized trials just noted have demonstrated a protective effect of carotid endarterectomy on ipsilateral stroke, the critical determinants of benefit for any given patient must include the overall perioperative event rate and expected long-term survival. Thus, the perioperative stroke and death rate for carotid endarterectomy needs to be very low to maintain the beneficial effects of surgery over medical therapy alone. Further, to compensate for the perioperative risk associated with surgery, the patient must have a reasonable life expectancy (12 to 18 months). The 30-day stroke and death rate of 2.3% for asymptomatic patients in ACAS (1987 to 1993) and 5.0% for symptomatic patients in NASCET (1988 to 1991) are often cited as benchmarks. More recent reports suggest a considerably less frequent event rate. For example, a prospective database study of 13,316 carotid endarterectomies performed in 2007 and 2008 reported a 30-day stroke and death rate of 1.3% in asymptomatic patients and 2.9% in symptomatic patients.[144] The 30-day mortality was significantly more frequent in patients who developed a stroke than in those who did not (12.9% versus 0.6%). Patients with high-risk anatomy, such as restenosis and contralateral carotid arterial occlusion, have the highest risk for perioperative stroke and death. Neurologic deficits occur more commonly in patients with poorly controlled preoperative hypertension and in those with hypertension or hypotension postoperatively. The incidence of perioperative MI in patients undergoing carotid endarterectomy ranges from 0% to 5%. Recent reports suggest the incidence of MI is relatively low. The General Anesthesia versus Local Anesthesia for Carotid Surgery (GALA) trial (discussed later) results reported only 13 patients of 3526 (0.37%) had a perioperative MI.[145] The four fatal perioperative MIs accounted for only 8.9% of the total 30-day mortality. Although the role of carotid endarterectomy in patients older than 80 years of age remains a concern, recent reports suggest that carotid endarterectomy can be performed safely in the very elderly and those deemed high risk, with combined stroke or death rates being comparable to those found in randomized trials (NASCET and ACAS).

PREOPERATIVE ASSESSMENT

The optimal preoperative assessment for patients undergoing carotid endarterectomy continues to be debated (see also Chapter 38). Patients with recently symptomatic carotid disease present a particular challenge because strong evidence exists to support surgical intervention within 2 weeks after manifestation of symptoms, thus limiting the time available for evaluation and optimization of relevant comorbidities as well as the initiation of new medications.[146] The medical management of patients with asymptomatic carotid disease should be optimized and includes β-blockers, statins, and antiplatelet agents. Poorly controlled hypertension should be addressed with

the patient's internist. The gradual decreasing of the arterial blood pressure over several weeks before surgery will restore intravascular volume, reset cerebral autoregulation to a more normal range, and improve perioperative management. Poorly controlled diabetes also warrants preoperative optimization, which may improve perioperative outcome.[147]

CAD is common in patients undergoing carotid endarterectomy and is a leading cause of both early and late mortality. Hertzer and co-workers[148] performed coronary angiograms in 506 patients scheduled for carotid endarterectomy and found significant (>70%) stenosis in one or more coronary artery, CAD in 83% of patients suspected of having CAD, and CAD in 40% thought to have no CAD. Despite the known frequent incidence of CAD in patients undergoing carotid endarterectomy, preoperative studies for the evaluation of myocardial function or ischemic potential are rarely undertaken. Exceptions to this practice are patients with unstable angina, recent MI with evidence of ongoing ischemia, decompensated congestive heart failure, and significant valvular disease. In general, specialized cardiac testing would be unlikely to result in cancellation of the procedure or alter perioperative management. Further, the relatively infrequent overall rates of perioperative nonfatal and fatal MI after carotid endarterectomy make aggressive strategies leading to prophylactic coronary revascularization less appealing.[145] A recent clinical trial reported on the safety and efficacy of coronary angiography and revascularization in preventing postoperative cardiac ischemic events after carotid endarterectomy. In a randomized fashion, 426 patients with no history of CAD were randomized to either coronary angiography before carotid endarterectomy (216 patients) or carotid endarterectomy without coronary angiography (210 patients). In the angiography group, 68 patients had a significant stenosis of the coronary arteries and underwent revascularization with PCI (66 patients) or CABG (2 patients). PCI was performed 1 to 8 days before surgery and always consisted of angioplasty and stenting. No patients in the angiography group had a postoperative cardiac ischemic event or complication related to PCI, whereas 9 patients in the group without angiography had an ischemic event (one fatal MI and eight ischemic events treated medically). Although all PCI patients received dual-antiplatelet therapy, no major bleeding or neck hematomas were observed. Long-term follow-up was not reported.

Patients with combined carotid stenosis and CAD requiring coronary revascularization represent somewhat of a management dilemma because it is often unclear which disease should be treated first.[149] The severity of carotid and coronary disease must be evaluated in terms of clinical symptoms and anatomic lesions, and a decision must be made to perform a combined, staged (carotid endarterectomy first), or reverse-staged (CABG first) procedure. Carotid revascularization is recommended before CABG (staged procedure) in patients with symptomatic carotid disease and bilateral severe asymptomatic carotid stenosis. The optimal management of severe unilateral asymptomatic carotid stenosis in patients undergoing CABG is unclear. The only randomized clinical trial to date randomized 185 patients with severe unilateral asymptomatic carotid stenosis undergoing CABG to a staged or combined procedure (94 patients) or a reverse-staged procedure (90 patients).[150] Although the perioperative mortality rates were equivalent (~1.0%), the 90-day stroke and death rates were significantly lower in the staged and combined group (1.0% versus 8.8%). Given the overall paucity of high-quality evidence, management of an individual patient should be guided by careful assessment of the relative severity of the coronary and carotid disease with particular emphasis on both surgeon-specific and institution-specific results in these patient populations. Carotid artery angioplasty and stenting is widely being applied as an alternative revascularization modality before staged CABG. More recently, a combined procedure (carotid angioplasty/stenting and CABG) has been introduced. In a small feasibility and safety study (90 patients), carotid artery angioplasty and stenting under local anesthesia followed immediately by CABG reported a 30-day stroke and death rate of 2.2%.[151]

