Identifying inhaled anesthetic binding sites on plausible target proteins is difficult because of their low-affinity interactions, the paucity of atomic resolution structures of pharmacologically relevant target proteins, and the lack of specific antagonists. Consequently, most anesthetic binding sites have been identified in well-characterized model proteins for which three-dimensional atomic resolution structures are available, but which are not themselves relevant to anesthesia, such as luciferase and albumin.[14,115] These studies indicate that anesthetics bind in pockets with both nonpolar and polar noncovalent chemical interactions. Binding involves weak hydrogen bond interactions with polar amino acid residues and water molecules, nonpolar van der Waals interactions, and a polarizing effect of the amphiphilic binding cavity on the relatively hydrophobic anesthetic molecules. Internal cavities are important for the conformational flexibility required for ion channel gating and ligand-induced signal transduction of receptor proteins. Occupation of a critical volume within these cavities by anesthetics provides a plausible mechanism for alteration of receptor and ion channel function by selective stabilization of a particular confirmation (e.g., an open or inactivated state of an ion channel). Anesthetics also gain binding energy from the entropy generated by displacing bound water from these relatively promiscuous binding sites. Studies of glycine, $GABA_A$, and NMDA receptors provide convincing evidence for the existence of anesthetic binding sites in critical neuronal signaling proteins.[14] Amino acid

residues critical for volatile anesthetic actions, and, by inference, binding, have been identified in the α-subunit of the $GABA_A$ receptor.[14]

Structural studies using the more accessible prokaryotic homologues of eukaryotic ion channels have provided a powerful tool for the study of anesthetic binding sites in biologically plausible proteins. For example, both propofol and desflurane have been co-crystalized with GLIC, a bacterial homologue of eukaryotic inhibitory ligand-gated ion channels (glycine and $GABA_A$ receptors). Both anesthetics bind a common preexisting site in the upper part of the transmembrane domain between the transmembrane segments of a single subunit (Fig. 25-6).[116] Molecular modeling based on structurally homologous proteins has also been used to identify putative anesthetic binding sites in the transmembrane domains of vertebrate $GABA_A$ and glycine receptors (Fig. 25-7). These models suggest that different drugs may either bind in different orientations within a single amphiphilic cavity or occupy different cavities within the protein, causing similar functional effects. Refinement of these molecular models will continue to provide new insights in the molecular basis for general anesthetic action that can be experimentally tested. For example, potential sites of interaction of xenon and isoflurane with the NMDA receptor have also been identified using this approach. One site, which can contain up to three xenon atoms or one molecule of isoflurane, overlaps the known binding site for the co-agonist glycine in the NR1 subunit.[117] This suggests that two chemically dissimilar inhaled anesthetics inhibit NMDA receptors by direct competitive inhibition of co-agonist binding.

Molecular Targets of Inhaled Anesthetics

Ion channels have emerged as the most promising molecular targets for inhaled anesthetics. Neurotransmitter-gated ion channels, in particular $GABA_A$, glycine, and NMDA-type glutamate receptors, are leading candidates owing to their appropriate CNS distributions, essential physiologic roles in inhibitory and excitatory synaptic transmission, and sensitivities to clinically relevant concentrations of anesthetics.[16,118] Other ion channels that are sensitive to inhaled anesthetics include the hyperpolarization-activated cyclic nucleotide (HCN)-gated family of channels that give rise to pacemaker currents[118] and regulate dendritic excitability, two-pore domain (K_{2P}) "leak" K^+ channels that maintain resting membrane potential in many cells,[119] and voltage-gated Na^+ and Ca^{2+} channels.[118]

Inhaled anesthetics can be divided into two classes based on their distinct pharmacologic properties. The first class is the potent inhaled (volatile) anesthetics, which exhibit positive modulation of $GABA_A$ receptors and also produce significant, anesthesia-compatible effects on a number of other receptors/channels, including enhancement of inhibitory glycine receptors, inhibition of excitatory NMDA and neuronal nicotinic acetylcholine receptors, activation of K_{2P} channels, and inhibition of presynaptic Na^+ channels. Intravenous anesthetics such as propofol and etomidate represent more potent and specific positive modulators of $GABA_A$ receptors. The second class is the gaseous inhaled anesthetics, which include cyclopropane, nitrous oxide, and xenon. These anesthetics are inactive at $GABA_A$ receptors but block NMDA receptors and activate certain K_{2P} channels at clinical concentrations.

LIGAND-GATED ION CHANNELS

Potentiation of Inhibitory $GABA_A$ and Glycine Receptors

The ether anesthetics (including isoflurane, sevoflurane, and desflurane), the alkane anesthetic halothane, most intravenous anesthetics (including propofol, etomidate, barbiturates), and the neurosteroid anesthetics enhance $GABA_A$ and glycine receptor (GlyR) function. $GABA_A$ and GlyRs are members of the same cys-loop ligand-gated ion channel superfamily that also includes the cation-permeable nicotinic acetylcholine and $5HT_3$ receptors. $GABA_A$ receptors are the principal transmitter-gated Cl^- channels in the neocortex and allocortex, whereas GlyRs

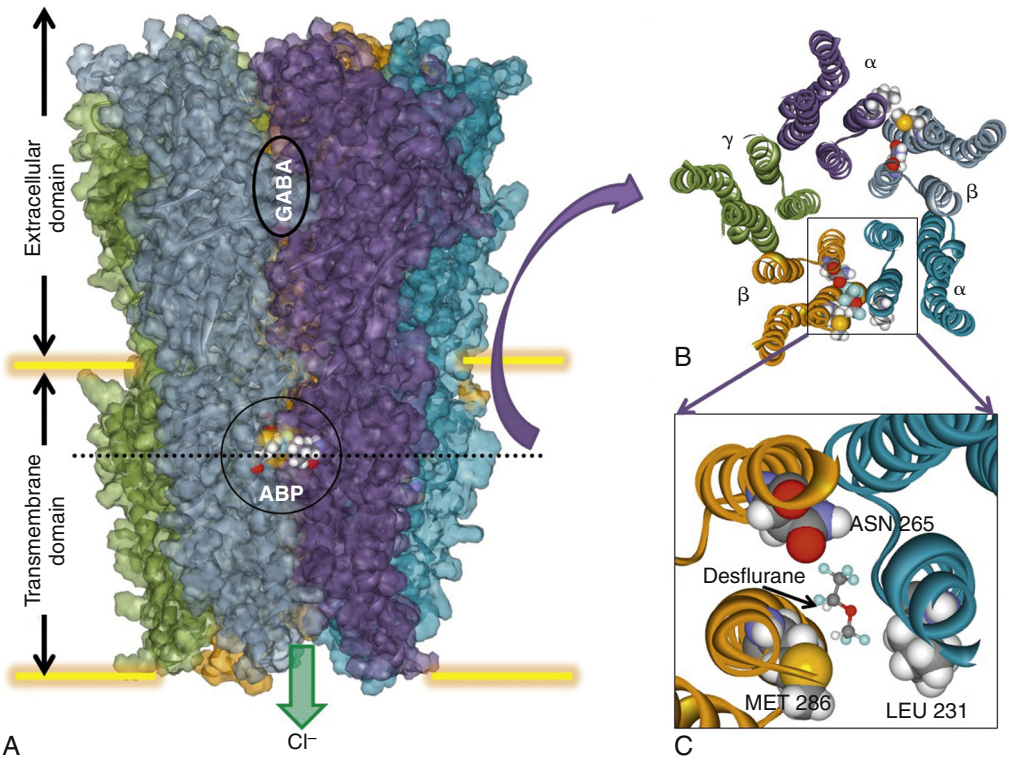

Figure 25-7. Putative anesthetic binding sites on $GABA_A$ receptors identified by molecular modeling. **A,** Molecular model of the mouse $GABA_A$ receptor built using homology modeling techniques with computational chemistry optimizations and molecular dockings. The amino acid backbone is displayed in ribbon format and outlined by the transparent solvent-accessible molecular surface. Each of the five subunits is colored uniquely. The GABA binding site is noted in the extracellular domain, whereas the putative anesthetic binding pocket (ABP) for potentiation is noted in the outer third of the transmembrane domain between the α and β subunits. Two binding sites are shown but only one has computationally docked desflurane. **B,** Cross-section at the *dotted line* level in **A** showing orientation of subunits with pentameric symmetry about a central ion pore. **C,** Magnified region of intersubunit anesthetic binding site derived from region in **B** showing relevant amino acid positions (in space-filling format) interacting with desflurane (in ball-and-stick format at the same scale). *(Courtesy the Bertaccini laboratory, Stanford University.)*

fulfill this function in the spinal cord, with some overlap in the diencephalon and brainstem. Activated receptors conduct chloride ions, driving the membrane potential toward the Cl^- equilibrium potential. Both receptors are inhibitory because the Cl^- equilibrium potential is usually more negative than the normal resting potential. Channel opening also reduces membrane resistance and "shunts" excitatory responses. Most functional $GABA_A$ and GlyRs are heteropentamers, typically consisting of three different $GABA_A$ subunits (e.g., two α, two β, and one γ or ∂) or two different GlyR subunits (three α and two β).[120] The subunit composition of $GABA_A$ receptors determines their physiologic and pharmacologic properties and varies between and within brain areas, as well as between different compartments of individual neurons. Examples are the preferential expression of the α_5-subunit in the dendritic field of the hippocampal CA1 area (a region important for memory formation), of the α_4-subunit in the thalamus, and of the α_6-subunit in the cerebellum. Presence of a γ-subunit is required for benzodiazepine modulation of $GABA_A$ receptors and can also influence modulation by inhaled anesthetics. Although the molecular mechanisms of receptor modulation by inhaled anesthetics are not clear, these receptors have been key to our understanding of anesthetic-receptor interactions. Using chimeric receptor constructs between anesthetic-sensitive $GABA_A$ and insensitive GlyR subunits, specific amino acid residues in transmembrane domains 2 and 3 critical to the action of inhaled anesthetics have been identified.[121] This laid the groundwork for the construction of anesthetic-resistant $GABA_A$ receptors and the generation of transgenic mice with altered anesthetic sensitivity (discussed later).

The related cation-permeable 5-hydroxytryptamine (serotonin)-3 ($5HT_3$) receptors are similarly potentiated by volatile anesthetics.[122] $5HT_3$ receptors are involved with autonomic reflexes and also probably contribute to the emetogenic properties of volatile anesthetics (see Chapter 97).

Inhibition of Excitatory Acetylcholine and Glutamate Receptors

Neuronal nicotinic acetylcholine receptors (nnAChRs), like the other members of the cys-loop family, are heteropentameric ligand-gated ion channels, but are cation selective. They are composed of α- and β-subunits, but functional homomeric receptors can be formed by certain α-subunits. In the CNS, nnAChRs are localized primarily presynaptically.[123] Homomeric α_7-receptors have high permeability to Ca^{2+} that can exceed that of NMDA receptors.[123] In contrast to $GABA_A$ and GlyRs, nnAChRs pass cations when activated and therefore depolarize

the membrane potential. Receptors containing $\alpha_4\beta_2$ subunits are very sensitive to block by isoflurane and propofol.[124,125] Relevance of nnAChR block to immobilization, sedation, and unconsciousness by inhaled anesthetics is unlikely because nnAChRs are also blocked by nonimmobilizers, although it is possible that they do contribute to amnesia.

NMDA receptors are a major postsynaptic receptor subtype of inotropic receptors for glutamate, the principal excitatory neurotransmitter in the mammalian CNS.[126] Typical NMDA receptors, defined pharmacologically by their selective activation by the exogenous agonist NMDA, are heteromers consisting of an obligatory GluN1 subunit and modulatory GluN2 subunits. Channel opening requires glutamate (or another synthetic agonist such as NMDA) binding to the GluN2 subunit while the endogenous co-agonist glycine binds to the GluN1 subunit. NMDA receptors also require membrane depolarization to relieve voltage-dependent block by Mg^{2+}. Depolarization is typically provided by binding of glutamate to non-NMDA glutamate receptors (discussed later). Because of this requirement for both presynaptic transmitter release and postsynaptic depolarization, synaptic NMDA receptors function as coincidence detectors, and this characteristic is thought to be central to their role in learning and memory. NMDA receptors are also involved in the development of chronic pain, perhaps because of mechanisms similar to those underlying synaptic plasticity, and in ischemia-induced excitotoxicity by virtue of their capacity to allow entry of the ubiquitous intracellular signal Ca^{2+}. The nonhalogenated inhaled anesthetics xenon, nitrous oxide, and cyclopropane have minimal effects on $GABA_A$ receptors but depress excitatory glutamatergic synaptic transmission postsynaptically via NMDA glutamate receptor blockade (see Fig. 25-8).[70,127] Volatile anesthetics can also inhibit isolated NMDA receptors at higher concentrations.[128] Along with presynaptic inhibition of glutamate release, this might contribute to their depression of NMDA receptor–mediated excitatory transmission.

A second class of inotropic glutamate receptors includes the non-NMDA receptors, which are subdivided into α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) and kainate receptors based again on their sensitivities to selective exogenous agonists.[126] Inhaled anesthetics only weakly inhibit AMPA receptors, hence this action is unlikely to be important in their actions.[129] Interestingly, kainate receptors are enhanced by inhaled anesthetics, but this is unlikely to be involved in immobility because MAC is not altered in mice deficient in the GluR6 receptor subunit.[130] Most evidence suggests that the principal mechanism for depression of glutamatergic transmission by volatile anesthetics is presynaptic, with minor contributions from postsynaptic receptor blockade[131-133] (see "Cellular Mechanisms").

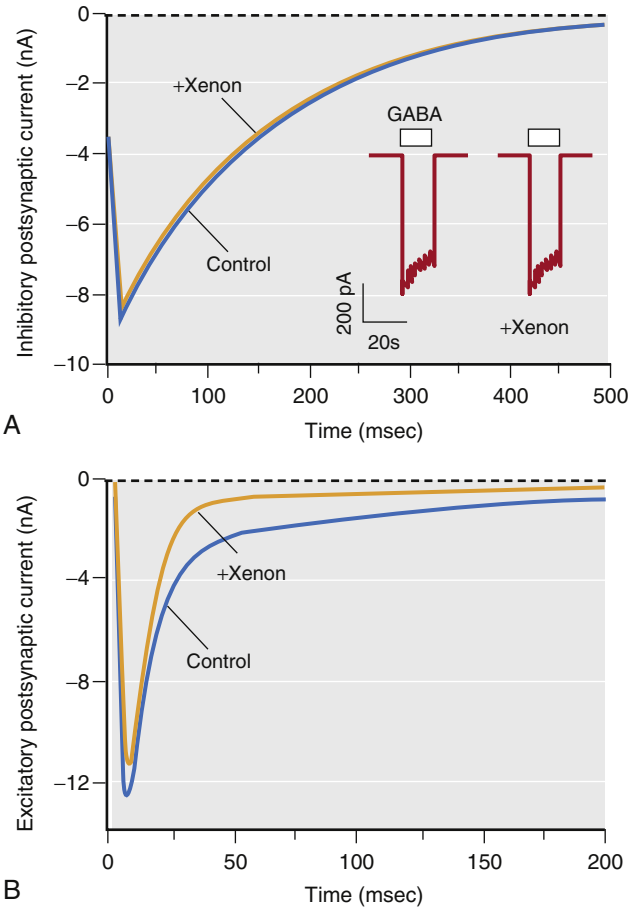

Figure 25-8. The actions of xenon on inhibitory GABAergic and excitatory glutamatergic synapses in cultured rat hippocampal neurons. Xenon (3.4 mM, ~1 MAC) has no significant effect on the inhibitory postsynaptic current (**A**) but depresses the excitatory glutamatergic synaptic current, almost exclusively the slow NMDA receptor-mediated component of the current (**B**). In contrast, the principal effects of ~1 MAC isoflurane are a prolongation in the inhibitory current decay and a reduction in excitatory current peak height, with little change in time course (not shown, see Fig. 25-10). *(Reprinted in modified form by permission from de Sousa SLM, et al: Contrasting synaptic activity of the inhalational general anesthetics isoflurane and xenon,* Anesthesiology *92:1055-1066, 2000.)*

VOLTAGE-GATED AND OTHER ION CHANNELS

Inhibition of Excitatory Na^+ Channels

Voltage-gated Na^+ channels are critical to axonal conduction, synaptic integration, and neuronal excitability. In contrast to findings in invertebrate giant axons,[134] axonal conduction in small (0.1 to 0.2 μm) unmyelinated hippocampal axons is depressed by volatile anesthetics,[135,136] and small reductions in preterminal action potential amplitude significantly depress transmitter release and hence postsynaptic responses at a mammalian synapse.[137] Heterologously expressed mammalian voltage-gated Na^+ channels are sensitive to clinically relevant concentrations of volatile anesthetics. The Na^+ channel family consists of nine homologous pore-forming α-subunits with distinct cellular and subcellular distributions.[138] Isoflurane and other volatile anesthetics inhibit the major mammalian Na^+ channel isoforms, including neuronal ($Na_v1.2$), skeletal muscle ($Na_v1.4$), cardiac ($Na_v1.5$), and peripheral ($Na_v1.8$) isoforms.[139] Volatile anesthetics, but not nonimmobilizers, also inhibit native neuronal and nerve terminal Na^+ channels,[140-143] lending support to the notion that Na^+

channel blockade contributes to the depression of synaptic neurotransmitter release.[143] In contrast, xenon has no detectable effect on Na^+, Ca^{2+}, or K^+ channels in isolated cardiomyocytes.[92] The demonstration that NaChBac, a prokaryotic homologue of voltage-gated Na^+ channels, is also inhibited by volatile anesthetics opens the way for structure-function studies of these channels.[141]

Inhibition of Ca^{2+} Channels

Multiple cellular functions depend on the tightly controlled concentration of intracellular free Ca^{2+} ($[Ca^{2+}]_i$), which is determined by the integrated activities of voltage-gated Ca^{2+} channels, capacitative Ca^{2+} channels, plasma membrane and sarcoplasmic/endoplasmic reticulum Ca^{2+}-adenosine triphosphatases (pumps), Na^+/Ca^{2+} exchangers, and mitochondrial Ca^{2+} sequestration. Alteration of any of these mechanisms by anesthetics can affect the many cellular processes regulated by the second messenger actions of Ca^{2+}, including synaptic transmission, gene expression, cytotoxicity, and muscle excitation–contraction coupling. Excitable cells translate their electrical activity into action by Ca^{2+} fluxes mediated primarily by voltage-gated Ca^{2+} channels in the plasma membrane. Distinct Ca^{2+} channel subtypes are expressed in various cells and tissues and are classified pharmacologically and functionally by the degree of depolarization required to gate the channel, such as low voltage–activated (LVA; T-type) and high voltage–activated (HVA; L-, N-, R-, and P/Q-type) channels. More recently, the molecular identity of their pore-forming α-subunits has been used for classification.[144] There is convincing evidence that volatile anesthetics inhibit certain Ca^{2+} channel isoforms but not others.[145]

Inhibition of presynaptic voltage-gated Ca^{2+} channels coupled to transmitter release has been proposed as a mechanism by which volatile anesthetics reduce excitatory transmission.[146] Indeed, N-type ($Ca_v2.2$) and P-type ($Ca_v2.1$) channels, which mediate Ca^{2+} entry coupled to neurotransmitter release, are modestly sensitive to volatile anesthetics,[147,148] but not in all neuron types,[149] suggesting the importance of auxiliary subunits, posttranslational modification, or other potential modulators of anesthetic sensitivity. A modest contribution of R-type Ca^{2+} channels ($Ca_v2.3$) to anesthesia is suggested by their sensitivity to volatile anesthetics and a small increase in MAC produced by genetic deletion in mice.[150] T-type Ca^{2+} channels are particularly sensitive to volatile anesthetics[151] and nitrous oxide.[152] However, mutant mice lacking a major neuronal T-type Ca^{2+} channel isoform ($Ca_v3.1$) have normal volatile anesthetic sensitivity, although the onset of anesthesia is delayed.[153] Thus the role that inhibition of these or other Ca^{2+} channels play in the CNS effects of inhaled anesthetics is unclear.