ANESTHETIC MANAGEMENT

Anesthetic management goals for carotid endarterectomy include protection of the heart and brain from ischemic injury, control of the heart rate and arterial blood pressure, and ablation of the surgical pain and stress responses. These goals must be achieved with another important goal in mind—to have an awake patient at the end of surgery for the purpose of neurologic examination.

The preoperative visit is particularly important in patients undergoing carotid surgery. During this visit, a series of arterial blood pressure and heart rate measurements are obtained from which acceptable ranges for perioperative management can be determined. Patients are instructed to continue all long-term cardiac medications up to and including the morning of surgery. Aspirin therapy should be continued throughout the perioperative period. As noted earlier, discontinuation of aspirin therapy may be related to an increased rate of MI and transient ischemic events in patients undergoing carotid endarterectomy. When patients arrive at the hospital on the day of surgery, they are queried regarding any new cardiovascular or cerebrovascular symptoms. Long-term cardiovascular medications not taken at home should be administered in the preoperative holding area whenever possible. Patient reassurance is particularly important at this time because anxiety is associated with increases in heart rate, systemic vascular resistance, and myocardial O_2 consumption, which in this patient population could precipitate myocardial ischemia.

ECG monitoring should include continuous leads II and V_5 for detection of rhythm disturbances and ST-segment changes. Online ST-segment analysis can be particularly helpful. An intraarterial catheter for beat-to-beat blood pressure monitoring should be considered routine. Noninvasive arterial blood pressure measurement in the contralateral arm is recommended. Central venous and pulmonary artery catheters are rarely indicated for carotid surgery. The rare patient with uncompensated heart failure or recent MI with ongoing ischemia requiring emergent surgery is a possible exception. If such monitors are used, the subclavian or femoral insertion sites are most

practical because inadvertent carotid puncture could compromise blood flow as a result of hematoma. In my experience, the most common reason for central access is difficult or inadequate peripheral access. IV access for fluid and drug administration can be accomplished with a single, secure, medium-bore (16-gauge) catheter. Because both arms will be tucked to the patient's sides, the IV catheter must run well after patient positioning.

General Anesthesia

Any of the drugs commonly used to induce anesthesia, maintenance anesthetics, and nondepolarizing muscle relaxants can be used safely during carotid endarterectomy, given that stable hemodynamics are maintained and the patient is awake at the end of the procedure. A conventional technique is as follows. Sedative premedication (e.g., midazolam) has the potential to compromise early neurologic assessment and is universally avoided. After placement of routine monitors and administration of O_2 by facemask, small doses of opioid (e.g., fentanyl 0.5 to 1 μg/kg) are administered during arterial line placement. Induction of anesthesia is accomplished with incremental dosages of propofol supplemented with additional opioid (total fentanyl dose 2 to 4 μg/kg). Etomidate also may be used and is preferred in patients with limited cardiac reserve. Neuromuscular relaxation with a short-acting to intermediate-acting nondepolarizing muscle relaxant such as vecuronium facilitates tracheal intubation. Esmolol is particularly effective in blunting the increases in heart rate and blood pressure during laryngoscopy and endotracheal intubation and is used liberally during the induction period. Arterial blood pressure responses during and after endotracheal intubation are unpredictable in this patient population, and the clinician must be prepared for immediate treatment of extremes in blood pressure. My preference is to use short-acting drugs, such as phenylephrine 50 to 100 μg for hypotension and sodium nitroprusside 5 to 25 μg for hypertension. Patients with poorly controlled hypertension (diastolic blood pressure >100 mm Hg) require special care. These patients are often intravascularly volume depleted and may have significant hypotension with induction of anesthesia. Administration of fluids intravenously (5 mL/kg), careful titration of anesthetics, and immediate treatment of hypotension are especially important.

Anesthesia is maintained with 50% N_2O in O_2 and low-dose (i.e., less than half the minimum alveolar concentration [MAC]) inhaled volatile anesthetics. Isoflurane is often preferred because fewer ischemic electroencephalographic (EEG) changes occur during carotid occlusion than with halothane or enflurane. Studies using EEG and regional cerebral blood flow (rCBF) measurements suggest that the critical rCBF (the rCBF below which EEG changes of cerebral ischemia occur) is lower for isoflurane than for halothane or enflurane. Sevoflurane is a good alternative because its critical rCBF in patients undergoing endarterectomy is similar to that determined with isoflurane[152] and it may facilitate more rapid emergence.[153] Additional opioid is rarely administered after skin incision. I do not use a cervical plexus block or request local anesthetic infiltration for skin incisions because the surgical stimulation is minimal and arterial blood pressure needs to be frequently supported. A combined remifentanil and propofol anesthetic technique has been reported but offered little advantage over inhaled anesthetics.[154]

Despite only modest surgical stimulation, hemodynamic fluctuations are common during carotid endarterectomy. Arterial blood pressure and heart rate are controlled within predetermined and individualized ranges during the surgical procedure with short-acting drugs whenever possible (esmolol, phenylephrine, nitroglycerin, and sodium nitroprusside). Arterial blood pressure should be maintained in the high-normal range throughout the procedure and particularly during the period of carotid clamping in an attempt to increase collateral flow and prevent cerebral ischemia. In patients with contralateral internal carotid artery occlusion or severe stenosis, induced hypertension to approximately 10% to 20% above baseline is advocated during the period of carotid clamping when neurophysiologic monitoring is not used. Arterial blood pressure preservation or augmentation can be accomplished by maintaining light levels of general anesthesia or by administering sympathomimetic drugs such as phenylephrine and ephedrine. Some caution must be exercised when using vasopressors to augment blood pressure during carotid endarterectomy because the increases in blood pressure and heart rate may increase myocardial O_2 requirements, as well as the risk for myocardial ischemia[155] or infarction. The restrictive use of vasopressors for specific instances of cerebral ischemia has been advocated.[156] In one report, induced hypertension during the period of carotid occlusion was not associated with myocardial ischemia.[157]

Surgical manipulation of the carotid sinus with activation of the baroreceptor reflexes can cause abrupt bradycardia and hypotension. Cessation of surgical manipulation promptly restores the hemodynamics, and infiltration of the carotid bifurcation with 1% lidocaine usually prevents further episodes. Infiltration may, however, increase the incidence of both intraoperative and postoperative hypertension. I do not advocate routine infiltration of the carotid bifurcation.[158]

With closure of the deep fascial layers in the neck, isoflurane is discontinued, N_2O is increased to 70%, and ventilation is controlled manually. On application of the surgical dressings, drugs used to reverse neuromuscular blockade (i.e., neostigmine) are administered, and O_2 is increased to 100%. At this time external stimuli to the patient are decreased by quieting the room, turning off the overhead surgical lights, and placing the patient in a head-up recumbent position. Ventilation is gently assisted until the patient exhibits spontaneous eye opening or movement. With rare exceptions, all tracheas are extubated after neurologic integrity is established. Neurologic deficits on emergence require immediate discussion with the surgeon about the need for angiography, reoperation, or both. The period of emergence and extubation may be associated with marked hypertension and tachycardia, which may require aggressive pharmacologic intervention. Tight hemodynamic control during this period is likely to be more demanding than during induction. Greater hemodynamic stability and decreased pharmacologic intervention during emergence have been reported in patients undergoing carotid endarterectomy

with propofol versus isoflurane. In addition, a significantly less frequent incidence of myocardial ischemia on emergence was found in the propofol group than in the isoflurane group (1 of 14 versus 6 of 13). Of particular note, all patients with myocardial ischemia on emergence had systolic blood pressure higher than 200 mm Hg.

Regional and Local Anesthesia

Regional and local anesthetic techniques for carotid endarterectomy have been in use for more than 50 years, and many centers consider them to be the techniques of choice. Regional anesthesia is accomplished by blocking the C2 to C4 dermatomes by use of a superficial, intermediate, deep, or combined cervical plexus block (see also Chapter 57). Adequate anesthesia can be obtained with an isolated superficial or intermediate cervical plexus block, likely as a result of spread of local anesthetic to the cervical nerve roots.[159] Local infiltration of the incisional site and surgical field can also provide the necessary sensory blockade. A recent systematic review including over 10,000 cervical plexus blocks for carotid endarterectomy found that the deep (or combined) block was associated with a higher serious complication rate rated to the injecting needle compared with a superficial (or intermediate) block (0.25% versus 0%).[160] The conversion rate to general anesthesia was also higher with the deep block (2.1% versus 0.4%). No difference was found in the incidence of serious systemic complications between the blocks. Although the incidence of serious complications from a cervical plexus block is infrequent, near-toxic levels of local anesthetic occurs in almost half of patients after superficial and deep cervical plexus block.[161] Although no major complications related to local anesthetic toxicity occurred, some caution should be exercised when requesting the surgeon to supplement with additional local anesthetic.

Regional and local anesthesia allows continuous neurologic assessment of the awake patient, which is widely considered to be the most sensitive method for detecting inadequate cerebral perfusion and function. Awake monitoring reduces the need for shunting and avoids the expense associated with indirect monitors of cerebral perfusion. Other advantages that have been reported include greater stability of blood pressure and decreased vasopressor requirements, reduced operative site bleeding, and reduced hospital costs. Potential disadvantages of local or regional anesthesia include an inability to use pharmacologic cerebral protection with anesthetics, patient panic or loss of cooperation, seizure or loss of consciousness with carotid clamping, and inadequate access to the airway should conversion to general anesthesia be necessary. The reported incidence of intraoperative neurologic changes during carotid endarterectomy under local or regional anesthesia varies widely (2.4% to 24%). Rates of conversion from regional anesthesia to general anesthesia of approximately 2% to 6% have been reported. Phrenic nerve paresis is common after cervical plexus block and is of little clinical consequence except in patients with severe COPD or contralateral diaphragmatic dysfunction.