By contrast, a role for Ca^{2+} channel inhibition in the negative inotropic effects of volatile anesthetics, prominent at higher doses, is well established. The force of myocardial contraction is determined by the magnitude of cytosolic Ca^{2+} increase after electrical excitation, the responsiveness of the contractile proteins to Ca^{2+}, and sarcomere length. Negative inotropic effects of volatile anesthetics are mediated by reductions in Ca^{2+} availability, Ca^{2+} sensitivity of the contractile proteins, and rate of cytosolic Ca^{2+} clearance. Volatile anesthetics reduce the Ca^{2+} transient and shorten action potential duration in cardiomyocytes primarily by inhibiting L-type ($Ca_v1.2$) Ca^{2+} currents, resulting in a negative inotropic effect and arrhythmogenicity.[97,106,154] In contrast, xenon does not depress myocardial function or inhibit L-type Ca^{2+}, Na^+, or K^+ currents in isolated cardiomyocytes.[98,99] Inhibition of trans-sarcolemmal Ca^{2+} influx through cardiac L-type Ca^{2+} channels plays a major role in the negative inotropic effects of volatile anesthetics—greatest for halothane—along with contributions from effects on myofilament Ca^{2+} sensitivity and sarcolemmal Ca^{2+} release.[106,155]

In contrast to voltage-gated Ca^{2+} channels that regulate the influx of extracellular Ca^{2+}, intracellular Ca^{2+} channels regulate Ca^{2+} release from intracellular stores, particularly the endoplasmic reticulum (ER) and sarcoplasmic reticulum (SR). These include 1,4,5-trisphosphate receptors (IP_3Rs), regulated by the second messenger IP_3, and ryanodine receptors (RyRs), which mediate the rapid release of intracellular Ca^{2+} critical to excitation-contraction coupling in muscle. Volatile anesthetic–induced Ca^{2+} leak occurs via both IP_3R and RyR channels, which leads to depletion of intracellular Ca^{2+} stores from the SR and ER. This blunts changes in intracellular Ca^{2+} in response to stimulation and contributes to the smooth muscle–relaxing properties of volatile anesthetics that underlie bronchodilation and vasodilation.[156] Malignant hyperthermia susceptibility is a pharmacogenetic disorder that manifests as a potentially fatal hypermetabolic crisis triggered by volatile anesthetics, particularly halothane. It is often associated with mutations in RyR1 and the physically associated L-type Ca^{2+} channel ($Ca_v1.1$) that functions as the voltage sensor.[157] Volatile anesthetics activate the abnormal RyRs, resulting in uncontrolled intracellular Ca^{2+} release, muscle contraction, and metabolic activity[158] (see Chapter 43).

K^+ Channels and HCN Channels

Potassium (K^+) channels are an extremely diverse ion channel family noted for their varied modes of activation. They regulate electrical excitability, muscle contractility, and neurotransmitter release. They are important in determining input resistance and in driving repolarization, and thus they determine excitability and action potential duration. Given the large diversity in K^+ channel structure, function, and anesthetic sensitivity, it is not surprising that there is considerable diversity in their sensitivity and response to inhaled anesthetics[159]: from relatively insensitive (voltage-gated K^+ channels $K_v1.1$, K_v3)[160] to sensitive (some members of the 2-pore domain K^+ channels [K_{2P}] family), resulting in either inhibition, activation, or no effect on K^+ currents.

Volatile anesthetic activation of certain "leak" K^+ channels was first observed in the snail *Lymnaea*,[161] although the molecular identity of the affected ion channels was unknown. Activation of K_{2P} channels by volatile and gaseous anesthetics, including xenon, nitrous oxide, and cyclopropane, was subsequently observed in mammals.[162] Increased K^+ conductance can hyperpolarize neurons, reducing responsiveness to excitatory synaptic input and possibly altering network synchrony. Targeted deletion of the TASK-1, TASK-3, and TREK-1 K_{2P} channels

in mice reduces sensitivity to immobilization by volatile anesthetics in an agent-specific manner, implicating these channels as contributory anesthetic targets in vivo.[32-34] Other members of this large family of K^+ channels are also sensitive to volatile anesthetics.[163]

The recognition that inherited channelopathies are arrhythmogenic and constitute an important contributor to sudden cardiac death,[164] particularly in young children,[165] highlights the importance of analyzing anesthetic modulation of cardiac ion channels. Recombinant hERG (human ether-a-go-go related) channels are moderately inhibited by halothane, and their depression likely contributes to arrhythmogenic effects of volatile anesthetics[106,166]; they are also involved in acquired (drug-induced) and inherited long QT syndrome. Cardiac inward-rectifying (K_{IR}), voltage-gated (K_v), and Ca^{2+}-activated K^+ channels are generally relatively insensitive to clinical concentrations of volatile anesthetics and xenon.[98,106,167] In contrast, there is considerable evidence that volatile anesthetics and xenon activate cardiac mitochondrial and sarcolemmal K_{ATP} channels,[107] an effect that plays a critical role in anesthetic preconditioning. Direct electrophysiologic effects of anesthetics with preconditioning properties have been demonstrated on both mitochondrial and sarcolemmal K_{ATP} channels, although the precise mechanisms remain to be clarified.

Volatile anesthetics also inhibit HCN pacemaker channels, reducing the rate of rise of pacemaker potentials and the bursting frequency of certain neurons that show autorhythmicity. They decrease the I_h conductance in neurons[168] and modulate recombinant HCN1 and HCN2 channel isoforms at clinically relevant concentrations.[169] Because HCN channels contribute to resting membrane potential; control action potential firing, dendritic integration, neuronal automaticity, and temporal summation; and determine periodicity and synchronization of oscillations in many neuronal networks,[170] the anesthetic modulation of these channels could play an important role in anesthetic effects on neuronal integrative functions.

INTRACELLULAR SIGNALING MECHANISMS

Cell signaling mechanisms are critical to all phases of organ function and have been attractive targets for explaining the broad effects of general anesthetics. Anesthetics have poorly understood actions on intracellular cell signaling pathways, which include processes downstream from cell surface receptors and ion channels, such as effects of second messengers, protein phosphorylation pathways, and other regulatory mechanisms.[171]

G Protein–Coupled Receptors

A variety of signals, including hormones, neurotransmitters, cytokines, pheromones, odorants, and photons, produce their intracellular actions by interactions with metabotropic receptors that activate heterotrimeric guanine nucleotide–binding proteins (G proteins). In contrast to the inotropic receptors that directly couple to ion-selective channels, G proteins act as indirect molecular switches to relay information from activated plasma membrane receptors to appropriate intracellular targets. Heterotrimeric G proteins consist of a large α-subunit and a smaller β/γ-subunit dimer, each expressed as multiple isoforms with distinct properties and downstream targets. G proteins regulate a plethora of downstream effectors to control the levels of cytosolic second messengers such as Ca^{2+}, cyclic adenosine monophosphate, and inositol triphosphate. These in turn regulate effector proteins such as ion channels and enzymes, either directly or via second messenger–regulated protein phosphorylation pathways. Drugs that act through G protein–coupled receptors (GPCRs), such as agonists for μ-opioid and α_2-adrenergic receptors, can affect anesthetic sensitivity (reduce MAC). Inhaled anesthetics can also directly affect signaling via GPCRs.[172] For example, volatile anesthetics activate multiple olfactory GPCRs in the rat in vivo in a receptor- and agent-selective manner.[173] Analogous effects on related GPCRs more relevant to critical anesthetic end points are possible but remain to be demonstrated. The observation that both volatile anesthetics and nonimmobilizers inhibit mGluR5 glutamate receptors, 5-HT_{2A} serotonin receptors, and muscarinic acetylcholine receptors suggests that these GPCR effects do not contribute to anesthetic immobilization.[174-176]

Protein Phosphorylation

Phosphorylation of proteins on specific serine, threonine, or tyrosine hydroxyl groups, a posttranslational modification involved in the regulation of many anesthetic-sensitive receptors and ion channels, is pivotal to synaptic plasticity (e.g., long-term potentiation [LTP]). Phosphorylation is controlled by the balance of activity between protein kinases and phosphatases, several of which are plausible anesthetic targets. The protein kinase C (PKC) family of multifunctional protein kinases is activated by the lipid-signaling molecule diacylglycerol and is involved in the regulation of many ion channels and receptors. Halothane[177] and sevoflurane[178] enhance the activity of some PKC isoforms and stimulate phosphorylation of specific PKC substrates. Structural studies have identified a potential binding site in the diacylglycerol binding domain of PKCδ, consistent with the ability of certain anesthetics to mimic this natural regulator by binding to the activating site.[179] A specific role for a direct pharmacologically relevant effect mediated by anesthetic activation of PKC or of any other kinase has yet to be demonstrated. Intrathecal injection of isoform-specific inhibitors of PKC does not affect sensitivity to halothane in vivo.[180] Knock-out mice lacking the PKCγ isoform show normal sensitivity to halothane and desflurane while isoflurane MAC was increased,[181] suggesting that PKC is not critical to volatile anesthetic immobilization.

An important role for effects of volatile anesthetics and xenon on cell signaling mechanisms has been discovered for anesthetic-induced preconditioning in the heart (see Chapter 28) and brain against ischemic damage.[83,87,81,85,109] Anesthetic-induced and ischemic cardiac preconditioning share critical signaling mechanisms, including activation of multiple GPCRs (e.g., adenosine, opioid, adrenergic) and protein kinases (e.g., src kinase, PKCδ, PKCε, Akt, mitogen-activated protein kinases [MAPKs]) and their downstream targets, particularly sarcolemmal and/or mitochondrial K_{ATP} channels, possibly

initiated by changes in reactive oxygen species as the critical second messenger.[95] Volatile anesthetics and xenon share cardioprotective and neuroprotective effects involving these signaling pathways.[109]

The effects of anesthetics on the phosphorylation of individual residues in specific substrates can be studied using phosphorylation state–specific antibodies that are able to detect the phosphorylated forms of kinase substrates. A comparison of the effects of three mechanistically diverse anesthetics (isoflurane, propofol, and ketamine) on critical intracellular protein phosphorylation signaling pathways that are known to integrate multiple second messenger systems reveals both shared and agent-specific actions in vivo.[182] All three anesthetics reduce phosphorylation of activating sites on NMDA and AMPA glutamate receptors and of the downstream extracellular signal-regulated kinase ERK2, which are known to be involved in synaptic plasticity, consistent with depression of normal glutamatergic synaptic transmission in the anesthetized mouse cerebral cortex. These effects are somewhat selective in that several other PKA substrates examined are not affected, indicating substrate-specific effects rather than a general inhibition of PKA activity.[183] Additional studies will be required to determine which anesthetic effects on kinase pathways represent direct effects, as occurs with PKC, and which are indirect because of anesthetic-induced alterations in signaling molecules known to regulate protein kinase and phosphatase activity such as Ca^{2+} and other second messengers.

Gene Expression

The ability of general anesthetics to alter gene expression in the brain was first observed for the highly reactive immediate early genes c-*fos* and c-*jun*.[184] Anesthetic effects on gene expression have since been observed for multiple anesthetics and organs.[185] In the hippocampus of aged rats, changes in gene expression persisted for up to 2 days in rats exposed to isoflurane and nitrous oxide,[186] and changes in protein expression have been observed 3 days after exposure to desflurane.[187] The significance of these changes in gene and protein expression persisting after recovery from the classic signs of anesthesia remains to be established (see review[77]).

CELLULAR MECHANISMS

NEURONAL EXCITABILITY

Neuronal excitability is determined by resting membrane potential, threshold for action potential initiation, and input resistance (an indication of overall channel activity), which can differ between compartments within an individual neuron owing to subcellular specializations (e.g., soma versus dendrite). Neurons show considerable diversity, and therefore anesthetic effects vary between neuronal populations with the state of the individual neuron and its network—that is, whether it is hyperpolarized or depolarized, stimulated by synaptic inputs, or quiescent. Therefore it should be recognized that results obtained even from traditional acute slice preparations only incompletely reflect anesthetic effects on neurons in vivo.

The intrinsic excitability of lumbar spinal motoneurons in vivo appears to be little affected by halothane.[188] Anesthetic effects on the firing properties of hippocampal pyramidal neurons are complex: increased or decreased thresholds and regional differences and dose-dependent effects on firing patterns have been reported.[189,190] By contrast, neurons in the ventral-posterior nucleus of the thalamus (possibly thalamic relay neurons) hyperpolarize in the presence of isoflurane and are less likely to fire action potentials because of a decrease in input resistance (increased shunting), attributed to increased K^+ conductance.[191] Similar effects are observed in hypoglossal motoneurons and neurons from the locus coeruleus, where a TASK-type K_{2P} channel has been causally implicated.[192]

A role for $GABA_A$ receptors located at extrasynaptic sites may include volatile anesthetic effects (Fig. 25-9). Extrasynaptic $GABA_A$ receptors, which differ from synaptic receptors in their subunit composition, mediate tonic inhibition (as opposed to phasic inhibition mediated by synaptic $GABA_A$ receptors) and are remarkably sensitive to many general anesthetics. Extrasynaptic $GABA_A$ receptors have a high affinity for GABA, desensitize slowly, and are tonically exposed to low ambient GABA concentrations,[193] at which the potentiating effect of anesthetics is most significant. The effects of anesthetics on tonic inhibition have been characterized in the hippocampus, which is critically involved in learning and memory. Hippocampal neurons generate a robust tonic current via activation of α_5-subunit–containing $GABA_A$ receptors[194-197] that are highly sensitive to etomidate, propofol, midazolam, and isoflurane. $GABA_A$ receptors containing the α_5-subunit are highly sensitive to low concentrations of propofol and isoflurane that produce amnesia but not unconsciousness, and may also be involved in their longer-lasting cognitive effects (discussed earlier). (Also see Chapters 26, 30, and 99.) Receptors containing α_5-subunits also contribute to slow phasic (synaptic) currents that have been discovered in many brain regions.[198] In the hippocampus, these currents termed $GABA_{Aslow}$ are substantially modulated by both etomidate and isoflurane at amnesic concentrations. The slow time course and the location of $GABA_{Aslow}$ matches that of synaptic NMDA receptor–mediated inputs in hippocampal pyramidal cells, placing them therefore in an ideal position to modulate synaptic plasticity. Thus these receptors provide a potential substrate for the amnesic properties of anesthetics.

PRESYNAPTIC VERSUS POSTSYNAPTIC EFFECTS ON SYNAPTIC TRANSMISSION

General anesthetics have potent and specific effects on synaptic transmission, including presynaptic actions (by altering transmitter release) and postsynaptic actions (by altering the postsynaptic responses of neurons to specific transmitters). The relative contributions of presynaptic compared with postsynaptic anesthetic effects on synaptic transmission have been difficult to resolve, probably because the effects are transmitter and synapse specific. The net effect of anesthetics on synaptic transmission is

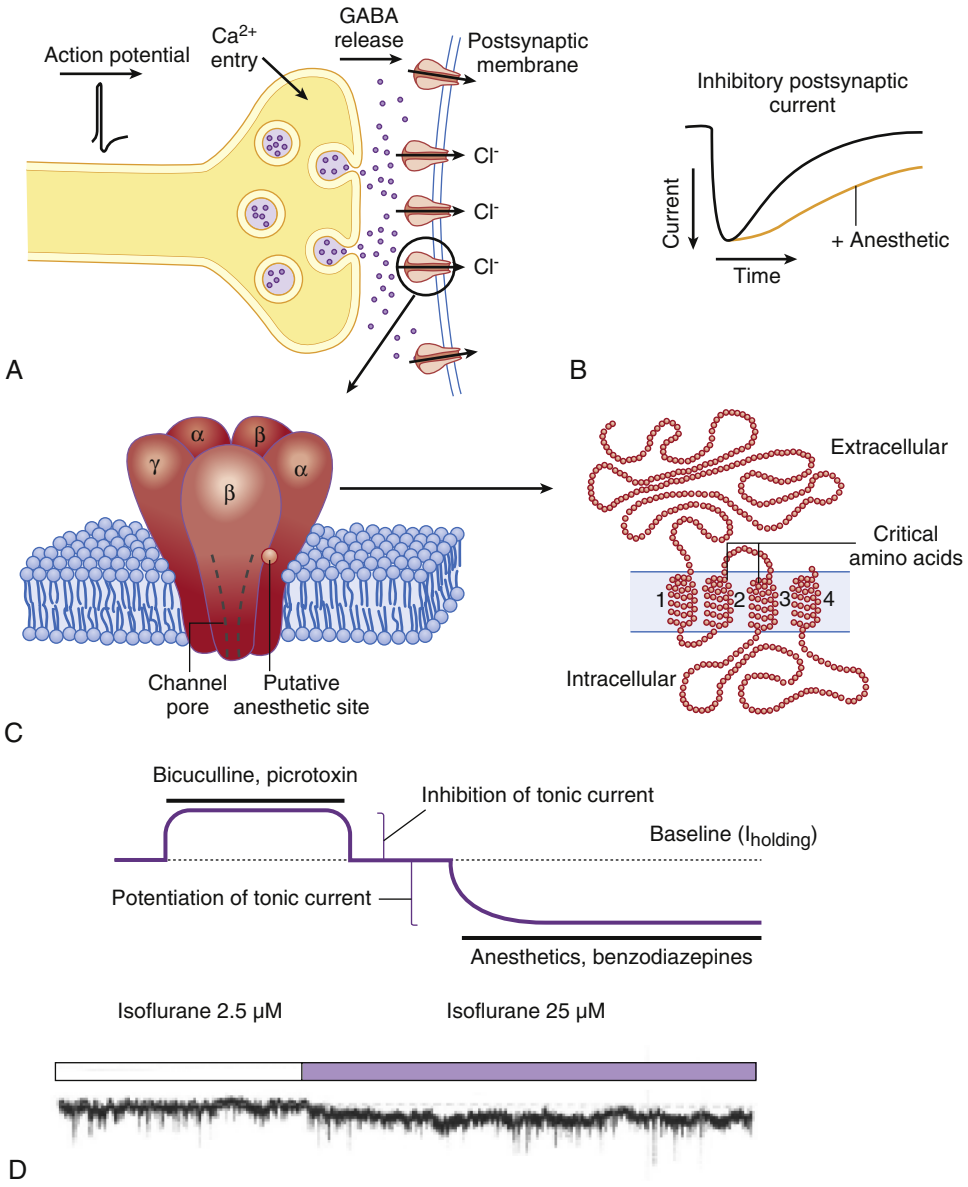

Figure 25-9. Synaptic and extrasynaptic $GABA_A$ receptors are targets for inhaled anesthetics. **A,** On binding of GABA (γ-aminobutyric acid) to the $GABA_A$ receptor, its chloride-permeable channel opens, leading to hyperpolarization. Volatile anesthetics have a relatively low potency but high efficacy at synaptic $GABA_A$ receptors and a high potency and low efficacy at extrasynaptic $GABA_A$ receptors. **B,** General anesthetics prolong channel opening and increase postsynaptic inhibition. The cartoon illustrates the prolongation of miniature inhibitory postsynaptic currents (mIPSCs) by the slowing of current decay. **C,** A pentameric $GABA_A$ receptor complex in the lipid bilayer membrane *(left),* with a blow-up of a single subunit showing the location of residues critical to anesthetic efficacy in the second and third transmembrane domains *(right).* **D,** A tonic inhibitory conductance is revealed by the application of a $GABA_A$ receptor antagonist (bicuculline or picrotoxin), as shown by the upward shift in the baseline current. Anesthetics and benzodiazepines increase the tonic conductance as indicated by the inward shift in the current. *(Modified from Hemmings HC Jr, Akabas MH, Goldstein PA, et al: Emerging molecular mechanisms of general anesthetic action,* Trends Pharmacol Sci *26:503-510, 2005.)*

determined by the relative magnitude and direction of both their presynaptic and postsynaptic effects.