Regional and local anesthesia requires significant patient cooperation throughout the procedure and is best maintained with constant communication and gentle handling of tissues. Supplemental infiltration of local anesthetic by the surgeon, especially at the lower border and ramus of the mandible, is frequently helpful. Sedation, if used at all, must be kept to a minimum to allow continuous neurologic assessment. The surgical drapes are "tented" over the head and face area to minimize claustrophobic anxiety. Levels of consciousness, speech, and contralateral handgrip are assessed throughout the procedure. If both arms are tucked to the patient's side, handgrip can be assessed with the use of a squeaky toy. Blood pressure is augmented with phenylephrine when patients exhibit neurologic changes during carotid artery test clamping or after shunt placement. A 2- to 3-minute test clamp in awake patients allows prompt identification of those who would benefit from shunt placement. Patient acceptance of regional anesthesia is frequent and common, as evidenced by a 92% preference for repeat cervical plexus block for future carotid endarterectomy. Perhaps, no absolute contradiction to regional anesthesia for carotid endarterectomy exists. I avoid regional anesthesia under the following circumstances: strong preference for general anesthesia expressed by the patient (i.e., claustrophobia), language barriers that make communication difficult, and difficult vascular anatomy. Difficult anatomy is usually manifested by a patient with a short neck and a high (more cephalad) bifurcation and may require vigorous submandibular surgical retraction.

Regional Versus General Anesthesia

For decades, the impact of anesthetic technique on outcome for carotid endarterectomy has been debated and studied. Until recently, nonrandomized studies dominated and largely supported that regional anesthesia was associated with significant reductions in the risk for perioperative death, stroke, MI, and pulmonary complications.[162] The lack of randomized data was addressed with the landmark GALA trial.[145] This multicenter, randomized controlled trial included 3526 patients with symptomatic or asymptomatic internal carotid stenosis from 95 medical centers in 24 countries. Patients were randomly assigned to carotid endarterectomy under general anesthesia (1753 patients) or local anesthesia (1773 patients) between 1999 and 2007. The primary outcome was a composite of perioperative death, MI, and stroke (including retinal infarction). The main finding was that anesthetic technique was not associated with a significant difference in the composite end point (4.8% for general versus 4.5% for local). Anesthetic technique was not associated with a significant difference in secondary outcomes, including duration of surgery, duration of ICU stay, length of hospital stay, or quality of life at 1 month after surgery. Other outcomes, including cranial nerve injury (10.5% versus 12.0%), wound hematoma (8.3% versus 8.5%), wound hematoma requiring reoperation (2.6% versus 2.3%), and chest infection, (2.0% versus 1.9%) were similar between patients receiving general anesthesia and local anesthesia, respectively. Of note, 4.4% of patients under local anesthesia (93% received a cervical plexus block) had complications that lead to cancellation of surgery or conversion to general anesthesia. Important limitations of the GALA trial include lack of standardization, absence of blinding, and possible investigator bias. Using patient-level data from the GALA trial, a recent report found that local anesthesia had a cost-effectiveness benefit over general anesthesia.[163]

Although randomized clinical trials, such as GALA, are considered to be the gold standard in clinical research, the conclusions are not always generalizable and therefore may not reflect actual practice in treating unselected patients. A recent report from a large international vascular registry, including 20,141 carotid endarterectomies performed in 10 countries between 2003 and 2007, found that anesthetic technique had no effect on perioperative mortality (0.5% overall) or stroke rate (1.5% overall).[164] These real-world results complement the data from the GALA trial. Thus, using major perioperative complications as a guide, there is no reason to routinely prefer one anesthetic technique over the other for carotid endarterectomy. The ultimate decision to use general anesthesia or regional anesthesia should be based on surgeon and the anesthesiologist experience and patient preference.

CARBON DIOXIDE AND GLUCOSE MANAGEMENT

Cerebrovascular CO_2 reactivity is part of the complex autoregulatory system to control cerebral blood flow. Normal cerebral autoregulation responds to acute changes in $Paco_2$ by decreasing cerebral blood flow (i.e., vasoconstriction) with hypocapnia and increasing cerebral blood flow (i.e., vasodilatation) with hypercapnia. In patients with carotid artery stenosis or occlusion, ipsilateral cerebral blood flow may be impaired because of poor intracerebral collateral blood flow. In the setting of poor collateralization and resultant cerebral hypoperfusion, cerebral resistance vessels in the hypoperfused territories will dilate in an effort to maintain cerebral blood flow. These chronically dilated resistance vessels may demonstrate a diminished or absent (i.e., vasomotor paralysis) cerebral blood flow response to CO_2. Impaired cerebrovascular reactivity to hypercapnia may play a role in the development of stroke ipsilateral to carotid stenosis or occlusion. Although one might expect that impaired CO_2 reactivity would increase the risk for cerebral ischemia after carotid artery clamping, the results of intraoperative cerebral monitoring suggest that no such relationship exists. Impaired cerebrovascular reactivity to CO_2 will significantly improve after carotid endarterectomy.

Control of ventilation and CO_2e during general anesthesia is a matter of some controversy. Hypercapnia may cause a "steal" phenomenon (i.e., shunting of blood away from hypoperfused territories with dilated vasculature) and is generally avoided. Hypocapnia, with its associated cerebral vasoconstriction, has been advocated to promote a reversal of this steal phenomenon. However, little clinical evidence exists for this "reverse" steal effect. Additionally, experimental data do not support the use of hypocapnia as a therapeutic maneuver to produce a favorable redistribution of blood flow during focal cerebral ischemia. Indeed, in this animal model of focal cerebral ischemia, hypocapnia ($Paco_2$ of 23 mm Hg) actually increased the size of the region at risk for ischemia. It is therefore common practice to maintain normocapnia or mild hypocapnia during carotid endarterectomy.

Evidence demonstrates increased ischemic injury to neural tissue when ischemia occurs in the presence of hyperglycemia. Data from The Johns Hopkins Hospital found that operative-day glucose greater than 200 mg/dL at the time of carotid endarterectomy was associated with an increased risk for perioperative stroke or transient ischemic attack, MI, and death.[147] Thus, until additional data become available, it may be beneficial to maintain a blood glucose level below 200 mg/dL in patients undergoing carotid endarterectomy. If hyperglycemia is treated with insulin preoperatively or intraoperatively, the blood glucose level should be carefully monitored, especially during general anesthesia, to avoid the dangers of hypoglycemia.