Synaptic excitation is decreased by volatile anesthetics (Fig. 25-10). Experiments in various slice preparations indicate that reduced excitation is primarily caused by presynaptic mechanisms.[131,188,199-202] A postsynaptic mechanism is also involved because the response to directly applied glutamate is reduced to some degree.[202-204] Volatile anesthetics have inconsistent effects on cloned AMPA or NMDA glutamate receptors, but they potentiate kainite receptors,[117,205-207] which is consistent with a predominantly presynaptic mechanism for inhibition of glutamatergic synapses. By contrast, the effects of the nonhalogenated inhaled anesthetics (xenon, nitrous oxide, cyclopropane) appear to be mediated primarily by inhibition of postsynaptic NMDA receptors (discussed earlier). Augmentation of GABAergic inhibition by most general anesthetics is mediated by both presynaptic and postsynaptic mechanisms. Enhancement of postsynaptic and extrasynaptic $GABA_A$ receptors is well recognized.[118] Remarkably, however, volatile anesthetics also increase spontaneous GABA release and inhibitory postsynaptic current (IPSC) frequency[208-212]—that is, their presynaptic effects at GABAergic terminals are distinct from those at glutamatergic synapses.

The mechanisms for the presynaptic effects of inhaled anesthetics, like those for their postsynaptic effects, are complex and involve multiple targets. Although a synapse-specific contribution of presynaptic Ca^{2+} channels is likely, presynaptic Na^+ channels are more sensitive than the Ca^{2+} channels coupled to glutamate release. This is consistent with observations that the predominant Ca^{2+} channel coupled to neurotransmitter release at hippocampal glutamatergic synapses (P/Q-type) is insensitive to isoflurane.[149] Other presynaptic mechanisms have been proposed, including actions on the vesicle fusion process as demonstrated in the model organism *Caenorhabditis elegans*.[213,214] However, isoflurane effects on

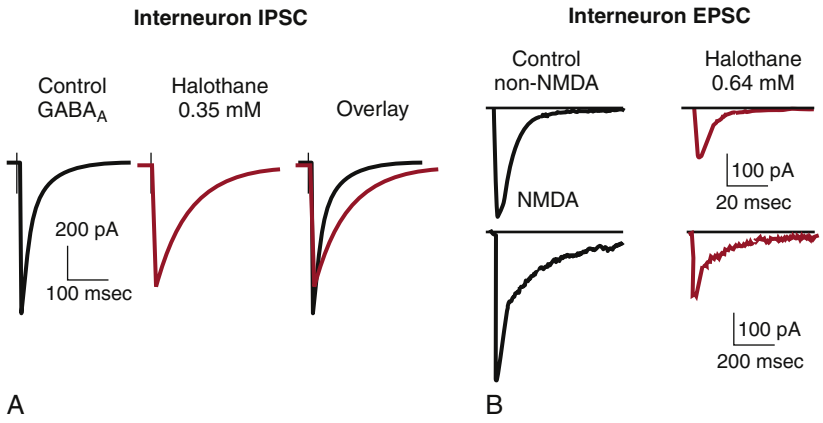

Figure 25-10. Halogenated anesthetics enhance inhibitory and depress excitatory synaptic transmission. Halothane slows the decay of $GABA_A$ receptor–mediated postsynaptic inhibitory currents (IPSCs) (**A**) and depresses the amplitude of glutamatergic excitatory postsynaptic currents (EPSCs) without affecting the decay (**B**) in hippocampal interneurons. (**A,** *Redrawn with permission from Nishikawa K, MacIver MB: Membrane and synaptic actions of halothane on rat hippocampal pyramidal neurons and inhibitory interneurons,* J Neurosci *20:5915-5923, 2000.* **B,** *Redrawn from Perouansky M, et al: Effects of halothane on glutamate receptor-mediated excitatory postsynaptic currents: a patch-clamp study in adult mouse hippocampal slices,* Anesthesiology *83:109-119, 1995.)*

exocytosis in rat hippocampal neurons occur primarily upstream of vesicle fusion.[137,215] (See review[117].)

The general effects of inhaled anesthetics are to increase inhibitory synaptic transmission and to inhibit excitatory synaptic transmission (Fig. 25-11). The relative importance of anesthetic effects on excitatory versus inhibitory synaptic transmission, and the mechanisms of these effects, is likely to differ for different anesthetics and for specific synapses and networks.[105,216] This concept extends to other putative targets and mechanisms and is incorporated in an "agent-specific multiple-site" hypothesis of anesthesia.[216,217]

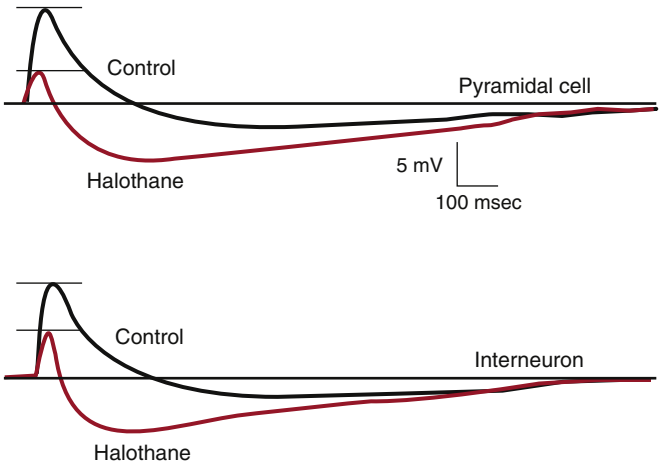

Figure 25-11. Anesthetics affect excitation and inhibition simultaneously in opposite directions. Halothane depresses the excitatory depolarization and augments the inhibitory hyperpolarization in both hippocampal pyramidal cells and interneurons. The net result will depend on the underlying neuronal state, the neuronal network, and its function. *(Redrawn form Nishikawa K, MacIver MB: Membrane and synaptic actions of halothane on rat hippocampal pyramidal neurons and inhibitory interneurons,* J Neurosci *20:5915-5923, 2000.)*

SIMPLE CIRCUITS AND COMPLEX NETWORKS

SIMPLE CIRCUIT PHENOMENA

The development of a mechanistic understanding of phenomena involving complex circuits has been greatly facilitated by the study of anatomically reduced (in vitro) or physiologically simplified (in vivo) preparations, complemented by computer simulations (in silico). These approaches are essential for integrating reductionist observations of the multiple molecular effects of anesthetics into functional models relevant to behavioral end points. Anesthetic effects have been studied in acute brain slice preparations from various regions of the CNS (hippocampus, amygdala, cortex, thalamus, brainstem, and spinal cord—most often from rodents). Brain slices preserve native connections but usually lack natural inputs and outputs. Slices from developing mammalian brain can be cultured in vitro. These "organotypic slice cultures" preserve a high degree of synaptic connectivity and display spontaneous network activity, typically absent from "acute slices." Simplified in vivo preparations involve phenomena (typically evoked responses) with *relatively* well-understood circuitry. Computer models and simulations can assist in generating hypotheses for experimental testing and developing hypotheses based on experimental data.

Synaptic Plasticity

Paired-pulse depression and paired-pulse facilitation are examples of short-term plasticity in response to external stimulation. Synaptic inhibition is prolonged by volatile anesthetics in vivo[218] and in vitro,[219] in general agreement with the notion that anesthetics enhance functional inhibition in the CNS. Enhancement of paired-pulse facilitation has been attributed to the presynaptic depressant effect of volatile agents (see Fig. 25-11).[131,201]

Long-term potentiation, a cellular model of learning and memory, consists of use-dependent strengthening of glutamatergic excitatory synaptic connections (see

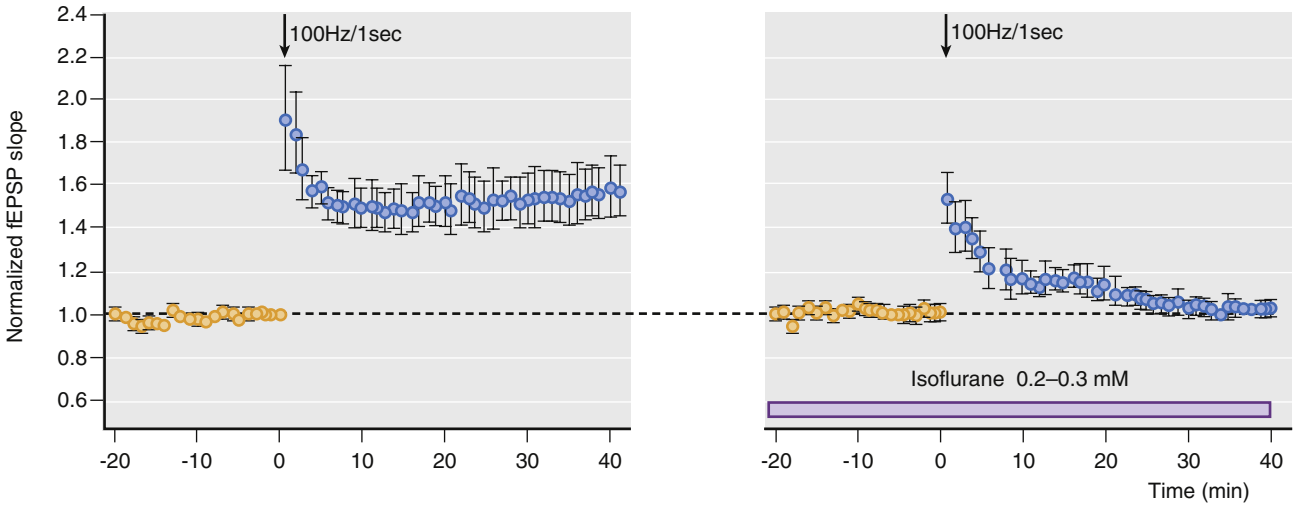

Figure 25-12. Isoflurane blocks the induction of synaptic plasticity in vitro (a model of learning and memory). Long-term potentiation (an increase in synaptic strength), indicated by the increase in normalized excitatory postsynaptic potential (EPSP) slope, in hippocampal slices evoked by tetanic stimulation of excitatory synapses, is blocked by 0.2 to 0.3 mM isoflurane. *(Redrawn from Simon W, et al: Isoflurane blocks synaptic plasticity in the mouse hippocampus,* Anesthesiology *94:1058-1065, 2001.)*

Chapter 13). Reported volatile anesthetic effects on LTP have been inconsistent: halothane, enflurane, and isoflurane do not block LTP induction in vivo, whereas ketamine does.[218] By contrast, isoflurane blocks LTP in the hippocampal slice by enhancing $GABA_A$ receptor–mediated inhibition (Fig. 25-12).[220] Long-term depression, a use-dependent weakening of excitatory connections that is effectively a homeostatic counterpart of LTP, is also blocked by isoflurane.[220] The discrepancy between these findings in vivo and in vitro remains unexplained.

Spontaneously Active Circuits

Spontaneous neuronal activity is decreased by volatile anesthetics both in vivo and in cortical brain slices. This effect is largely $GABA_A$ receptor dependent and marked even at low sedative concentrations.[76] Because the cortical brain slices lack subcortical input, these results suggest that volatile anesthetics can cause some effects (e.g., sedation) via direct cortical action. However, changes in raw neuronal firing rates do not provide a precise quantitative measure of higher cognitive function, which is better reflected by the relationship of firing patterns to strength and phase of cortical rhythms (see next section). Anesthetic effects have also been tested on the circuitry underlying locomotion, a well-studied central pattern generator. Effects of isoflurane on in vitro lamprey and rat spinal cord preparations support the spinal cord as the primary target for volatile anesthetic–induced immobility.[221,222]

RHYTHMS AND SIMULATIONS

The brain perpetually generates complex electrical rhythms (oscillations in extracellular field potentials) that range in frequency from fractions to hundreds of Hertz (Hz; cycles per second), as recorded on the surface of the scalp as the electroencephalogram (EEG; the higher frequency oscillations cannot be resolved in surface recordings). All oscillations are behavioral state dependent, and multiple oscillations coexist throughout the sleep-wake cycle. Lower frequency rhythms allow for integration over longer time periods and typically engage larger areas of the brain. By contrast, higher frequency rhythms allow for higher temporal resolution on local scales. Cross-frequency modulation allows for integration of both aspects of information processing. Although their physiologic roles are not clear, brain rhythms reflect, subserve, and/or constitute fundamental higher-order processing, such that their modulation by anesthetics is of great interest. The current nomenclature of brain rhythms reflects historical conventions and is not based on underlying mechanisms.

δ-Rhythms and Other Slow Rhythms

Oscillations with EEG frequencies from 1.5 to 4 Hz are generally referred to as δ-rhythms. Slower frequency rhythms are termed Slow-1 to Slow-4, with the higher numbers referring to slower rhythms.[223] Slow rhythms are prominent during non–rapid eye movement sleep (i.e., slow-wave sleep) and appear at loss of consciousness induced by propofol.[224] δ-Frequency rhythms are commonly observed under general anesthesia. During natural slow-wave sleep (SWS), δ-rhythms and sleep spindles are phase related to a slower oscillation, suggesting functional interaction.[225] Paroxysmal spindlelike waxing and waning oscillations overriding slower rhythms are also present in the cortical EEG under anesthesia, but the underlying physiology and functional significance are unknown.

θ-Rhythms

θ-Rhythms, present in various cortical structures but most prominent in the hippocampus, are thought to signal the "online state." They are associated with sensorimotor and mnemonic functions during waking behavior.[226] One component of the θ-rhythm (type I or atropine resistant) can be affected by amnestic concentrations of isoflurane as well as by the amnestic nonimmobilizer F6,[63] indicating a potential network-level signature effect for

anesthetic-induced amnesia. Type II θ-rhythm (atropine sensitive) can be evoked under anesthesia and is slowed and potentiated by halothane.[227]

γ-Rhythms

This designation includes an extremely broad and probably functionally and mechanistically heterogeneous spectrum of rhythms. It is frequently subdivided into slow γ (30 to 50 Hz; i.e., the spectrum above β-rhythms); γ (50 to 90 Hz), and fast-, ultra-γ, or ε-rhythms (>90 and up to hundreds of Hz).[224] Fast $GABA_A$-ergic synaptic inhibition and intrinsic resonant properties of neurons play important roles in γ-physiology, making these obvious candidates for anesthetic modulation. Isoflurane slows the frequency of evoked γ-oscillations (30 to 90 Hz, also known as "40- Hz rhythms") in humans.[228,229] Studies of γ-oscillations in vitro suggest that their frequency depends on the time constant of decay of $GABA_A$ receptor–mediated synaptic currents in inhibitory networks.[230] Isoflurane slows γ-rhythms in hippocampal[231] and neocortical slices[232] to a comparable degree as it does in humans,[229] providing a tentative link between receptor and circuit-level effects. However, the interaction between anesthetics and behaviorally relevant network effects is likely to be complex because flash-evoked γ-oscillations in the primary visual cortex are not affected by inhaled agents,[54] whereas feedback information transfer at γ-frequencies between the visual and frontal cortices is disrupted.[53,54] Moreover, brain rhythms are interlinked (e.g., θ-rhythms modulate γ-oscillations (θ–γ nesting). The nature of their modulation by anesthetics as well as relevance is far from clear.

Models and Simulations

On the atomic scale, modeling the interaction of anesthetic molecules with targets and model proteins has defined binding motifs that characterize the amphiphilic binding cavities for anesthetic molecules (see "Identification of Molecular Sites of Anesthetic Action," discussed earlier).[115] Modeling anesthetic interaction with firefly luciferase suggests that anesthetics act by disrupting the modes of motion essential for protein function.[233]

On the macroscopic scale, computer simulations can provide an integrated picture of modulation of dynamic neuronal and network activity. "Bottom-up" neuron-by-neuron approaches are based on computational models of individual neurons, known *anesthetic effects* on intrinsic and synaptic membrane conductances, and simple network models. Computer simulations of anesthetic effects on integrated outputs can thereby be generated (e.g., the firing of pacemaker neurons).[234] These models obviously rely on the accuracy of the derived characteristics of real neurons and networks as well as knowledge of the effects of anesthetics; the scale of simulations is limited by the complexity of its elements.[235] An alternative is a "top-down" approach, such as mean-field modeling, in which molecular and cellular individual accuracy detail is sacrificed in favor of global dynamics. Global cortical phenomena, such as anesthetic-induced seizures,[236] are modeled as phase transitions based on mean interactions between populations of averaged neurons (analogous to the EEG signal that also averages the signals of neuronal populations). This approach can be extended to other global cortical phenomena such as consciousness.[237] Neuronal modeling and computer simulations will likely gain importance in the future as bridges between theoretical and experimental studies of anesthesia.

RESEARCH STRATEGIES FOR THE FUTURE

The search for anesthetic mechanisms is driven by advances in the basic sciences. Some strategies that should facilitate understanding of anesthetic mechanisms include use of agonists or antagonists in vivo, nonanesthetics or nonimmobilizers, transgenic animals, and high-resolution imaging of the functioning brain.

PHARMACOLOGIC APPROACHES

Agonists, Antagonists, and Experimental Anesthetics

Use of receptor-specific agonists and antagonists provides a pharmacologic method for bridging in vitro with in vivo studies. In this approach, a receptor may be tested for its contribution to a specific end point (e.g., immobility) according to the criteria presented earlier. This approach was used to exclude an important role for NMDA receptor block in the immobilizing action of volatile anesthetics but did not yield conclusive results for the roles of $GABA_A$ and GlyR for immobilization,[238,239] probably owing to the intricacies of drug-receptor interactions on different levels of integration in complex networks like the spinal cord. A complementary pharmacologic approach using experimental anesthetics that inhibit NMDA receptors in vitro with different potencies supports the conclusion that NMDA receptor blockade does not contribute significantly to immobility by conventional volatile anesthetics.[240] Refinement of this strategy involves the anatomically discrete application of drugs to nuclei with known function. For example, the tuberomammillary nucleus (part of the endogenous sleep pathway) mediates the sedative component of anesthesia for some intravenous anesthetics (e.g., propofol).[23] A discrete site of general anesthetic action for GABAergic drugs in the mesopontine tegmentum has also been proposed based on this strategy.[22,241]

Nonimmobilizers

Nonimmobilizers are compounds with physicochemical characteristics similar to those of conventional inhaled anesthetics, but their predicted anesthetizing concentrations (based on their lipid solubility and the Meyer-Overton correlation [MAC_{pred}]) do not induce immobility.[11] Initially termed *nonanesthetics,* the terminology was revised when it was discovered that at least some of them cause amnesia at similar MAC_{pred} fractions as classic volatile anesthetics.[67] If a molecular or cellular process is affected in similar ways by an anesthetic and a nonimmobilizer, that process is not relevant for the anesthetic state, with the notable exception of amnesia. Despite this elegant rationale, only a limited number of receptors have been excluded because, compared with volatile anesthetics, nonimmobilizers are relatively

target selective. These compounds have the potential to provide insights beyond the initially envisaged receptor-level studies by allowing the separation of sedation from amnesia for the study of underlying network activity in vivo.[63]

Photoreactive Anesthetics

Recently, azi-isoflurane, a photoreactive analogue of isoflurane, was synthesized. This agent has similar (although not identical) physicochemical properties as isoflurane. When irradiated at a wavelength of 300 nm, azi-isoflurane reacts with amino acid residues surrounding putative isoflurane-binding sites. Use of azi-isoflurane and similar agents could help identify binding sites of inhaled agents on anesthesia-relevant molecular targets.[242]

GENETIC APPROACHES

Genetic strategies take two forms: forward and reverse.[243] The reverse genetic approach focuses on a particular gene, chosen because there are reasons to hypothesize that its product may be important to anesthesia. Examples of this strategy are targeted mutations that alter the sensitivity of specific neurotransmitter receptors to anesthetics.[121] Initially, these mutations were used to identify anesthetic binding sites. Subsequently, transgenic animals rendered resistant to anesthetics, either by deletion of a putative target protein from the genome or by expressing a target receptor engineered to be insensitive to an anesthetic, were used to test behavioral relevance of the altered gene product for the production of anesthesia. Forward genetics, by contrast, is a discovery process that involves the study of randomly generated mutations (either experimentally induced or naturally occurring polymorphisms) in a population that affect the phenotype of interest (i.e., anesthetic end points).

Knockout and Knock-in Animals

In the knockout approach, expression of the gene encoding a protein of interest is disrupted by a specific deletion or insertion. Nearly all such studies have been carried out in mice. A well-recognized problem with the global knockout approach is that extensive compensatory changes can be induced, from anomalies that are lethal in utero to insidious (but experimentally confounding) influences that might be expressed only at maturity. A complementary strategy is the conditional knockout, in which the genetic deletion is restricted—either anatomically (limited to certain brain regions) or temporally (at a known point in time). These strategies can minimize developmental anomalies and reduce the likelihood of compensatory changes. In the knock-in approach, a mutation, usually of a single amino acid residue, is targeted to produce a protein with altered sensitivity to a drug of interest. Ideally, this mutation remains completely silent in the absence of the drug—that is, it does not perturb the normal expression and function of the protein of interest or alter the expression of other genes.

$GABA_A$ Receptors. Results from transgenic animals illustrate both the utility and the difficulties of the genetic approach with respect to inhaled agents. The conditional forebrain-restricted $GABA_A$ receptor α_1-subunit knockout mouse was found to be less sensitive to isoflurane-induced amnesia than wild-type mice, and this led to the conclusion that action at these receptors contributes to its amnesic effects.[244] By contrast, a mouse harboring a mutation of the $GABA_A$ receptor α_1-subunit that renders the receptor insensitive to isoflurane in vitro did not show reduced sensitivity to either the amnesic or the immobilizing effects of isoflurane, leading to the conclusion that this subunit does not mediate the impairment of learning and memory by isoflurane.[31] Similar experiments indicate that action at the $GABA_A$ receptor β_3-subunit does not mediate immobility or amnesia by isoflurane.[30] This "bottom-up" genetic approach is a work-intensive but powerful tool that has yielded clear results with the receptor-specific intravenous anesthetics,[16] but it has proved more challenging to apply it to the more promiscuous inhaled agents.

Glycine α_1–Containing Receptors. Pharmacologic studies supported the notion that glycinergic neurotransmission might be the effector for the immobilizing action of inhaled anesthetics in the spinal cord, where glycine replaces GABA as the principal inhibitory transmitter. However, mice harboring mutations that render α_1 subunit–containing glycine receptors largely insensitive to alcohol and inhaled ether anesthetics did not demonstrate a concordant change in MAC values. Because α_1 is the most widely expressed subunit in adult animals, it is unlikely that action at glycine receptors plays an important part in the immobilizing action of inhaled agents.[245]

Two-Pore Domain K Channels. Use of mice harboring knockout mutations of several two-pore domain K^+ channel (K_{2P}) family members (TASK-1, TASK-3, TREK-1) has demonstrated a role for these channels in volatile anesthesia.[32-34] For example, TREK-1 knockout mice are partially resistant to all volatile anesthetics tested with respect to both loss of righting reflex (a measure of consciousness) and immobility, but anesthesia can still be induced, albeit at higher anesthetic concentrations. Interestingly, responses to pentobarbital are unaffected, indicating that the mutation does not cause a generalized resistance to anesthesia.

FORWARD AND POPULATION GENETICS

The nematode *Caenorhabditis elegans* and the fruit fly *Drosophila melanogaster*, with 302 and 100,000 neurons, respectively, have also been used as model organisms in anesthesia research. Mutations in a number of *C. elegans* genes affect sensitivity to volatile anesthetics, such as *unc*[64,214] *stomatin*,[246] and *gas1*. Mutation of the latter gene confers hypersensitivity to enflurane. This gene encodes the worm homologue of a subunit of NADH hydrogenase expressed in neurons.[247] Yeasts have also been used as model organisms, with even more obvious limitations with respect to identification of appropriate anesthetic end points.

Sensitivity to anesthetics is a quantitative trait (varying continuously in a population). Quantitative genetics is the study of the heritability of continuous traits. These

traits are controlled by genes represented in quantitative trait loci (QTLs). A top-down population-based approach has been used to localize QTLs that govern susceptibility of individuals to anesthetics, in higher and lower organisms. Starting from the observation that inbred mouse strains vary in their sensitivity to isoflurane, microsatellite-based linkage analysis and, alternatively, single-nucleotide polymorphism–based analysis of genetic variation localized a QTL for isoflurane immobilization to the proximal part of mouse chromosome 7.248 This type of analysis promises to assist in defining the genetic basis for variability in the susceptibility to both primary anesthetic end points and side effects.

HIGH-DENSITY EEG AND FUNCTIONAL IMAGING

Identification of the anatomic and functional substrates for anesthetic effects on consciousness, memory, and immobility is now approachable with improved imaging techniques. Imaging is based on mapping of either metabolic or hemodynamic changes as surrogate measures of neuronal activity, as in positron emission tomography (PET) and functional magnetic resonance imaging, or on mapping electrical activity with high-density EEG, magnetoencephalography, and low-resolution brain electromagnetic tomography (see also Chapters 15, 17, and 49). Properties of receptors can also be probed with radioactive ligands (PET). These techniques have the capacity to identify neuroanatomic substrates of drug action, with method-specific limitations. Results from functional PET imaging suggest that propofol suppresses episodic memory by targeting the prefrontal and posterior parietal cortex as opposed to the medial temporal lobe,[249] and that suppression of consciousness is caused by anesthetic action in the thalamus, parts of the medial and posterior parietal cortex, and/or the posterior cingulate and medial parietal cortex.[250] Although observations of regionally specific and global suppressive effects of anesthetics on metabolic activity are unlikely to provide a definitive mechanistic understanding, such information can facilitate hypotheses and experimentally testable predictions.

Advanced analytical approaches based on theories from mathematical and statistical sciences are being increasingly applied to enhance the power of existing technologies. Magnetic resonance images and high-density EEG recordings of the brain reveal strong interregional connections, but the considerable potential of this connectivity information to better understand the brain's response to anesthesia has only recently begun to be tapped. The growing use of invasive recording techniques (e.g., brain surface electrode grids and microelectrodes implanted deep into the brain for functional neurosurgical therapies) is also advancing the frontiers of neuroscience in general and the understanding of anesthetic mechanisms in particular.

SUMMARY

The mechanisms of inhaled anesthetics have proved more difficult to explain than was envisaged a generation ago, when the paradigm shifted from lipids to amphiphilic cavities in proteins as targets for anesthetics. Despite a remarkable accumulation of information, a comprehensive theory of general anesthetic action has yet to be formulated. Progress toward this goal has been difficult for several reasons. Important pharmacologic characteristics of inhaled anesthetics that have impeded identification of their relevant molecular targets are their low potency (millimolar), promiscuous activity at multiple targets, lack of specific antagonists, and limitations in the neuroscience of memory and consciousness. This contrasts with the situation for intravenous anesthetics that exhibit more conventional receptor pharmacology. Moreover, accumulating evidence indicates that no universal target exists to explain the actions of every general anesthetic, or even of a single anesthetic agent. It is now clear that the composite state of anesthesia and its core components (amnesia, sedation/unconsciousness, immobility) are separable behavioral states in vivo that have limited reproducibility in vitro. Resolution of these phenomena at the molecular and cellular levels represents the cutting edge of contemporary neuroscience. Of the multiple molecular and cellular anesthetic effects identified, it is unclear which are critical for the desired behavioral end points, which are harmless or beneficial side effects (e.g., preconditioning), and which, if any, could have long-lasting or delayed undesirable consequences (e.g., cell death, cognitive dysfunction). Progress in identifying the molecular targets of general anesthetics provides a foundation for identification of the network and systems level effects relevant to their behavioral and peripheral end points. As the biologic foundations of behaviors once thought to be exclusively the realm of psychology are unraveled, for which anesthetics provide a valuable investigative tool, a comprehensive theory of anesthesia will also develop.

Chapter 26

Inhaled Anesthetic Pharmacokinetics: Uptake, Distribution, Metabolism, and Toxicity

STUART A. FORMAN • YUMI ISHIZAWA

Acknowledgment: The editors and publisher would like to thank Dr. Edmond I. Eger II for contributing a chapter on this topic to the prior edition of this work. It has served as the foundation for the current chapter.

Key Points

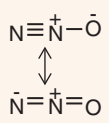
- The alveolar inhaled anesthetic concentration (F_A) or partial pressure (P_{alv}) is important, because it is the driving force determining anesthetic uptake into blood and target tissues in the central nervous system and it can be monitored as a readout of anesthetic dosage. P_{alv} is influenced by both delivery and uptake of anesthetic gas.
- Inhaled anesthetic delivery to patients can be augmented by increased fresh gas flows, vaporizer output settings, and minute ventilation.
- Initial anesthetic uptake into blood increases with increased pulmonary blood flow (cardiac output) and high blood solubility of anesthetic gas. Increased uptake (as with a highly blood-soluble drug or high cardiac output) slows the rate by which anesthesia is induced by slowing the rate of rise of P_{alv}. Conversely, low anesthetic solubility in blood is associated with rapid onset and offset of anesthesia.
- Uptake of anesthetic into blood slows as blood and tissue partial pressures increase, resulting in higher anesthetic partial pressure in mixed venous blood.
- The higher the inspired anesthetic concentration, the less it then diminishes because of uptake (the concentration effect). At 100% inspired concentration, uptake does not cause P_{alv} to change. Changes in alveolar volume result in a rapid initial uptake of N_2O, which sustains or increases concentrations of other alveolar gases (the second gas effect).
- Factors that affect anesthetic uptake similarly affect pulmonary clearance of anesthetics. The rate of clearance is also context sensitive; that is, equivalent decreases in alveolar and brain anesthetic concentrations are slower after a long exposure to inhaled anesthetics compared with a short period of exposure of equal depth.
- Toxicities of inhaled anesthetics are primarily related to their biotransformation (metabolism). Significant toxic effects are usually produced in the tissues, such as liver and kidney, in which metabolism occurs. Modern inhaled anesthetics undergo less metabolism than older drugs do, resulting in fewer toxicities.
- Halothane hepatitis is a potentially fatal syndrome of fulminant liver damage after exposure to reactive metabolites produced by oxidation of volatile anesthetics. These metabolites covalently modify liver proteins, creating neohaptens that elicit an immune response against hepatocytes. The incidence of the syndrome varies with different anesthetics, paralleling the extent of drug metabolism: halothane >> enflurane > isoflurane > desflurane.
- Defluorination of inhaled anesthetics occurs in both the liver and kidney. Free fluoride in blood can damage kidneys, resulting in high-output renal failure. Renal toxicity is almost exclusively associated with prolonged exposure to methoxyflurane. Sevoflurane metabolism also results in high fluoride levels in blood, but it does not damage kidneys. Factors that enhance the toxicity of methoxyflurane relative to sevoflurane include its high tissue solubility, slow clearance, and high degree of renal metabolism, resulting in high intrarenal fluoride levels for an extended time.

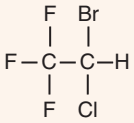
KEY POINTS—cont'd

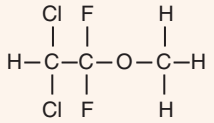
- Anesthetics react with strong bases, particularly potassium hydroxide (KOH), in carbon dioxide (CO_2) absorbents, resulting in production of several potentially toxic substances. Sevoflurane degrades to form compound A, which is associated with renal damage in rodents, but not in humans. This differential toxicity is associated with differential renal metabolism in rodents versus humans. Dry CO_2 absorbents in the anesthetic machine (see Chapter 29) react with inhaled anesthetics, releasing carbon monoxide and heat. New CO_2 absorbent materials that lack strong base chemicals prevent these reactions and subsequent potential harm to patients.
- Nitrous oxide (N_2O) is unique among anesthetics in its ability to inhibit methionine synthase oxidation by oxidizing a cofactor, vitamin B_{12}. In certain susceptible patients and in patients receiving many anesthetics that include N_2O, methionine synthase inhibition can lead to hematologic and neurologic dysfunction. After prolonged N_2O exposure, methionine synthase inhibition also increases blood homocysteine, which can increase vascular inflammation and the risk of thrombosis. Definitive clinical trials assessing the effects of N_2O on morbidity in vasculopathic patients are lacking.
- Inhaled anesthetics, when scavenged and ejected into the atmosphere, contribute to both global warming and ozone depletion. The environmental impact of anesthetics can be lessened by reducing waste through the routine use of low fresh gas flows or with the use of new technologies that trap scavenged anesthetic gases. Reprocessing and reusing trapped anesthetic gases further reduces the environmental impact of drug production.
- In experimental models of the developing brain, including nonhuman primates, general anesthetics produce signs of neurotoxicity that are associated with later neurocognitive deficits. Results from clinical cohort studies in children within the United States and Europe remain inconclusive about an association between early anesthetic exposures and learning or behavioral problems later in life (see Chapter 93). Regarding long-term effects of anesthesia and surgery on the adult brain, see Chapter 99.

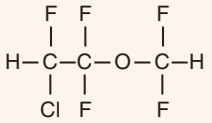
INTRODUCTION

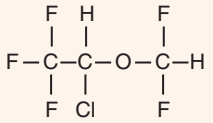
Modern inhaled anesthetics are important pharmacologic tools for reversibly altering central nervous system functions in patients. Because inhaled anesthetics are both taken up and eliminated through alveolar blood–gas exchange, drug dosage can be monitored in expired alveolar gases, and tissue-dependent metabolism is unnecessary for drug clearance. Optimal delivery of systemic drugs via inhalation requires a full understanding of the factors influencing how gas-phase compounds move into and out of various body tissues and how they are metabolized (pharmacokinetics) together with where and how these drugs and their metabolism affect tissue functions. Reversible anesthetic effects on the nervous, respiratory, and cardiovascular systems (pharmacodynamics) are covered elsewhere in this textbook (see Chapters 25, 27, and 28).

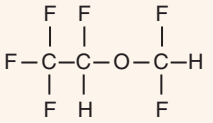


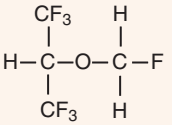












UPTAKE AND DISTRIBUTION OF INHALED ANESTHETICS

In the first part of this chapter, some of the basic concepts of chemical equilibria are reviewed and are applied to illuminate major factors influencing inhaled anesthetic uptake and distribution in patients. For this review, a physiologic model is used that closely simulates clinical observations. The model, an elaboration of that introduced in 1973 by Mapleson,[1] is described both qualitatively and quantitatively (using mathematical expressions) to convey important concepts to readers with different learning styles.

BIOPHYSICAL PROPERTIES OF INHALED ANESTHETICS: PARTIAL PRESSURE, HYDROPHOBICITY AND PARTITION COEFFICIENTS

Inhaled anesthetics are administered as a component of a gas mixture. The biophysical properties of inhaled anesthetics are summarized in Table 26-1. *Partial pressure* is the portion of total pressure contributed by one component of a gas mixture, where each component contributes pressure in direct proportion to its molar fraction. For example, 1.5% isoflurane in air (21% O_2 and 79% N_2) at 1 atm (760 mm Hg) is a mixture of O_2 at 157.2 mm Hg, N_2 at 591.4 mm Hg, and isoflurane at 11.4 mm Hg. The partial pressure of an anesthetic gas is a measure of thermodynamic activity of the gas and determines its pharmacologic effect. The partial pressure of an anesthetic is usually reported as the percentage (or fraction)

TABLE 26-1 **CHEMICAL STRUCTURES AND PROPERTIES OF INHALED ANESTHETICS***

Anesthetic	Nitrous Oxide	Halothane	Methoxyflurane	Enflurane	Isoflurane	Desflurane	Sevoflurane
Year introduced into clinic	1840s	1956	1960	1966	1969	1990	1981
Chemical structure							
Molecular weight	44.0	197.4	165.0	184.5	184.5	168	200.1
Boiling point (° C)	–88.5	50.2	104.8	56.5	48.5	22.8	58.6
Density (g/mL)	1.84×10^{-3}	1.86	1.42	1.52	1.5	1.45	1.50
Vapor pressure (mm Hg)	43,880	243	22.5	175	238	664	157
Oil/gas partition coefficient at 37° C	1.3	197	950	98.5	90.8	19	47-54
Blood/gas partition coefficient at 37° C	0.47	2.5	12	1.9	1.4	0.45	0.65
MAC-immobility (% atm/mm Hg)†	104/800	0.75/5.7	0.2/1.52	1.58/12.0	1.28/9.7	6.0/45.6	2.05/15.6
MAC-awake†	71/540	0.41/3.21	0.081/0.62	0.51/3.88	0.43/3.27	2.4/19	0.63/4.79

Partition coefficients are from References 2-6.
MAC-immobility and MAC-awake values are from References 2, 8-11, 38.
*Properties are measured at standard temperature (20° C) and pressure (1 atm) unless otherwise specified.
†MAC is minimum alveolar concentration for subjects approximately age 40 years.

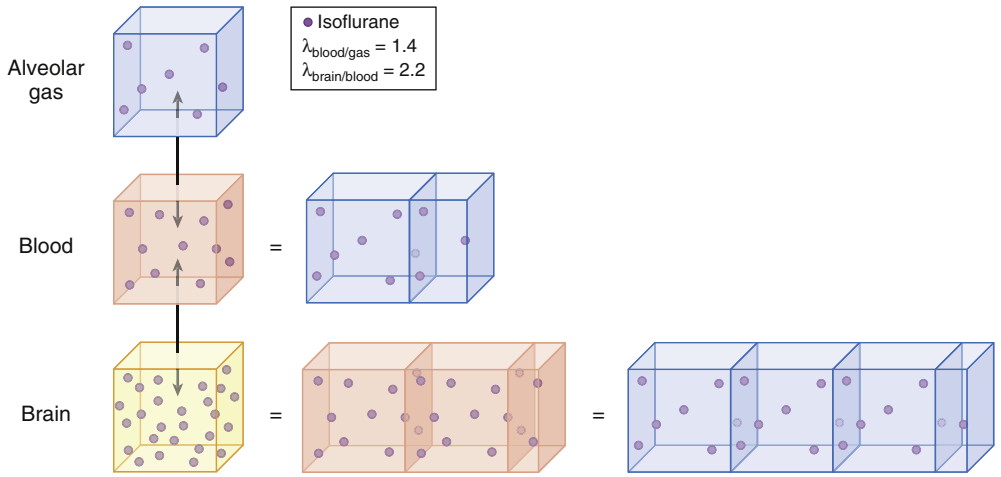


Figure 26-1. Partitioning of anesthetic gases between different biophases. *Left,* Depicts the partitioning of isoflurane between gas phase *(blue)*, blood *(red)*, and brain *(yellow)*. The blood/gas partition coefficient ($\lambda_{b/g}$) for isoflurane is 1.4. The brain/blood partition coefficient ($\lambda_{CNS/blood}$) is 2.2 (see Table 26-2). At equilibrium, defined as equal isoflurane partial pressure in all compartments, a volume of blood contains 1.4-fold the quantity of isoflurane as the same volume of alveolar gas, whereas a volume of brain tissue contains 2.2-fold the quantity of isoflurane as the same volume of blood. *Right,* We also Depicts partition coefficients as effective (equivalent) volumes of another biophase. For example, one volume of blood contains the same amount of isoflurane as 1.4 volumes of alveolar gas, whereas 1 volume of brain contains the same amount of isoflurane as 2.2 volumes of blood or 3.1 volumes of gas.

of the delivered gas mixture, where atmospheric pressure is near 1 atm (760 mm Hg). Correcting these values to absolute partial pressure is important under conditions when local atmospheric pressure differs significantly from standard, such as at high altitude, underwater, or in a hyperbaric chamber. The same inhaled concentration of an anesthetic gas results in a reduced pharmacologic effect at higher altitudes because the partial pressure of the anesthetic is lower. Because partial pressure is the thermodynamic force for gas movement in a system, anesthetics move from regions of high partial pressure to low partial pressure, unaffected by the other components of the gas mixture, and equilibrium is achieved when the partial pressure of an anesthetic is equal in the different compartments.

The maximal partial pressure of a volatile compound is its *vapor pressure*; this is the partial pressure of volatile anesthetic within the drug reservoir of a vaporizer. Vapor pressure is unique to each anesthetic and increases with increasing temperature. Volatile anesthetics are defined by a vapor pressure less than 1 atm at 20° C and a boiling point above 20° C (see Table 26-1). Gaseous anesthetics are defined by a vapor pressure greater than 1 atm at 20° C and a boiling point below 20° C (see Table 26-1). Volatile anesthetics typically account for a small fraction of the gas mixture delivered to patients. In contrast, gaseous anesthetics such as nitrous oxide (N_2O) and xenon, because of their relative lack of potency, typically compose a large fraction of an inhaled gas mixture and thus produce additional effects (e.g., concentration effect, second gas effect, and airspace expansion) that are negligible with potent volatile anesthetics.