NEUROLOGIC MONITORING AND CEREBRAL PERFUSION

Intraoperative monitoring for cerebral ischemia or hypoperfusion and, more recently, for cerebral emboli during carotid endarterectomy is controversial (see also Chapter 49). Monitoring techniques include internal carotid artery stump pressure determinations, rCBF measurements, EEG monitoring, SSEP monitoring, transcranial Doppler ultrasonography (TCD), and cerebral oximetry monitoring. The rationale for the use of such monitoring is based on the need to prevent intraoperative strokes. The primary clinical utility of cerebral monitoring is to identify patients who may benefit from shunting during the period of arterial clamping. Secondarily, cerebral monitoring is used to identify patients who may benefit from blood pressure augmentation or change in surgical technique. Despite a tremendous amount of investigative effort, only limited data support the assumption that cerebral monitoring actually improves patient outcome after carotid endarterectomy. To further complicate the issue, several large series have reported excellent results from carotid endarterectomy with routine shunting, routine no shunting, and selective shunting using one or more of the methods discussed later. In a review, the mean reported stroke rate with routine shunting was 1.4% and for routine no shunting was 2%.[165] The mean perioperative stroke rates for selective shunting were 1.6% using stump pressure, 1.6% using EEG, 1.8% using SSEP, and 4.8% using TCD.[165]

Carotid Artery Stump Pressure

The internal carotid artery stump pressure represents the back-pressure resulting from collateral flow through the circle of Willis via the contralateral carotid artery and the vertebrobasilar system. The advantages of monitoring carotid stump pressure are that it is inexpensive, relatively easy to obtain, and continuously available during carotid clamping (dynamic stump pressure). Despite these advantages, few centers use stump pressure monitoring. A recent single center report of 1135 consecutive carotid endarterectomies under general anesthesia used a stump pressure of below 45 mm Hg as a guide for selective shunting.[166] The 30-day stroke rate was 3% for patients selectively shunted (21%), 0.5% for patients not shunted (79%), and 1% overall. The overall 30-day mortality was 0.5%. Of note, no patient had a stroke caused by global intraoperative cerebral hypoperfusion. A recent prospective randomized trial comparing routine shunting versus selective shunting based on stump pressure below 40 mm Hg in 200 patients undergoing carotid endarterectomy under

general anesthesia found both methods were associated with an infrequent perioperative stroke rate (0% versus 2%).[167] The two strokes in the selective shunting cohort were related to carotid artery thrombosis. No patients died perioperatively. Although an old method, stump pressure monitoring appears to have survived the test of time.

Regional Cerebral Blood Flow

rCBF measurements during carotid endarterectomy are obtained by IV or ipsilateral carotid artery injection of radioactive xenon and analysis of decay curves obtained from detectors placed over the area of the ipsilateral cortex supplied by the middle cerebral artery. Measurements are typically obtained before, during, and immediately after carotid clamping. This technology, combined with the EEG monitoring, has provided important insight into the relationship between rCBF and EEG evidence of cerebral ischemia and the critical rCBF associated with various anesthetics.[168,169] The critical rCBF varies depending on the volatile anesthetic used. In patients receiving N_2O plus a volatile anesthetic, rCBF is approximately 20, 15, 10, and 10 mL/100 g of brain tissue per minute for halothane, enflurane, isoflurane, and sevoflurane, respectively.[152,168,169] The expense and the expertise required to make and interpret these blood flow measurements have limited the use of this technology to only a few centers.

Electroencephalography

Many centers advocate intraoperative use of EEG monitoring for the detection of cerebral ischemia and subsequent selective shunting (see also Chapter 49). The full 16-channel strip-chart EEG and the processed (compressed spectral array) EEG monitor are used for this purpose. Although the processed EEG monitor is more easily interpreted, it is less sensitive than the raw EEG monitor. Significant ischemic EEG changes occur in 7.5% to 20% of monitored patients during carotid clamping under general anesthesia. Significant EEG changes occur more frequently in patients with contralateral carotid disease than in those without (14.3% versus 5.1%). The presence of a contralateral carotid occlusion may increase the rate of significant ischemic EEG changes to nearly 50% during carotid clamping. Because contralateral occlusion is highly predictive of ischemic EEG changes with carotid clamping, it has been recommended that EEG monitoring be eliminated in this circumstance. Ischemic EEG changes may also be seen with shunt malfunction, hypotension, or cerebral emboli.

When the electroencephalogram is used for cerebral ischemia monitoring during carotid endarterectomy, a stable physiologic and anesthetic milieu is mandatory. Isoflurane, desflurane, and sevoflurane produce similar ECG changes at equipotent levels and, when used at 0.5 MAC, allow for reliable ECG cerebral ischemia monitoring.

The clinical usefulness of intraoperative EEG monitoring for ischemia during carotid endarterectomy is limited by several factors. First, it may not detect subcortical or small cortical infarcts. Second, false-negative results (i.e., neurologic deficit with no ischemic EEG changes intraoperatively) are not uncommon. Patients with preexisting stroke or reversible neurologic deficits may have a particularly high incidence of such results. Third, EEG monitoring is not specific for ischemia and may be affected by changes in temperature, blood pressure, and anesthesia depth. Fourth, false-positive results (i.e., no perioperative neurologic deficit with significant ischemic EEG changes intraoperatively) occur because not all cerebral ischemia uniformly proceeds to infarction. Finally, intraoperative EEG monitoring is inherently limited because most intraoperative strokes are thought to be thromboembolic and most perioperative strokes occur postoperatively. At present, no consistent data demonstrate that EEG monitoring is clearly superior to other methods of intraoperative cerebral monitoring or that the use of EEG monitoring improves outcome.