Hydrophobicity is a molecular property of certain chemicals, including most general anesthetics that do not readily form hydrogen bonds and therefore display low water solubility. Hydrophobic compounds are also usually lipophilic, demonstrating high solubility in low polarity solvents such as oils. Common measures of hydrophobicity are *partition coefficients* between water and olive oil (which is mostly oleic acid, an 18-carbon fatty acid) or between water and *n*-octanol. Usually represented by the Greek letter lambda (λ), a partition coefficient is the ratio of two solute concentrations at equilibrium (i.e., at equal partial pressure) in two separate but adjacent solvents or compartments such that the solute moves freely between the compartments (Fig. 26-1). Another useful way to conceptualize a partition coefficient is that it represents the relative volume of two compartments that contain equal concentrations of the solute at equilibrium (see Fig. 26-1).

Anesthetic partition coefficients between blood and gas ($\lambda_{b/g}$) and between tissue and blood ($\lambda_{t/b}$) are important factors in uptake and distribution of inhaled anesthetics as they move from pulmonary airspace to pulmonary blood, then from blood to various tissues (Table 26-2). Blood solubility of anesthetic gases (and other gases such as O_2, N_2, and CO_2) increases as temperature decreases.[16,17] Because most anesthetics are hydrophobic, they tend to display high solubility in tissues with high lipid content (e.g., fat), and they bind to many proteins that form hydrophobic or amphiphilic pockets.[12] Anesthetic partitioning into blood (blood solubility) increases after ingestion of fatty foods[18] and may decrease in anemic or malnourished patients. Methoxyflurane (no longer in clinical use) and halothane are notable for high blood solubility. N_2O, sevoflurane, and desflurane are characterized by low blood solubility.

ANESTHETIC DELIVERY, UPTAKE, AND DISTRIBUTION: A MULTICOMPARTMENTAL MODEL

Delivering an inhaled anesthetic drug to patients is analogous to an intravenous drug infusion with two obvious

*Based on a 70-kg patient at rest. Blood and tissue partition coefficients are from References 6, 12-14. Tissue volumes and blood flow values are approximate (Levitt,[12] Kennedy and colleagues[15]). Effective volumes are calculated as Tissue volume × λTissue / Blood, and exchange time constant (τ) for each compartment is V_{eff} / Blood flow.

CNS, Central nervous system; *VRG,* vessel-rich group.

major differences: (1) entry of drug into the body is via transalveolar exchange from gas to blood and (2) clearance is mostly via the same route. Thus, inhaled anesthetic delivery is dependent on pulmonary ventilation, whereas uptake and clearance of inhaled anesthetics are dependent on pulmonary perfusion.

Upstream and Downstream Compartments and Anesthetic Transfer: Bulk Flow and Pressure Gradients

Uptake and distribution of inhaled anesthetic can be readily understood as a series of transfer steps from upstream compartments with high partial pressure to downstream compartments with low partial pressure as depicted in Figure 26-2. First, the drug is transferred from an anesthesia delivery device, typically an anesthesia machine with a vaporizer designed to deliver specified concentrations (in percent atm) of volatile anesthetic, into a fresh gas mixture flowing in a breathing circuit. Second, ventilation transfers gases from the circuit to the alveolar airspace in the lung. Third, the anesthetic moves by transcapillary diffusion into pulmonary venous blood. Fourth, arterial blood distributes the anesthetic to various tissues including the primary target tissue, the central nervous system (CNS). Fifth, venous outflow from tissues converges in the pulmonary artery, and sixth, the mixed venous blood passes through alveolar capillaries where it again equilibrates with alveolar gases.

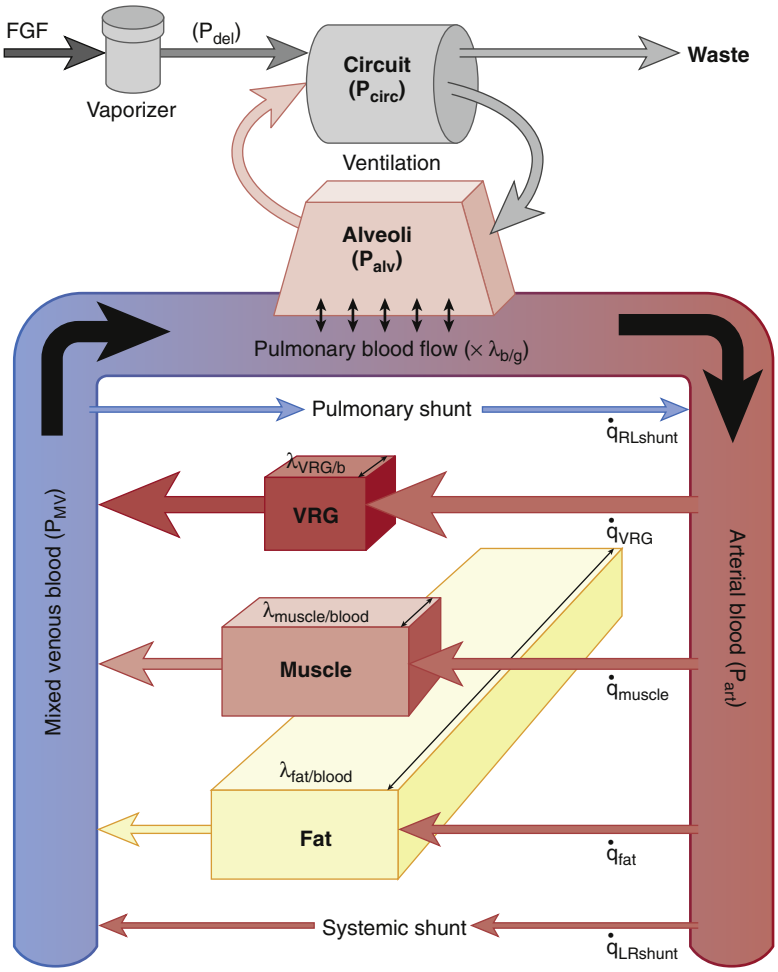

Figure 26-2. Flow diagram for uptake and distribution of inhaled anesthetics. Major compartments for anesthetic flow are depicted, including the breathing circuit, alveolar gas space, and three major tissue compartments: vessel-rich group (VRG), muscle, and fat. The physiologic volumes of the tissue compartments are approximately in proportion to the labeled face of the compartment, while the blood-tissue partition coefficients are depicted as the depth of the compartment. Thus, the effective volume of the VRG is much smaller than that of muscle, which in turn is much smaller than that of fat. Carrier flows and exchange in different parts of the model are depicted by arrows. Fresh gas flow (FGF) moves anesthetic from the vaporizer to the circuit; ventilation drives exchange of anesthetic between the circuit and alveoli; pulmonary blood flow transfers anesthetic from alveoli into the circulation, which then distributes drug to different compartments depending on blood flow to various tissues. Relative blood flow is approximately proportional to the width of the arrows into and out of tissue compartments, as well as for shunts. The diagram depicts an early phase of anesthetic uptake when organs of the VRG, including the brain, are approaching equilibrium with alveolar and arterial anesthetic partial pressure, while anesthetic partial pressures in muscle and fat remain relatively low. Quantitative modeling of anesthetic gas movement in this system was performed using numerical integration of equations describing anesthetic flow into and out of each compartment (Equations 5, 8, 9, 10, and 11). Figures 26-4, 26-5, 26-6, 26-7, 26-9, 26-10, and 26-12 were all generated using this model. Standardized parameters used in the model are summarized in Table 26-2. P_{circ}, Partial pressure in the circuit; P_{del}, delivered anesthetic partial pressure.

Gas flow from the machine into the breathing circuit is unidirectional. Blood circulation is also largely unidirectional. In transfers from machine (the fresh gas outlet) to breathing circuit and then to alveolar airspace, anesthetic flow can simply be understood as an exchange from upstream compartments into downstream gas phase compartments. In later steps, such as exchange between alveolar gases and pulmonary capillary blood, the flow of anesthetic molecules occurs via diffusion between adjacent compartments separated by a permeable membrane. For simplicity, we have not treated blood as a separate compartment in our model. Distribution of anesthetic to and from various tissues involves both bulk transfer via blood flow and diffusive equilibration across capillary membranes. Note that when anesthetic transfer occurs between gas and blood or between blood and tissue, the effective volume of the downstream compartment must be adjusted with the appropriate partition coefficient (see Table 26-2).

Rate of Wash-in of the Circuit: Equilibration between Vaporizer and Circuit

Equipment for controlled delivery of inhaled anesthetic drugs is described in Chapter 29. Wash-in of the ventilator breathing circuit represents an example of bulk transfer exchange, wherein the gas in the circuit components is replaced by fresh gases emerging from the gas outlet of the anesthesia machine.

Anesthetic Delivery from the Vaporizer. Volatile anesthetic delivery from a vaporizer is simply the product of the delivered anesthetic concentration (Fraction = F_{del} or Partial pressure = P_{del}) of the anesthetic gas and fresh gas flow (FGF).

$$dV_{del}/dt = P_{del} \times FGF \quad (1)$$

Thus, we can readily calculate the volume of delivered gas-phase anesthetic by simply integrating this function over time. In the simplest case where P_{del} and FGF remain constant:

$$V_{del}(t) = P_{del} \times FGF \times t \quad (2)$$

Fresh Gas Wash-in to the Breathing Circuit. The factors that affect the speed at which the gas mixture delivered from the anesthesia machine replaces gases in the breathing circuit (wash-in) are FGF and the breathing circuit volume (V_{circ}). Consider a typical situation in which FGF at the beginning of an anesthetic is 6 L/min and the gas volume inside the components of a breathing circuit is 6 L. If FGF is doubled to 12 L/min, then wash-in will proceed at twice the rate (halving the time). Conversely, if the V_{circ} doubles to 12 L, then wash-in will proceed at half the rate (doubling the time).

The gas exchange process is independent of the concentration of anesthetic in the circuit, because the exchange is simply through bulk flow and mixing. However, the difference between the delivered concentration and that in the circuit determines the magnitude and direction of net anesthetic gas flow. When the delivered anesthetic partial pressure (P_{del}) is greater than that in the circuit (P_{circ}), net anesthetic flow is into the circuit (and subsequently into the patient). To remove anesthetic from the circuit, P_{del} must be less than P_{circ}. When there is no concentration gradient (i.e., equal partial pressures), bulk flow exchange may replace all the old gas molecules with new ones, but there is no net flow and anesthetic concentrations in the circuit remain unchanged.

Mathematically, we can describe the breathing circuit exchange process as a differential equation that incorporates all of the above factors:

$$\frac{dP_{circ}}{dt} = \frac{FGF}{V_{circ}} \times (P_{del} - P_{circ}) \quad (3)$$

If P_{del} is constant, integrating this equation results in a single exponential function that defines P_{circ} at any given time following a change in P_{del} at $t = 0$:

$$P_{circ}(t) = P_{circ}(0) + (P_{del} - P_{circ}(0)) \times \left(1 - e^{-t/[Vcirc/FGF]}\right) \quad (4)$$

P_{circ} approaches P_{del} following an exponential time course with a time constant of $\tau = V_{circ}/FGF$. Thus, if V_{circ} = 6 L and FGF = 6 L/min, the exponential time constant will be 1 minute (Fig. 26-3). Each minute results in the fraction of old gas in the breathing circuit dropping by 63.1%, and after 4 minutes, less than 2% old gas remains. The half-life for the process (time for halving the vaporizer-circuit concentration difference) is 0.693 × τ.

Breathing circuit components, such as CO_2 adsorbents and the plastic or rubber of the circuit tubing and connectors, influence the rate of equilibration between vaporizer and circuit, because such materials can absorb volatile anesthetics, increasing the effective circuit volume.[19] The more hydrophobic volatile anesthetics absorb more into

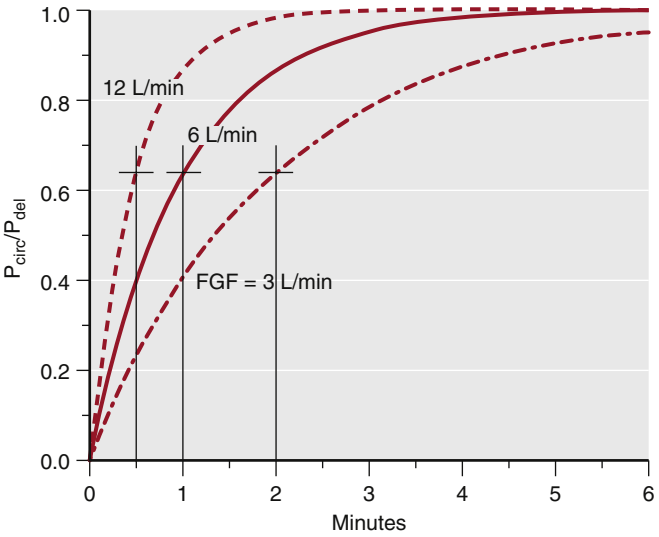

Figure 26-3. Wash-in of the breathing circuit depends on fresh gas flow (FGF). The *curves* depict the rate of rise of anesthetic concentration (partial pressure) in a breathing circuit with 6 L of gas volume, depending on FGF. Higher FGF results in more rapid exchange of circuit gases with fresh gas. The exponential time constant for the wash-in process is the circuit volume in liters divided by fresh gas flow in liters per minute (see Equation 4). *Cross marks* overlaying the curves indicate time constants under different gas flow rates. Each time constant correlates with a 63.1% exchange.

circuit components, whereas absorption negligibly affects wash-in and wash-out of low-solubility anesthetics.

The clinical relevance of the wash-in process is readily appreciated. An example of the importance of FGF is "priming" the anesthetic circuit for a single-breath induction technique. The FGF setting and the circuit volume influence the required duration of priming. More generally, whenever the vaporizer settings are altered, the speed at which the new settings influence the wash-in or wash-out of the circuit (and subsequently the patient) depend on FGF. Open (nonrebreathing) anesthetic breathing circuits are designed to have low exchange volumes and to be used with high fresh-gas flows. These features allow rapid changes in the delivered anesthetic concentration, while minimizing rebreathing of exhaled gases. The choice of an open versus rebreathing system influences the effects of various other factors that can affect uptake and distribution of inhaled anesthetics downstream from the breathing circuit. Some of the subsequent figures show models for both conditions.

Equilibration between Circuit and Pulmonary Airspace

Transfer of anesthetic gases from the breathing circuit to the pulmonary airspace is another bulk exchange process similar to that from vaporizer to breathing circuit. In this case, gas flow via ventilation is cyclical and bidirectional, and the factors that determine the rate of anesthetic exchange are minute ventilation (MV) and total pulmonary airspace volume (V_{pulm}).[20] Because transfer from the circuit to the lungs represents anesthetic flow out of the circuit, we alter Equation 3 to include both inflow to the circuit and outflow from the circuit:

$$\frac{dP_{circ}}{dt} = \frac{FGF}{V_{circ}} \times (P_{del} - P_{circ}) - \frac{MV}{V_{pulm}} \times (P_{circ} - P_{pulm}) \quad (5)$$

where P_{pulm} is a weighted average of the anesthetic partial pressure in deadspace and alveolar space.

Equation 5 describes how rebreathing affects the inhaled (breathing circuit) anesthetic concentration. Most inhaled anesthetics are delivered using a rebreathing circuit, which includes one-way flow valves and adsorbent material to remove exhaled CO_2 chemically. Rebreathing depends primarily on the balance between fresh gas flow and minute ventilation. The anesthetic gas in the breathing circuit represents a mixture of fresh gas and exhaled gases. Increased FGF reduces rebreathing, whereas increased MV increases rebreathing.

Alveolar Anesthetic Concentration

The alveolar anesthetic concentration (P_{alv} or F_A) is a critically important factor in anesthetic uptake and distribution because (1) it is in rapid equilibrium with circulating blood and highly perfused tissues, including target tissues in the CNS, and (2) P_{alv} can be measured in exhaled end-tidal gases. Thus, except during periods of rapid change, P_{alv} in exhaled breath represents a useful estimate of the anesthetic concentration in the patient's CNS and other highly perfused organs.

Because only alveolar gas is relevant to transpulmonary exchange of anesthetic into and out of the body, *alveolar ventilation* ($\dot{V}_{alv}$) is the proper gas flow to calculate anesthetic exchange into this part of the pulmonary airspace.

$$\frac{dP_{alv}}{dt} = \frac{\dot{V}_{alv}}{V_{alv}} \times (P_{circ} - P_{alv}) \quad (6)$$

where $\dot{V}_{alv}$ is MV corrected for deadspace ventilation.

Alveolar Uptake of Anesthetic into Pulmonary Blood

During inhaled anesthetic induction, anesthetic flows from alveolar gas to pulmonary blood across the alveolar–capillary interface separating these compartments and is driven by the partial pressure gradient between alveolar gas (P_{alv}) and mixed venous blood (P_{MV}) entering the pulmonary arteries. The net flow of anesthetic reverses during anesthetic wash-out when P_{alv} drops below P_{MV}. Anesthetic uptake into blood also depends on the pulmonary blood flow (which is typically close to cardiac output, $\dot{Q}$) and the blood's capacity to solvate anesthetic from the gas state (the blood/gas partition coefficient, $\lambda_{b/g}$):

$$\text{Uptake} = \dot{Q} \times \lambda_{b/g} \times (P_{alv} - P_{MV}) \quad (7)$$

We therefore correct Equation 6 to reflect both anesthetic inflow into alveolar airspace and its uptake into blood:

$$\frac{dP_{alv}}{dt} = \frac{\dot{V}_{alv}}{V_{alv}} \times (P_{circ} - P_{alv}) - \frac{\dot{Q} \times \lambda_{b/g}}{V_{alv}} \times (P_{alv} - P_{MV}) \quad (8)$$

Thus, during an inhaled induction of anesthesia, the rate of increase of P_{alv} relative to P_{circ} is governed by (1) alveolar ventilation, (2) cardiac output, and (3) anesthetic solubility in blood. Increased ventilation delivers more anesthetic from circuit to alveoli and increases P_{alv}/P_{circ} (Fig. 26-4). Yet increased pulmonary blood flow removes more anesthetic from alveoli, thereby decreasing the rate of increase in alveolar concentration of anesthetic (P_{alv}/P_{circ}; Fig. 26-5). Indeed, significant decreases in cardiac output are likely when end-tidal CO_2 ($ETCO_2$) decreases and end-tidal concentrations of volatile anesthetic increase.[21] The more soluble an anesthetic is in blood (i.e., the higher its $\lambda_{b/g}$), the more each volume of blood can take up anesthetic from alveolar gases (i.e., the larger the effective blood flow). Thus, as $\lambda_{b/g}$ increases, P_{alv}/P_{circ} increases more slowly (Fig. 26-6).

Other Factors That Affect the Rate of Rise of P_{alv}

Other factors affecting alveolar uptake of anesthetic include ventilation–perfusion matching and the absolute concentration of anesthetic in alveolar gases.

Deadspace. Deadspace (i.e., ventilated but not perfused pulmonary regions) reduces effective alveolar ventilation (see Equations 7 and 8), and thus slows anesthetic uptake. This effect is strongest under open-circuit (high FGF) conditions and with low blood-solubility inhaled anesthetics. Under conditions of limited anesthetic delivery and

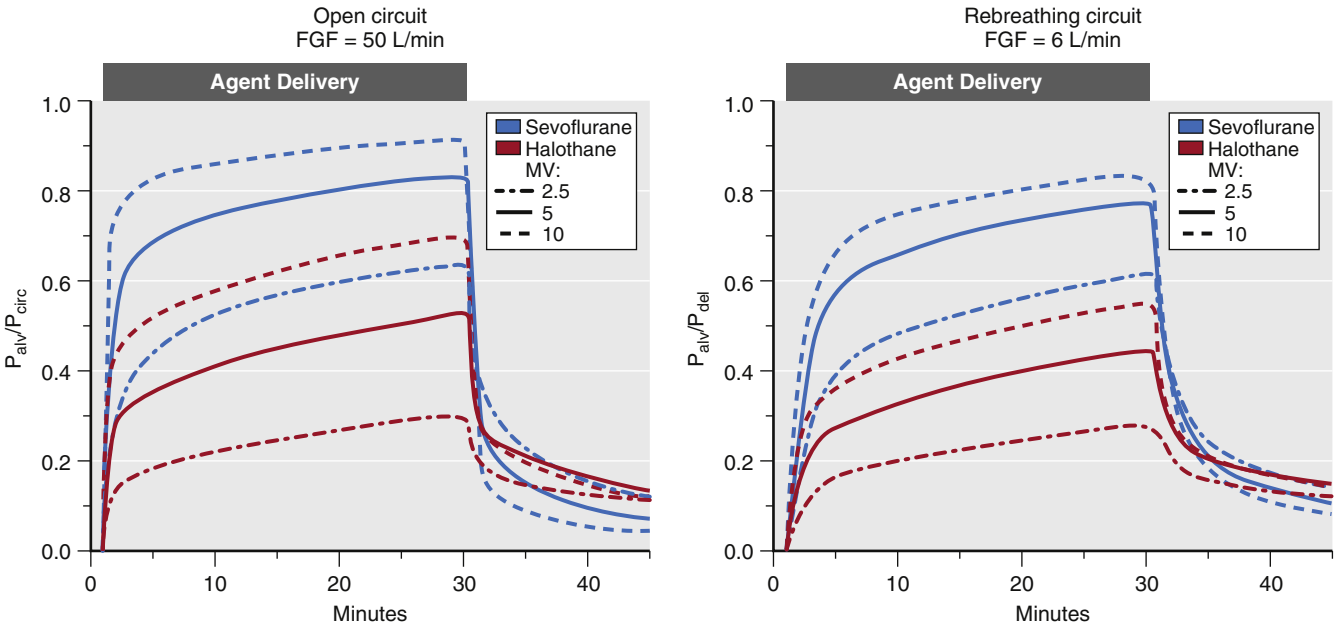

Figure 26-4. Effect of ventilation on the rise of alveolar anesthetic partial pressure (P_{alv}). *Left,* A traditional open-circuit model with very high fresh gas flow (FGF) and therefore constant $P_{del} = P_{circ}$. *Right,* A more common clinical situation with constant vaporizer output (P_{del}) and partial rebreathing at a 6 L/min fresh gas flow rate. Raising minute ventilation accelerates the rise of P_{alv} by delivering more anesthetic to the lungs. The effect is seen whether anesthetic is highly soluble in blood (e.g., halothane) or relatively insoluble (e.g., sevoflurane). However, the relative size of the ventilation effect is greater for soluble agents. Increased ventilation also accelerates clearance of anesthetic agents after delivery ceases. P_{circ}, Partial pressure in the circuit; P_{del}, delivered anesthetic partial pressure.

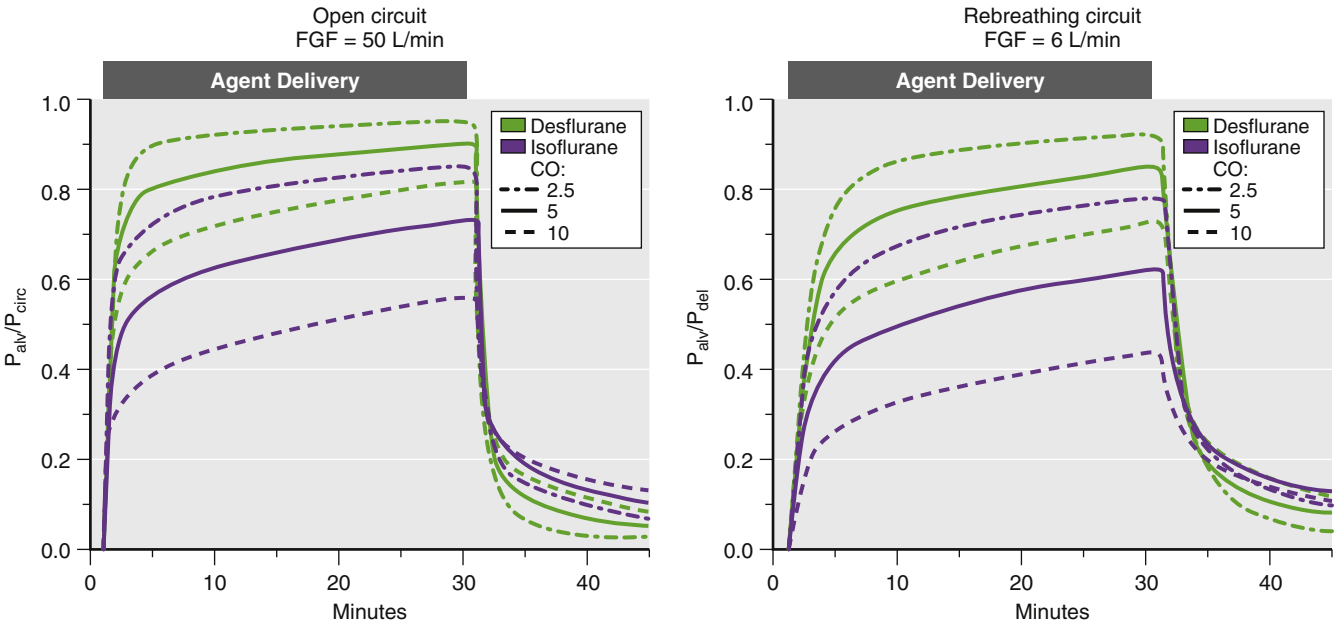

Figure 26-5. Effect of cardiac output on the rise of alveolar anesthetic partial pressure (P_{alv}). *Left,* A traditional open-circuit model with very high fresh gas flow (FGF) and therefore constant $P_{del} = P_{circ}$. *Right,* A common clinical situation with constant vaporizer output (P_{del}) and partial rebreathing at a 6 L/min FGF rate. Raising cardiac output slows the rise of P_{alv} by increasing anesthetic uptake into blood (removing anesthetic from alveolar gases). This effect is observed for both highly soluble and relatively insoluble (e.g., isoflurane) anesthetics, but the relative effect is greater for soluble agents. Cardiac output also affects clearance of anesthetics from the lungs in the same way it affects uptake (i.e., increased cardiac output slows anesthetic clearance rate). P_{circ}, Partial pressure in the circuit; P_{del}, delivered anesthetic partial pressure.

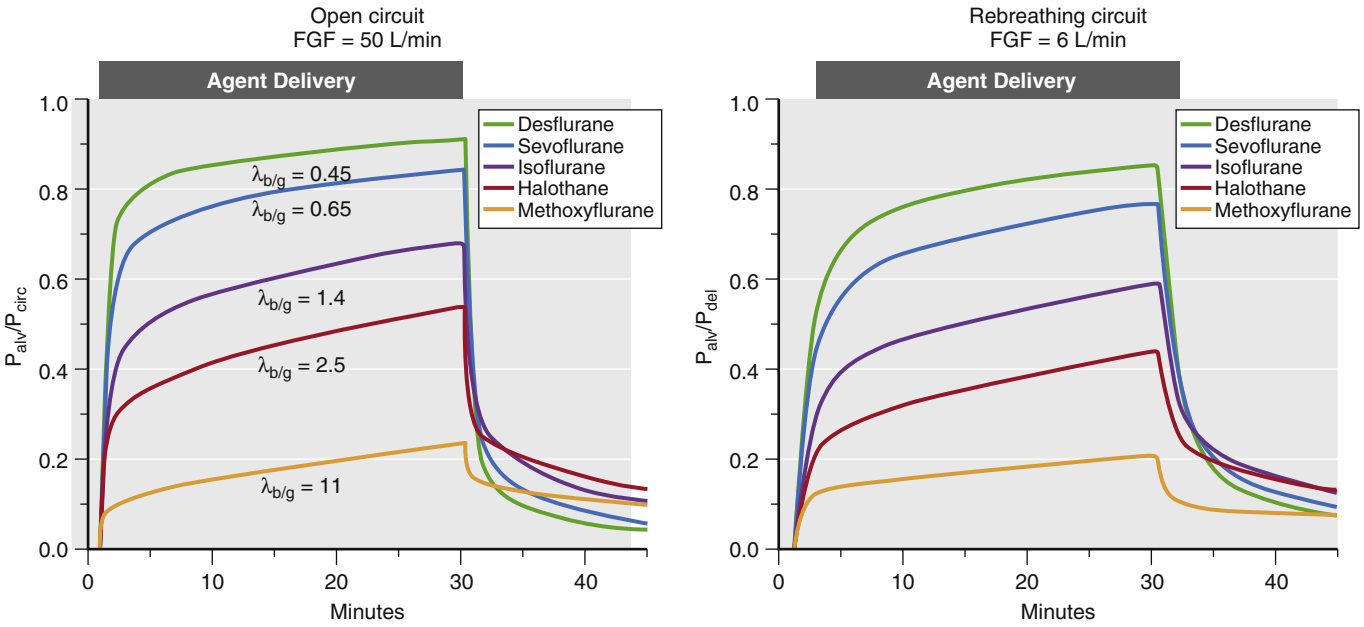

Figure 26-6. Effect of blood solubility on the rise of alveolar anesthetic partial pressure (P_{alv}). *Left,* A traditional open-circuit model with very high fresh gas flow (FGF) and therefore constant $P_{del} = P_{circ}$. *Right,* A more common clinical situation with constant vaporizer output (P_{del}) and partial rebreathing at a 6 L/min FGF rate. As blood solubility ($\lambda_{b/g}$) increases, the rate of rise in P_{alv} slows, because uptake into blood is greater for high solubility agents. The major effect of blood solubility is the magnitude of the rapid initial rise in P_{alv}, which represents a balance between anesthetic delivery and uptake into pulmonary blood. Blood solubility similarly affects clearance from alveoli after anesthetic delivery ceases (i.e., increased blood solubility results in slower clearance from alveolar gas). P_{circ}, Partial pressure in the circuit; P_{del}, delivered anesthetic partial pressure.

high uptake such as low FGF and a highly blood-soluble anesthetic, alveolar ventilation and therefore uptake are reduced. The inspired anesthetic concentration (P_{circ}) and the concentration gradient for alveolar exchange change very little. This compensates somewhat for the effect of deadspace on alveolar ventilation, reducing its overall effect on P_{alv}.

Pulmonary (Right to Left) Shunting. Pulmonary (right to left) shunting can be physiologic, pathologic, or iatrogenic, such as during one-lung ventilation. Right-to-left shunting results in a difference between P_{alv} and the partial pressure of anesthetic in arterial blood (P_{art}). This is because arterial blood represents a mixture of shunted mixed venous blood with blood that equilibrates with alveolar gases (Equation 9). Because such shunts also reduce transcapillary gas exchange in the lung and slow anesthetic uptake (Equations 7 and 8, after correcting pulmonary blood flow for shunt), right-to-left shunting, sustains P_{circ}, an effect that is more pronounced for highly soluble versus insoluble anesthetics. Thus, shunt reduces the ratio of P_{art}:P_{alv} more for insoluble anesthetics, such as N_2O[22,23] (Fig. 26-7).

$$P_{art} = P_{MV} \times \dot{q}_{RLshunt} + P_{alv} \times \left(\dot{Q} - \dot{q}_{RLshunt}\right) \quad (9)$$

Concentration and Second Gas Effects. The absolute concentration of an inhaled anesthetic influences its uptake. In the previous discussion and illustrations, an inhaled anesthetic has been assumed to represent a small fraction of the inhaled gas mixture, and that transalveolar uptake of the anesthetic results in a decrease in P_{alv}

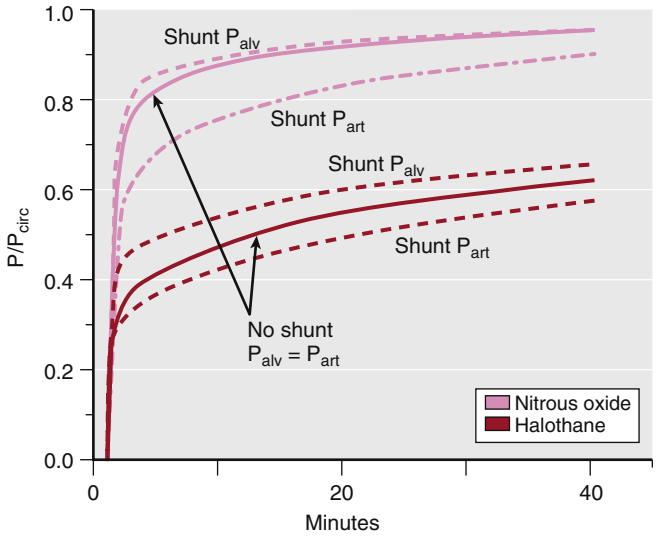

Figure 26-7. Effect of right-to-left pulmonary shunt on the anesthetic partial pressure in alveolar gas and arterial blood. The *curves* represent anesthetic partial pressures in alveolar gases (*dashed lines*) and arterial blood (*dash-dot lines*) under conditions of 40% right-to-left shunt and no shunt (*solid lines*). Pulmonary right-to-left shunting bypasses alveolar uptake, so that less anesthetic is removed from pulmonary gases; this accelerates the rise in P_{alv}. In addition, the anesthetic partial pressure in arterial blood (P_{art}) is a mixture of pulmonary venous blood at P_{alv} and shunted mixed venous blood at P_{MV}. Thus P_{art}, which determines the rate of anesthetic uptake into tissues, rises more slowly than P_{alv} when R-to-L shunting is present. The shunt effect on P_{art} versus P_{alv} is larger for insoluble anesthetics (e.g., N_2O) than for soluble anesthetics (e.g., halothane). Other model parameters were set for open circuit delivery (constant P_{circ}) with MV = 6 L/min and C.O. = 5 L/min. P_{alv}, Alveolar anesthetic partial pressure. *CO,* Cardiac output; *MV,* minute ventilation; P_{MV}, anesthetic partial pressure in mixed venous blood.

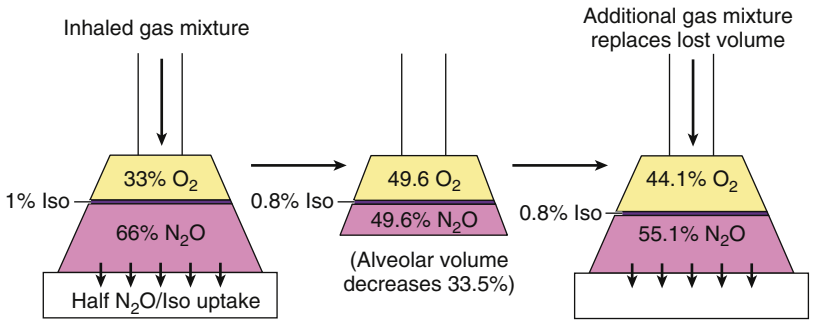

Figure 26-8. Concentration and second gas effects. The figure depicts alveolar gases at the beginning of an anesthetic. After an initial inspiratory breath, alveoli are filled with the gas mixture in the circuit (66% N_2O, 33% O_2, 1% isoflurane) at their normal end-inspiratory volume *(left panel)*. After half of the N_2O and isoflurane are absorbed into pulmonary blood, the alveolar gas volume is reduced by 33.5%. At this point, the volume of N_2O equals the volume of O_2, and the gas mixture is 49.6% N_2O, 49.6% O_2, and 0.8% isoflurane. Inflow of additional inspired gas mixture returns alveolar volume to its original value, resulting in a gas mixture of 55.1% N_2O, 44.1% O_2, and 0.8% isoflurane. The alveolar partial pressure of N_2O falls much less than the fractional uptake (the concentration effect). In addition, the partial pressure of O_2 increases relative to the inspired gas O_2 content, and the partial pressure of isoflurane is sustained close to the inspired value, increasing its rate of uptake (the second gas effect). *Iso,* Isoflurane.

and negligible changes in alveolar gas volume. However, when the inhaled anesthetic represents a large fraction of the inhaled gas mixture, its rapid uptake results in a smaller relative alveolar anesthetic concentration drop, because the volume of alveolar gas also decreases. This is known as the *concentration effect*.[24] In an imaginary situation in which a patient is breathing 100% anesthetic, uptake into pulmonary blood reduces the volume of anesthetic gas in the alveoli without altering its concentration or partial pressure (oxygen-induced atelectasis occurs through a similar mechanism). A typical situation, illustrated in Figure 26-8, is delivery of 66% N_2O with 33% O_2, and 1% isoflurane. Assuming cardiac output equals 5 L/min, the initial rates of N_2O uptake is given by Equation 7 as 5000 mL/min × 0.47 × 0.66 atm = 1550 mL/min N_2O, indicating that a large fraction of N_2O is initially taken up during the first few breaths. If we assume that half the N_2O and half the isoflurane are rapidly taken up following the first breath of this gas mixture, then alveolar volume drops by 33.5% and the remaining alveolar gas contains 33 parts N_2O, 33 parts O_2, and 0.5 parts isoflurane (49.6% N_2O, 49.6% O_2, and 0.8% isoflurane). Despite 50% uptake of N_2O, the significant reduction in alveolar gas volume results in a concentration of remaining alveolar N_2O that is only 24% less than its initial value.

The *second gas effect* is also evident in this example: the rapid uptake of N_2O and reduced alveolar gas volume sustains P_{iso} near its original inspired value and increases alveolar P_{O2}, thereby augmenting uptake of these gases.[25] Note also that the rapid uptake of N_2O into blood results in an effective increase in minute ventilation, because more circuit gas is passively drawn into alveoli as alveolar gas is absorbed rapidly. These effects have been demonstrated in humans[26] and animals,[25] and theoretically are short-lived and pertain only to the period of initial rapid transfer of N_2O from alveoli to blood. The second gas effect may persist beyond the initial rapid phase of N_2O uptake.[27]

Distribution of Anesthetic into Tissues

Blood exiting the pulmonary capillaries enters the pulmonary vein and the left heart. Inhaled anesthetics are then distributed via arterial blood to various body tissues. The rate of increase of anesthetic partial pressure within each tissue is determined by tissue-specific arterial blood flow ($\dot{q}$), effective volume (the product of anatomic volume and tissue/blood partition coefficient, $\lambda_{t/b}$), and the anesthetic partial pressure gradient between arterial blood and the tissue:

$$\frac{dP_i}{dt} = \frac{\dot{q}_i}{V_i \times \lambda_{i/b}} \times (P_{art} - P_i) \qquad (10)$$

where *i* designates a particular organ or type of tissue. Values used in model calculations are summarized in Table 26-2. The time required for anesthetic partial pressure equilibration between arterial blood ($P_{art} = P_{alv}$) and a specified tissue is shorter if its blood flow is high, and longer if that tissue has a large effective volume (Figs. 26-2, 26-9).