Somatosensory Evoked Potentials

SSEP monitoring is based on the response of the sensory cortex to electrical impulses from peripheral sensory nerve stimulation. The sensory cortex, being primarily supplied by the middle cerebral artery, is at risk during carotid artery clamping. SSEP monitoring, unlike EEG monitoring, is able to detect subcortical sensory pathway ischemia. Characteristic SSEP tracings (i.e., decrease in amplitude, increase in latency, or both) occur with decreased rCBF and are abolished in primates when flow decreases to less than 12 mL/100 g of brain tissue per minute. No specific reduction in amplitude or increase in latency has been established as a physiologic marker of impaired rCBF under operative conditions in humans. Anesthetics, hypothermia, and blood pressure may affect SSEPs significantly, and false-negative results have been reported. The validity of SSEPs as an intraoperative monitor of cerebral ischemia during carotid endarterectomy has not been definitively established.

Transcranial Doppler Ultrasonography

TCD allows continuous measurement of mean blood flow velocity and detection of microembolic events in the middle cerebral artery (see also Chapter 49). These parameters have important clinical implications because most perioperative neurologic deficits are thought to be thromboembolic in origin. With TCD, intraoperative embolization has been detected in more than 90% of patients undergoing carotid endarterectomy. Most intraoperative emboli are characteristic of air and are not associated with adverse neurologic outcomes. TCD may provide useful information regarding shunt function, malfunction, and the incidence of emboli during shunt insertion. Embolization during carotid artery dissection may indicate plaque instability and the need for early carotid artery clamping. Embolization during dissection and wound closure is associated with operative stroke. One center has reported that combined TCD monitoring and completion angiography resulted in a reduction in the intraoperative stroke rate from 4% to 0%. Early postoperative embolization has been detected in more than 70% of patients after carotid endarterectomy and is exclusively particulate in nature. Most TCD-detected emboli occur in the first 2 to 3 hours after surgery. Persistent particulate embolization in the early postoperative period has been shown to predict thrombosis and the development of a major neurologic deficit. Frequent early postoperative TCD embolic signals have been demonstrated to be highly predictive of early postoperative ipsilateral focal

cerebral ischemia. Intervention with dextran has been shown to reduce and ultimately stop sustained embolization after carotid endarterectomy. Perioperative microembolization is more common in women and patients with symptomatic carotid disease. TCD monitoring has been reported to detect early asymptomatic carotid artery occlusion and hyperperfusion syndrome after carotid endarterectomy. Although TCD monitoring holds some promise, conclusive evidence demonstrating improved outcome has not been reported. Additionally, the high rate of technical failures significantly limits the clinical utility of this monitoring modality.[170]

Cerebral Oxygenation

Direct monitoring of cerebral oxygenation can be obtained with jugular bulb venous monitoring. Such monitoring allows determination of the arterial–jugular venous O_2 content difference and jugular venous O_2 saturation and therefore provides information on global cerebral O_2 metabolism. Jugular venous samples are obtained from a catheter inserted into the jugular bulb ipsilateral to the surgical site. Continuous fiberoptic jugular venous oximetry catheters are available as well. Significant technical and methodologic shortcomings have limited the clinical application of this monitoring during carotid endarterectomy.

Near-infrared spectrophotometry is a noninvasive technique that allows continuous monitoring of regional cerebral O_2 saturation through the scalp and skull. Similar to pulse oximetry, cerebral oximetry is based on the different absorption characteristics of the near-infrared spectrum of oxygenated and deoxygenated hemoglobin. However, unlike pulse oximeters, cerebral oximeters measure the O_2 saturation of hemoglobin in the entire tissue bed (i.e., brain tissue and arterial and venous blood), which is predominately venous blood, and therefore approximates venous blood O_2 saturation. A commercially available cerebral oximetry sensor is applied to the forehead skin ipsilateral to the surgical site, and regional cerebral O_2 saturation from a small sample of the frontal cortex below the sensor is provided. To date, wide patient-to-patient variability in baseline cerebral O_2 saturation and the lack of a clinical threshold of a decrease in cerebral O_2 saturation predictive of the need for shunt placement have impeded the widespread use of this novel monitoring modality.

POSTOPERATIVE CONSIDERATIONS

Most neurologic complications (transient and permanent) after carotid endarterectomy are explained by intraoperative embolization, hypoperfusion during carotid clamping, and postoperative embolization or thrombosis from the endarterectomy site. It is generally accepted that most neurologic complications are related to surgical technique. Thromboembolic (rather than hemodynamic) factors appear to be the major mechanism of perioperative neurologic complications and most occur in the postoperative period. Neurologic complications attributable to carotid artery thrombosis may occur with an incidence as frequent as 3.3% and are associated with a high rate of major stroke or death despite immediate operative intervention. Other important, but less common neurologic complications include intracerebral hemorrhage and cerebral hyperperfusion. The reported incidence of intracerebral hemorrhage after carotid endarterectomy ranges from 0.4% to 2.0%. Most intracerebral hemorrhages occur 1 to 5 days after the operation and are associated with significant morbidity and mortality.