Traditionally, anesthetic distribution has been described for four distinct tissue groups. The vessel-rich group (VRG) includes the heart, brain, spinal cord, liver, and kidney. Together, these organs compose approximately 10% of the adult human body mass; however, they receive approximately 70% of cardiac output under normal resting conditions. As a result, time constants for anesthetic equilibration between blood and these organs are typically only a few minutes (see Table 26-2). Of particular interest is the equilibration time for the CNS, where anesthetic effects are mediated. After the highly perfused VRG tissues, skeletal muscle is the next compartment to equilibrate with inhaled anesthetics. Muscle composes approximately 40% of body mass in a healthy adult, making muscle the largest single compartment based on weight. Moreover, most inhaled anesthetics partition into muscle more than into brain, resulting in an increased effective volume for anesthetic uptake into this compartment. At rest, muscle receives 10% to 15% of cardiac output (20 mL/kg/min), but this value can increase dramatically during exercise, stress, fever, or other states associated with high cardiac output.[28] Taken together, these factors generally result in slow equilibration between anesthetic in blood and muscle, with typical time constants of hours (see Table 26-2). The third tissue

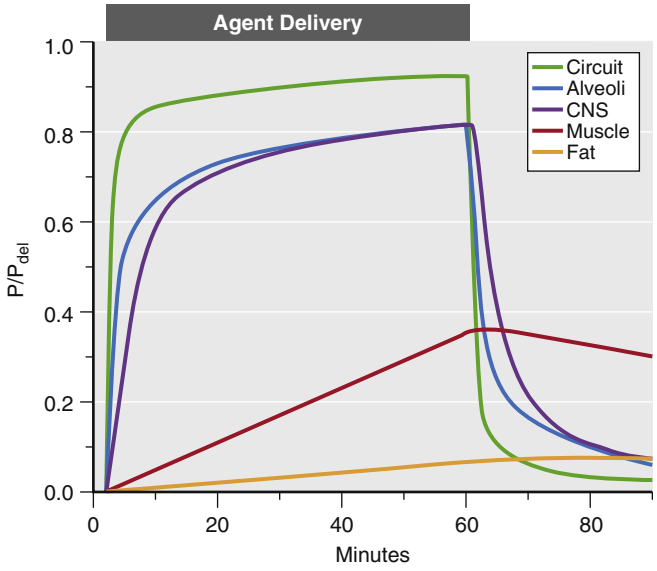

Figure 26-9. The rate of anesthetic partial pressure rise in different tissue compartments. The *curves* represent model calculations for sevoflurane delivered at 6 L/min fresh gas flow, with 5 L/min ventilation and 5 L/min cardiac output. The anesthetic partial pressure in the central nervous system (CNS; *purple line*), part of the vessel rich group, equilibrates rapidly with P_{alv} (*blue line*), although a lag-time of several minutes is evident when P_{alv} is rapidly rising or falling. The anesthetic partial pressures in both muscle *(red line)* and fat *(orange line)* rise and fall much more slowly, because muscle and fat compartments represent much larger effective volumes (see Fig. 26-2) and have lower blood flow than the vessel-rich group does. Note that anesthetic partial pressure in fat continues to rise after anesthetic delivery stops, as long as partial pressure in alveolar gas (and arterial blood) is greater than that in the fat compartment.

group is *fat*, which in a normal adult composes 25% of body mass and receives 10% of cardiac output.[29] Potent volatile anesthetics partition avidly into fat; therefore, fat represents the largest effective volume for uptake of these drugs (see Fig. 26-2, Table 26-2). The extremely large effective volume coupled with relatively low blood flow results in very slow equilibration of anesthetics between blood and fat, with time constants approaching days. A fourth group, including skin, cortical bone, and connective tissue, is referred to as *vessel poor tissues*. These tissues compose approximately 15% of an average adult body while receiving less than 5% of cardiac output at rest. Induction of general anesthesia impairs normal sympathetic nervous function, resulting in increased blood flow to normally cool skin in the extremities.[30] The blood volume represents approximately 7% of body mass and may be considered another compartment for anesthetic uptake, while also conveying drug to other tissue compartments.

As stated previously, increased cardiac output results in increased anesthetic uptake and a slower rate of rise of P_{alv}. Without confounding factors, increasing cardiac output slows the induction of general anesthesia with inhaled anesthetics.[21,31] This result can seem counterintuitive when increasing cardiac output increases uptake of anesthetic into the patient's body and hastens its delivery to the tissues. However, during induction the anesthetic partial pressure in blood and downstream tissue compartments cannot be higher than that in the upstream alveolar compartment. Increased cardiac output slows the rate of increase of P_{alv} and thus also slows the rate of increase of the anesthetic partial pressure in blood (P_{art}), the CNS (P_{CNS}), and other highly perfused tissues. The extra anesthetic uptake is primarily into muscle, which is a large tissue compartment with a high capacity for anesthetic and is where much of the excess cardiac output flows. For example, a 50% increase in cardiac output can more than double muscle blood flow, diverting the majority of anesthetic to muscle, lowering P_{alv}, and thus slowing anesthetic uptake into target tissues in the CNS. If one could manipulate inhaled anesthetic delivery to maintain constant P_{alv}, which may be achievable with automated feedback control of vaporizer output and FGF,[32] and then increasing cardiac output might have a different effect. Model simulations where P_{alv} is maintained at a constant level show that uptake into VRG tissues, including brain tissue, increases more rapidly as cardiac output increases.[33]

In pediatric patients (see Chapter 93), the balance of cardiac output to various tissue beds differs from that in adults. Thus, although cardiac output per kilogram body weight is larger in children than in adults, induction of anesthesia is more rapid in young children than in adults, because a disproportionate amount of perfusion goes to the vessel rich organs, such as the brain.[34]

The equilibrium distribution volumes for most inhaled anesthetics are extremely large, with the largest compartment by far being fat. However, equilibration with fat is so slow that this compartment usually plays a relatively minor role in the pharmacokinetics of inhaled anesthetics. During a typical general anesthetic lasting from 30 minutes to several hours, the blood, VRG organs, and muscle are the compartments into which inhaled anesthetics mostly distribute.

Although the model in Figure 26-2 illustrates anesthetic distribution only *via* arterial blood flow, intertissue diffusion takes place between abutting tissues that have large interfacial surface areas. In particular, direct diffusion from organs with high anesthetic partial pressures to abutting tissues with low partial pressure and high capacity for anesthetic uptake may also contribute to drug distribution. Examples of this process include anesthetic diffusion from the heart, liver, and kidneys to surrounding fat in the pericardium and abdomen.[35,36]

Mixed Venous Anesthetic Partial Pressure

The anesthetic partial pressure in mixed venous blood entering the pulmonary circulation is a weighted average of the venous outflows from all tissues and organs, which converge in the right ventricle:

$$P_{MV} = \sum_{i=1}^{n} \frac{\dot{Q}_i}{\dot{Q}} \times P_i \qquad (11)$$

As P_{MV} rises, the gradient driving uptake of inhaled anesthetics from alveoli weakens. The difference between the delivered (inspired) and the alveolar (end-expiratory) anesthetic concentrations also shrinks, causing transpulmonary uptake to slow (Equation 7). Systemic (left to right) shunting causes P_{MV} to increase more rapidly than it would in the absence of such shunts. When blood flow to other tissues remains normal and the left-to-right shunt

simply represents excess cardiac output, the resulting increase in anesthetic uptake (Equation 7) is offset by the increase in P_{MV}, resulting in a slight increase in the rate of anesthetic delivery or uptake into the brain, muscle, and other tissues. In cases where large left-to-right shunts result in reduced blood flow to other tissues, anesthetic equilibration in those tissues will be relatively slow.

SYNTHESIS OF THE MODEL AND INHALED ANESTHETIC INDUCTION: PK/PD

The rate of equilibration (pharmacokinetics) of inhaled anesthetics among the various compartments involved in delivery to a patient, vaporizer, circuit, lung, blood, and various tissues, has been discussed. However, in a clinical setting, the goal of the anesthesia provider is the reversible production of certain desired effects (amnesia, unconsciousness, and immobility) in the patient in a reasonable amount of time. To achieve these goals, pharmacokinetics must be combined with knowledge of the effects produced at different anesthetic partial pressures in target tissues (i.e., dose-response or pharmacodynamics). The most relevant pharmacodynamic guidelines are minimum alveolar concentration (MAC)–immobility,[37] the alveolar anesthetic concentration preventing movement response to surgical stimulus in 50% of subjects, and MAC-awake,[7] the alveolar anesthetic concentration preventing perceptive awareness in 50% of subjects, both measured under conditions where P_{alv} is in equilibrium with anesthetic partial pressure in the central nervous system (P_{CNS}). MAC-awake for potent volatile anesthetics is typically 0.34 × MAC-immobility,[38] whereas MAC-awake for N_2O is approximately 0.7 × MAC immobility (see Table 26-1). During induction of anesthesia, the goal may be achieving a high probability of immobility following incision ($P_{CNS} \approx 1.2 \times$ MAC-immobility) within 15 minutes, while avoiding the deleterious effects of overly deep anesthesia. At the end of an anesthetic, return of consciousness is likely to occur when P_{CNS} decreases to less than MAC-awake. The targets used for this illustrative model patient are estimates. In clinical practice, targets for anesthetic depth vary widely depending on patient factors, the presence of noxious stimuli, and other drugs that may be administered.

There are a variety of strategies to deliver inhaled anesthetics and meet the goals just discussed. The first important consideration is that P_{del} from the vaporizer must be higher than the target P_{alv} or P_{CNS} (overpressure). The more overpressure used, the more rapidly anesthetic is delivered. High fresh gas flows, large minute ventilation, and a low-solubility drug will also increase the rate of anesthetic delivery and the rate of rise of P_{alv} and P_{CNS}. These factors, and particularly overpressure, also increase the risk of delivering an overdose of anesthetic drug. A common strategy is to initiate inhaled anesthetic delivery with moderate to high fresh gas flows (≥6 L/min) and moderate overpressure ($P_{del} = 2 \times$ MAC-immobility), and reduce P_{del} after P_{alv} reaches or slightly exceeds the target level (Fig. 26-10, *left*). The need to maintain overpressure and slightly overshoot P_{alv} derives from the fact that distribution of drug to muscle maintains a high delivery requirement after the initial rapid phase of uptake. If P_{del} is decreased too quickly, then P_{alv} can decrease below the target. P_{del} or FGF is slowly adjusted downward as the anesthetic inspired-to-expired difference in anesthetic partial pressures ($P_{del} - P_{alv}$) decreases.

CLOSED-CIRCUIT OR LOW-FLOW DELIVERY OF ANESTHESIA

The use of high or moderate fresh gas flows, while enabling use of less overpressure, results in far more anesthetic drug being delivered than being taken up into tissues. Note in the left panel of Figure 26-10, the amount of isoflurane delivered is 4.5-fold more than that taken up, whereas delivered sevoflurane is 7.2-fold greater than absorbed drug. Thus, over 80% of delivered volatile anesthetic is waste using the moderately high FGF approach illustrated in this example. Rebreathing circuits allow the use of fresh gas flows well below minute ventilation, which results in reduced anesthetic discharge into the waste-scavenging system. Less waste discharge translates into both reduced costs and reduced global environmental impact of anesthetic gases within the atmosphere, where these anesthetics contribute to climate change (reviewed later). Additional benefits of low FGF and rebreathing include retention of expired heat and water vapor in rebreathed gas, improving airway epithelial health, and reducing accumulation of dried airway secretions.

Closed-circuit anesthesia represents the ultimate limit of low gas flows, where fresh gases are delivered only in quantities sufficient to replace those taken up into tissues, metabolized (especially O_2), or otherwise lost to the environment, and the vast majority of gas in the breathing circuit undergoes rebreathing.[39] Achieving this goal requires a leak-free breathing circuit, complete removal of CO_2, and careful attention to the inspired-to-expired values of oxygen and anesthetic gases, and even to the build-up of expired nitrogen that can slowly accumulate in the breathing circuit. Under these conditions, oxygen consumption in an anesthetized patient can be lower than 3 mL/kg/min, translating to O_2 replacement of around 200 mL/min in a patient weighing 70 kg. There are several significant limitations to this technique. Because all exhaled CO_2 must be removed by adsorbents, closed circuit anesthesia increases the risk of rebreathing CO_2 as adsorbent capacity diminishes. Anesthetic breakdown products, carbon monoxide (CO), and slowly degassing nitrogen from blood can accumulate in the breathing circuit.[40] Clinicians must be aware that patient metabolism may deplete oxygen from the breathing circuit and can result in delivery of a hypoxic gas mixture during use of closed circuit anesthesia. When using very low FGF values, changes in the vaporizer output (P_{del}) result in extremely slow changes in P_{circ} and the subsequent depth of anesthesia. Closed circuit anesthetic administration can be guided by the "square root of time" rule, proposed by Severinghaus[41] and detailed in now classic descriptions.[42] This rule states that the rate of anesthetic uptake decreases approximately at the square root of delivery time. We can estimate the uptake of 1.2 MAC isoflurane during the first minute of anesthesia using Equation 7. Thus, Cardiac output × $\lambda_{b/g}$ × 1.2 MAC = Initial uptake of isoflurane

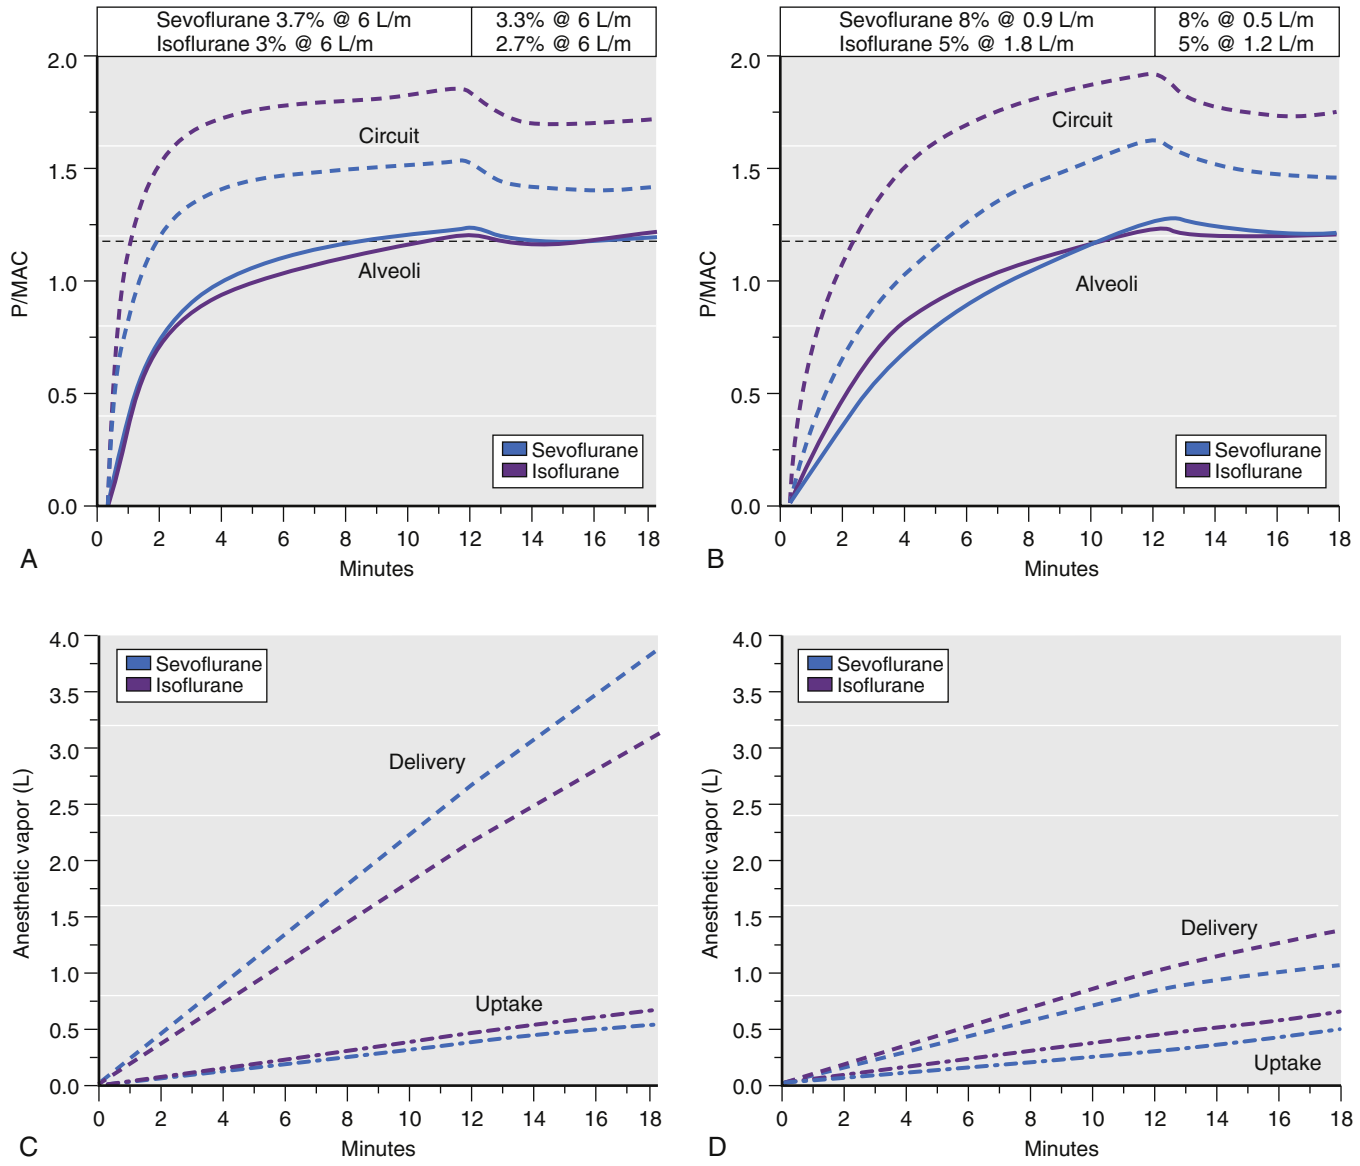

Figure 26-10. Effect of induction technique on uptake and delivery of inhaled anesthetics. **A,** Anesthetic partial pressures in both the circuit and alveoli during inhalation induction with moderate (6 L/min) fresh gas flows and modest (twofold to threefold) overpressure for sevoflurane *(blue)* and isoflurane *(purple)*. P_{alv} reaches 1.2 × MAC in approximately 12 minutes, and approximately 10% downward adjustment of vaporizer settings results in maintenance of P_{alv} near this target level. Additional downward adjustments in vaporizer setting or fresh gas flows, or both, would be needed to maintain this P_{alv} level. **B,** Anesthetic partial pressures in both the circuit and alveoli during inhalation induction with low (less than 2 L/min) fresh gas flows and maximal (fourfold) overpressure for sevoflurane *(blue)* and isoflurane *(purple)*. P_{alv} reaches 1.2 × MAC in approximately 12 minutes, and a downward adjustment of fresh gas flow results in maintenance of P_{alv} near this target level. **C,** The total anesthetic vapor delivered and taken up into the model patient from panel *A*. Note that delivery far exceeds uptake, more so for the low solubility anesthetic (sevoflurane). **D,** The total amount of anesthetic vapor delivered and taken up into the model patient from panel *B*. Note that uptake is similar, whereas delivery is much lower than that using a high-FGF technique. The low-FGF technique reduces waste more so for anesthetics with low blood solubility (e.g., sevoflurane) than for highly soluble drugs (e.g., isoflurane). $P_{alv,}$ Alveolar anesthetic partial pressure; *MAC,* minimum alveolar concentration.

vapor (5000 mL/min × 1.4 × 0.0128 atm = 90 mL/min). Using the square root of time rule, uptake at 4 minutes would be half of the initial rate (45 mL/min), and uptake at 9 minutes would be one third of the initial rate (30 mL/min). To deliver 90 mL/min of isoflurane vapor (0.54 mL of liquid isoflurane at 20° C) at a maximal vaporizer setting of 5% requires 1800 mL/min of fresh gas flow, far greater than the target flow for closed circuit. Anesthetists can overcome this limitation by directly injecting small volumes of liquid anesthetic into the expiratory limb of the breathing circuit[43]; however, this approach requires vigilant attention to the clock along with many other factors. In inexperienced hands, miscalculation or mistiming of anesthetic injection runs the risk of overdose.

Because of the challenges of closed-circuit administration, a more common practice is to use moderate to high fresh gas-flows to achieve rapid changes during induction of anesthesia, reserving closed-circuit anesthesia to periods where the P_{circ} to P_{alv} difference is small. Even so, changes in a patient's metabolism because of temperature variation, degree of muscle relaxation, or surgical stimulation can result in the need for frequent adjustments

to oxygen flow and anesthetic depth, making anesthesia delivery in a closed-circuit system relatively unstable and difficult.

Low-flow anesthetic delivery, typically with fresh gas flows of 0.5 to 1.0 L/min during maintenance, is a compromise between closed-circuit delivery of anesthesia and the use of high fresh gas flows. Much of the waste and other problems associated with high fresh gas flows are avoided, whereas the instability associated with a strict closed-circuit technique is also moderated. As noted earlier (see Equilibration between Circuit and Pulmonary Airspace), the inspired anesthetic concentration (P_{circ}) depends on both P_{del} and P_{pulm} when rebreathing occurs. Thus, as FGF diminishes, P_{del} must be adjusted upward to compensate for diminished delivery. Given that the maximal output setting on most vaporizers is approximately 4 × MAC-immobility, anesthetic delivery at 1 L/min and maximal P_{del} is still far less than the previous example with 6 L/min and P_{del} = 2 × MAC isoflurane. Higher FGF or a less soluble anesthetic drug, or both, are needed to achieve target P_{CNS} in less than 15 minutes, but as uptake diminishes, FGF can be gradually reduced (see Fig. 26-10, *right*). With soluble anesthetics such as isoflurane, maximal vaporizer settings and FGF near 2 L/min is required for reasonably rapid induction. FGF can be decreased incrementally as P_{alv} reaches the target level, and eventually vaporizer output is decreased as well. With low solubility anesthetics such as desflurane or sevoflurane, initial FGF values near 1.0 L/min can be used in combination with maximal vaporizer settings and a similar strategy of reducing FGF. As a result, vaporizer output results in reasonably rapid induction while minimizing waste of volatile anesthetics. Low FGF can be maintained until high FGF is again needed to achieve emergence at the end of the anesthetic administration.