Hypertension is common in the postoperative period after carotid endarterectomy. Not surprisingly, patients with poorly controlled preoperative hypertension often have severe hypertension postoperatively. The causes are not well understood, but surgical denervation of the carotid sinus baroreceptors is probably contributory. Regional anesthesia is associated with less hypertension. Other causes of postoperative hypertension, such as hypoxemia, hypercapnia, bladder distention, and pain, should be excluded or treated. Because neurologic and cardiac complications may be associated with postoperative hypertension, blood pressure should be aggressively controlled to near preoperative values after surgery. Short-acting drugs are the safest and most effective. Patients with persistent hypertension can be converted to longer-acting IV or oral agents before discharge from the ICU.

Postoperative cerebral hyperperfusion syndrome is an abrupt increase in blood flow with loss of autoregulation in the surgically reperfused brain and is manifested as headache, seizure, focal neurologic signs, brain edema, and possibly intracerebral hemorrhage. Unfortunately, little is actually known about the cause and management of this syndrome. Typically, this syndrome does not occur until several days after carotid endarterectomy. Patients with severe postoperative hypertension and severe preoperative internal carotid artery stenosis are believed to be at increased risk for this syndrome. However, more recent data do not corroborate this common belief and suggest that recent contralateral carotid endarterectomy may be predictive of cerebral hyperperfusion.[171]

Postoperative hypotension occurs almost as frequently as hypertension after carotid endarterectomy. Carotid sinus baroreceptor hypersensitivity or reactivation probably plays an important role. Postoperative hypotension may be more common after regional anesthesia. To avoid cerebral and myocardial ischemia, hypotension should be corrected promptly. Cardiac output is frequently normal or elevated and systemic vascular resistance reduced in hypotensive patients after carotid endarterectomy. Intensive surveillance for evidence of myocardial and cerebral ischemia and judicious use of fluids and vasopressors are recommended for postoperative hypotension. In most cases the hypotension resolves over a period of 12 to 24 hours.

Cranial and cervical nerve dysfunction after carotid endarterectomy is well documented in the literature. Although most injuries are transient, permanent injuries can lead to significant disability. Patients should be examined for injury to the recurrent laryngeal, superior laryngeal, hypoglossal, and marginal mandibular nerves shortly after extubation. Unilateral recurrent laryngeal nerve injury may result in ipsilateral true vocal cord paralysis in the paramedian position. Although most patients have hoarseness and an impaired cough mechanism, the injury is usually well tolerated. However, bilateral recurrent laryngeal nerve injury and resultant bilateral vocal cord paralysis can result in life-threatening upper airway obstruction. This situation must be anticipated in

patients who have previously undergone contralateral carotid endarterectomy or neck surgery.

Carotid body denervation may occur after carotid endarterectomy as a result of surgical manipulation. Unilateral loss of carotid body function may result in an impaired ventilatory response to mild hypoxemia and is rarely of clinical significance. Bilateral carotid endarterectomy is associated with loss of the normal ventilatory and arterial pressure responses to acute hypoxia and an increased resting partial pressure of arterial CO_2. In this situation, the central chemoreceptors are the primary sensors for maintaining ventilation, and serious respiratory depression may result from opioid administration. Fortunately, most patients require little more than acetaminophen or ketorolac for postoperative pain.

Wound hematoma probably occurs more frequently than reported in the literature. In the North American Symptomatic Carotid Endarterectomy Trial,[136] 5.5% of patients had wound hematomas. Most cases are the result of venous oozing and require little more than external compression for 5 to 10 minutes. Expanding hematomas require prompt evaluation at the bedside and immediate evacuation if airway compromise is evident. Aggressive postoperative blood pressure control may help reduce the incidence of hematoma.

Although some clinicians believe that intensive care monitoring is not routinely required after carotid surgery, a significant number of patients do require intensive monitoring and active intervention. I think all patients should be monitored in an intensive care setting for at least 8 hours after carotid endarterectomy, because most events requiring intervention occur within this timeframe.[172,173]

ENDOVASCULAR TREATMENT OF CAROTID DISEASE: CAROTID ARTERY STENTING

Endovascular treatment of carotid disease is an innovation in evolution for stroke prevention and currently involves percutaneous transluminal angioplasty and stenting. Significant procedural advancements include the use of dual antiplatelet therapy, self-expanding stents, and emboli protection devices. Over the last decade, major randomized clinical trials comparing carotid endarterectomy with carotid artery stenting have been published. A recent systematic review of randomized trials (16 trials involving 7572 patients) found that endovascular treatment (including balloon angioplasty or stenting) was associated with an increased risk for periprocedural stroke or death compared with endarterectomy.[174] Of note, the increase in risk appeared to be limited to patients 70 years of age and older. Endovascular treatment was associated with lower risks for MI, cranial nerve palsy, and access site hematomas. The rate of ipsilateral stroke after the periprocedural period was not different between treatment groups. Among patients unfit for surgery, the rate of death or stroke did not differ between endovascular treatment and medical care. Updated guidelines provide specific recommendations for revascularization of symptomatic and asymptomatic patients.[131]

The carotid artery stenting procedure consists of the following steps: femoral access, aortic arch angiogram, selective cannulation of the common carotid artery origin and angiogram, guidewire advancement into the external carotid artery, carotid sheath placement and advancement into the common carotid artery, placement of embolic protection device, balloon angioplasty of lesion, advancement of stent delivery catheter across dilated lesion, deployment of self-expanding stent, balloon dilatation of stent, completion angiogram, and access site management. The femoral artery approach is considered standard, but brachial artery and high radial artery access have been reported with high procedural success. Embolic protection devices are considered mandatory and include distal protection in the form of a filter or occlusion balloon and proximal protection in the form of flow interruption or flow reversal. Cardiologists and radiologists currently perform a large percentage of these procedures in specialized endovascular suites.

Most carotid artery stenting procedures are performed under local anesthesia with light or no sedation to facilitate patient cooperation and continuous neurologic assessment. In addition to routine monitors, an arterial line is placed for continuous blood pressure monitoring. Some degree of hemodynamic instability is common in patients during and after carotid artery stenting. Bradycardia and hypotension occur much more frequently after carotid artery stenting with balloon angioplasty than without angioplasty.[175] A recent, large retrospective study reported asystole in 4.9% of patients after carotid stenting.[176] Asystole was more likely to occur in patients undergoing a right-sided procedure, in those with significant contralateral stenosis, and in those with a reduced left ventricular ejection fraction. The administration of prophylactic atropine before balloon inflation decreases the incidence of intraoperative bradycardia and cardiac morbidity in primary carotid stenting patients.[177]

POSTOPERATIVE MANAGEMENT OF VASCULAR SURGERY PATIENTS

Vascular surgery patients require special attention during the postoperative period because most complications occur postoperatively and other problems may arise that require immediate attention. Conventional practice is to monitor all vascular surgery patients in an ICU setting after surgery. Some centers have set up specialized vascular step-down units in which lower risk patients can be evaluated frequently by specialized nursing staff. There are, however, no clinical trials to support this practice.

Myocardial ischemia and cardiac morbidity occur most frequently in the postoperative period. Patients should be carefully monitored for signs and symptoms of myocardial ischemia, realizing that up to 90% of ischemic episodes are asymptomatic. Troponin surveillance may be beneficial in high-risk patients. The determinants of myocardial O_2 supply and demand should be optimized for all patients (Fig. 69-18) to prevent ischemia before it develops. β-Blocker and statin therapy should be continued throughout the postoperative period. Dysrhythmias are common and may be secondary to ischemia or to sympathectomy associated with regional anesthesia.

Besides myocardial ischemia and cardiac morbidity, other problems include coagulopathy, from either residual

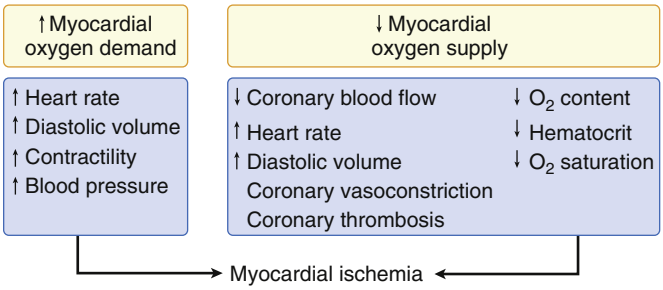

Figure 69-18. Determinants of myocardial oxygen supply and demand that lead to myocardial ischemia. During the perioperative period, virtually every determinant is altered by factors such as fluid shifts, blood loss, pain, catecholamines, altered coagulability, and ventilatory insufficiency. (Modified from Beattie C, Fleisher LA: Perioperative myocardial ischemia and infarction, *Int Anesthesiol Clin* 30:1-17, 1992.)

heparin or dilutional coagulopathy after massive transfusion. Even in the absence of coagulopathy, bleeding through fresh vascular anastomoses may occur when significant postoperative hypertension is untreated. Hypovolemia occurs after aortic surgery as a result of significant third-space fluid loss and bleeding. Hypovolemia may lead to hypotension and hypoperfusion of vital organs or lower extremity vascular grafts. Graft occlusion in the lower extremities occurs in 3% to 10% of patients after lower extremity or aortic surgery and should be recognized immediately and surgically corrected. Lower extremity pulses should be checked at hourly intervals. Some patients require the administration of heparin or dextran to prevent thrombosis when the surgical repair is questionable or when patients have diffuse atherosclerotic disease.

Residual hypothermia in the early postoperative period is associated with an increased incidence of myocardial ischemia and cardiac morbidity; therefore, body temperature should be carefully monitored and controlled in all vascular surgery patients. In the early postoperative period, vascular surgery patients have a twofold to threefold greater incidence of myocardial ischemia when core temperature is less than 35° C.[178] Even mild hypothermia of approximately 35° C is associated with a 200% to 700% increase in norepinephrine levels,[179,180] generalized vasoconstriction,[181] and increased blood pressure in postoperative patients.[179] Shivering occurs and increases total-body O_2 consumption by approximately 40% in the typical elderly vascular patient.[182] In a prospective randomized trial, the relative risk for early postoperative cardiac morbidity was reduced by 55% when normothermia was maintained by use of a forced-air warming system.[183]

The stress response needs to be controlled in the postoperative period. This includes preventing the potential triggers for myocardial ischemia such as pain, anemia, hypothermia, hemodynamic extremes, and ventilatory insufficiency. In mechanically ventilated patients, the weaning period is especially stressful, and myocardial ischemia occurs frequently during this time. Careful sedation and expeditious weaning are desirable. When possible, extubation in the operating room is less stressful and is preferable for carotid and lower extremity vascular surgery patients. For more invasive surgical procedures (TAA and AAA), postoperative mechanical ventilation is usually necessary.

Vascular surgery continues to challenge the anesthesiologist, given the significant physiologic stress superimposed on a relatively elderly patient population with a high incidence of coexisting disease. Clinical studies and society guidelines provide insight into the preoperative assessment and optimization of cardiac risk, the implications of anesthetic technique, and the diagnosis, prevention, and treatment of myocardial ischemia in vascular surgery patients. These studies and guidelines have improved our ability to care for vascular surgery patients with reduced morbidity and better overall outcome.