When using high vaporizer output settings, diligence must be maintained to avoid overdosing the patient by reducing FGF and the vaporizer setting in a timely and deliberate manner. Thus, low-FGF techniques combined with significant overpressure should not be applied in situations when other clinical issues require the attention of the anesthesia provider.

PHARMACODYNAMIC EFFECTS OF ANESTHETICS ON UPTAKE AND DISTRIBUTION

The pharmacodynamic effects of most inhaled anesthetics also include changes in ventilatory and cardiac function that thereby introduce dynamic changes in the drug pharmacokinetics. Spontaneous ventilation is reduced by inhalation of potent volatile anesthetics in a dose-dependent manner.[44] As a result, spontaneously breathing patients will autoregulate to some degree by reducing their uptake of anesthetic as depth of anesthesia increases. This autoregulation provides a degree of safety that is absent in manually or mechanically ventilated patients, who may be subjected to excessive delivery of these anesthetics if a vaporizer is inadvertently set to deliver overpressure.[45] Inhaled anesthetics also reduce cardiac output, a pharmacodynamic effect that leads to a more rapid increase in P_{alv}/P_{circ} and consequently a more rapid increase in the anesthetic partial pressure in heart, brain, and other highly perfused tissues.[46] Halothane is the anesthetic associated with the greatest decrease in cardiac output. If anesthetic delivery continues with a decreasing cardiac output, a positive feedback loop of worsening cardiac depression and a rapid descent toward hemodynamic collapse can occur. For more details on the effects of inhaled anesthetics on the respiratory and circulatory systems, see Chapters 27 and 28.

EFFECT OF NITROUS OXIDE ON GAS-FILLED SPACES

Because N_2O is often used at high partial pressure, it diffuses into, and accumulates in, spaces containing air or other immobile gases, with potentially deleterious physiologic consequences. Clinically relevant examples include intravascular air emboli,[47] pneumothorax,[48] air in the inner chamber of the ear,[49] intravitreal gas bubbles (see Chapter 84),[50] intrathecal air, pneumoencephalus,[51] and air in the gastrointestinal tract.[48] Air-filled spaces contain mostly nitrogen, a gas that composes 78% of air, but is thirtyfold less soluble in blood than N_2O ($\lambda_{b/g}$ for N_2 is 0.015). Thus, N_2O diffuses down its pressure gradient from blood and surrounding tissues into air-filled spaces, whereas N_2 removal from these spaces is far slower, even with inspired $P_{N2} = 0$. As N_2O enters and the total number of gas molecules in an air space increases, it will expand in volume, increase in pressure, or both, depending on the compliance of the space.

In highly compliant air-filled spaces, such as intravascular air bubbles or small pneumothoraces, N_2O accumulation increases the total volume of gas (Fig. 26-11, *A*) with minimal changes in pressure. Air spaces expand as N_2O enters until the P_{N2O} within the air space matches that in surrounding blood, establishing equilibrium. The maximum potential gas volume expansion in a highly compliant space is:

$$\frac{V}{V_{init}} = \frac{1}{1 - P_{N2O}} \qquad (12)$$

Thus, administration of 50% N_2O can double air-space volume, whereas 67% can potentially triple air-space volume. N_2O can significantly worsen the cardiovascular or tissue consequences of intravascular air emboli, potentially making a nonlethal volume of venous air embolus lethal.[47] Expansion of intracranial air or gastrointestinal gas volume by N_2O can result in life-threatening intracranial expansion of this gas volume or impede surgical exposure or abdominal wound closure. Gas-space compartment compliance eventually decreases as volume expands, resulting in increased pressure. For example, N_2O can expand a small pneumothorax to a point where intrathoracic pressure increases, compressing lung, displacing the mediastinum, and reducing venous return (tension pneumothorax). The endotracheal tube cuff filled with air is also susceptible to expansion by N_2O. Increased tracheal cuff pressure can impair perfusion of surrounding mucosa.[52] Air-filled laryngeal mask airway

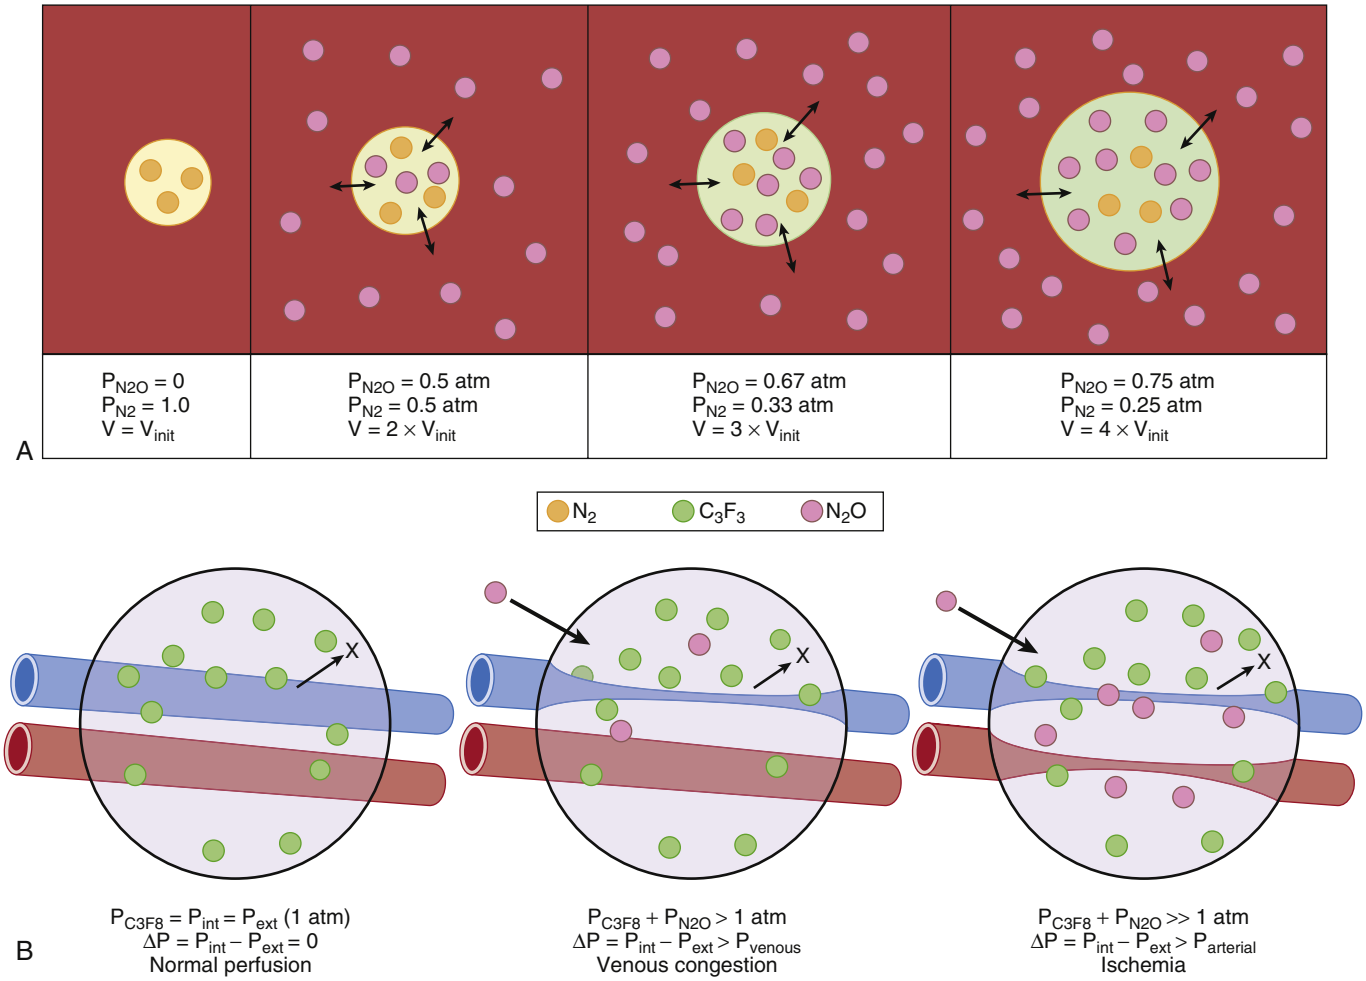

Figure 26-11. Nitrous oxide accumulation in gas-filled spaces. **A,** Expansion of a compliant air-filled space (a small vascular air embolus) occurs as the partial pressure of nitrous oxide in surrounding blood increases. Each panel depicts the equilibrium condition with P_{N2O} inside the bubble equal to that in blood. Labels below each panel summarize the partial pressures of N_2O and N_2 in the bubble as well as the bubble volume relative to its initial value (V_{init}). **B,** The increase in pressure inside a noncompliant, gas-filled compartment (e.g., an eye following perfluoropropane [C_3F_8] injection) with blood vessels passing through it. As N_2O accumulates, the pressure in the compartment increases, which can result in venous congestion *(middle panel)* or ischemia *(right panel)* in tissues that are perfused by the vessels in this compartment (e.g., the retina).

cuffs[53] and the air-filled balloon of a Swan-Ganz catheter[54] can similarly expand during N_2O administration.

In noncompliant gas-filled spaces, gas pressure rises as N_2O enters, until P_{N2O} within the air space matches that in blood. The maximal potential pressure in such a space, relative to surrounding ambient pressure, is therefore P_{N2O}. Thus, in a patient inhaling 50% N_2O, pressure in such a gas-filled compartment could approach 380 mm Hg, far greater than typical arterial perfusion pressures. A clinically important example is that of intravitreal sulfur hexafluoride (SF_6) or perfluoropropane (C_3F_8) bubbles, which are injected as the sclera is closed at the end of intraocular or retinal surgery[50] (see Fig. 26-11, *B*). These gases persist even longer than N_2 does because of their low blood solubility. If N_2O is administered to these patients at the time of intravitreal bubble injection, its diffusion into the bubble can rapidly increase intraocular pressure above that in retinal veins, producing retinal congestion. If the pressure in the eye further increases above systolic arterial pressure, retinal ischemia resulting in blindness might ensue (see Chapter 84).

The rate of N_2O diffusion into gas-filled spaces in the body depends on local blood flow and the surface-to-volume ratio of the space. Thus, small air emboli expand within seconds, because they have high surface/volume ratios and they are surrounded by a relatively infinite supply of blood containing dissolved N_2O. Larger air emboli expand more slowly, because their surface/volume ratio is smaller (spherical surface/volume is inversely proportional to radius). Small pneumothoraces typically have large surface/volume ratios and high local blood flow. Animal experiments show that inhalation of 75% N_2O approximately doubles pneumothorax volume in 10 minutes and triples it in 30 minutes (Fig. 26-12). Compared with pneumothorax air pockets, gastrointestinal air pockets have lower surface/volume ratios and lower blood flow. Thus, expansion of gas in the gastrointestinal tract is much slower than that in a pneumothorax. In animal studies (see Fig. 26-12), inhalation of 70% to 80% N_2O doubled intestinal gas volume after approximately 2 hours.[48]

N_2O is contraindicated in patients with pneumothorax, pneumocephalus, and closed dura or in those at high risk for vascular air embolus. Air-space expansion can impede surgery when substantial gastrointestinal air is present and N_2O exposure is prolonged, or it can be of

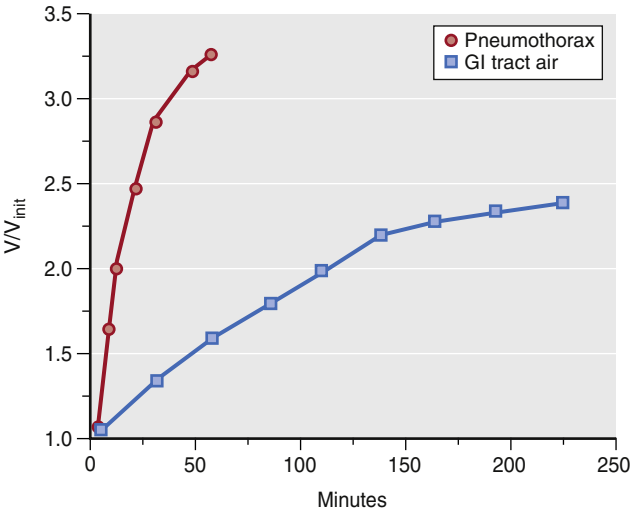

Figure 26-12. The rate of air-space expansion during nitrous oxide administration. The rate and extent of expansion of air pockets injected into either the pleural space *(red circles)* or the gastrointestinal tract *(blue squares)* of dogs during the inhalation of a 25% O_2/75% N_2O gas mixture is shown. Air pockets in stomach, small intestine, and colon expand more slowly than those in a pneumothorax do. *GI,* Gastrointestinal. *(Data are approximations from Eger EI II, Saidman LJ: Hazards of nitrous oxide anesthesia in bowel obstruction and pneumothorax,* Anesthesiology *26:61-66, 1965.)*

little consequence when the initial volume of gas in the gut is small or when the surgery is brief.

RECOVERY FROM ANESTHESIA

Similarities and Differences to Induction

Clearance of inhaled anesthetics from target tissues (brain and spinal cord) is primarily via the same pathways used for anesthetic induction: anesthetic gases flow from tissue into venous blood and then to the lungs. If P_{alv} is less than P_{MV}, then the net flow of anesthetic will be out of the blood and into alveoli, where it is subsequently exhaled. To achieve the fastest clearance possible, P_{circ} must therefore be as low as possible, and this is achieved using high flows of nonanesthetic carrier gases (oxygen and air) after discontinuing delivery of anesthetic. The same factors that affect transalveolar anesthetic exchange during induction also affect clearance via this route. Increasing ventilation will accelerate clearance (see Fig. 26-4), whereas increased cardiac output slows clearance, because more gas-exchange volumes are required to remove anesthetic from the larger blood flow (see Fig. 26-5). Highly blood-soluble anesthetics, which increase the effective blood flow, clear more slowly than insoluble anesthetics (see Fig. 26-6). Return to consciousness, which usually occurs after P_{CNS} drops below MAC-awake, is faster following desflurane or sevoflurane anesthesia than after isoflurane anesthesia. N_2O, which is characterized by blood solubility similar to that of desflurane, provides an even faster return to consciousness, because of two additional advantages. First, the concentration effect works in reverse during clearance for N_2O, increasing effective alveolar ventilation and maintaining the gradient for flow from pulmonary blood to alveoli. Second, MAC-awake for N_2O (0.71 atm at 40 years old) is near typical inhaled concentrations during general anesthesia; therefore, elimination of only a small fraction of this drug is associated with return to consciousness. This is also why N_2O as the sole hypnotic drug is associated with a high risk of intraoperative awareness, which can be prevented by using a balanced gas mixture of N_2O together with end-tidal concentrations of approximately 1 × MAC-awake of a second potent inhaled anesthetic.

Body composition has an increasing effect as the length of anesthetic exposure increases, especially for highly soluble anesthetics. Compared with standard models, patients with increased muscle or fat have larger volumes of anesthetic drug distribution over time, resulting in slower clearance rates.[55] One important difference between anesthetic uptake and clearance is that although overpressure can be used to hasten uptake and induction of anesthesia, the vaporizer setting cannot be set to less than zero. Thus, the most readily modifiable factors to affect the rate of anesthetic clearance are fresh gas flow and minute ventilation.

Context Sensitive Recovery from Anesthesia

Although the concept of context-sensitive half-time is typically applied to continuously infused intravenous drugs that distribute among multiple pharmacokinetic compartments, the concept also applies to inhaled anesthetics.[56] After a short period of inhalation and uptake, anesthetic clearance from blood is rapid through both exhalation and distribution to muscle and other tissues. As a result, P_{alv} decreases rapidly to a low value after discontinuing anesthetic delivery. After prolonged periods of inhalation and uptake, the anesthetic partial pressures in muscle and other compartments increase closer to that in blood, reducing the contribution of distributive clearance. Instead, clearance from the central blood compartment is slowed by the reverse flow of anesthetic from the high-capacity tissues. Thus, in comparison with a short period of inhalation, prolonged inhaled anesthesia is followed by a smaller initial decrease in P_{alv} and a more pronounced slow clearance phase, resulting in slower recovery from anesthesia (Fig. 26-13). As with other factors, context sensitivity is exaggerated in highly soluble anesthetics, and it has less impact with anesthetics that display low blood and tissue solubilities.[57] The relative advantage of low blood solubility anesthetics increases with the duration of anesthesia. There is only a small difference (2.5 minutes) between predicted times to awakening after a short anesthetic with isoflurane versus desflurane, but significantly faster awakening can be achieved using the low-solubility drug for long cases.

Percutaneous and Visceral Anesthetic Loss

Aside from pulmonary exchange, some portion of inhaled anesthetics is lost by diffusion through other large area interfaces between the body and surrounding air. The skin surface area of an average human is approximately 2 m^2, and blood flow through skin during general anesthesia may be substantial because of inhibition of normal thermoregulatory vasoconstriction.[30] Nonetheless, transcutaneous losses of general anesthetics probably contribute negligibly to their clearance.[58,59] During open abdominal or thoracic surgery, visceral surfaces are also

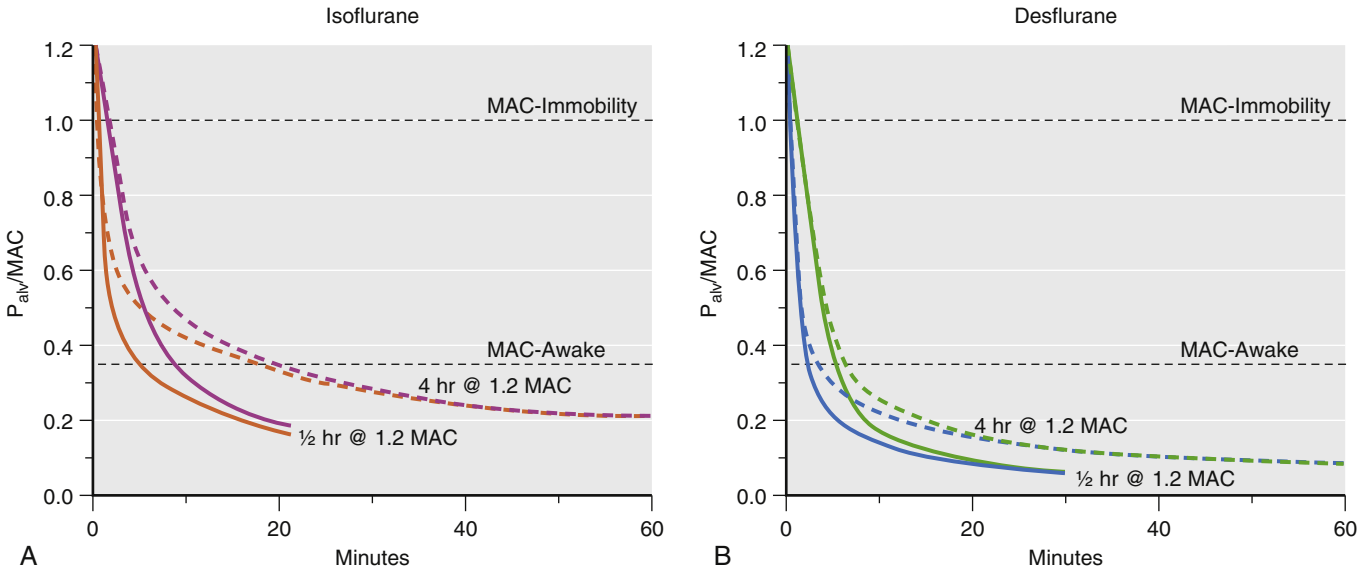

Figure 26-13. Inhaled anesthetic washout and time to awakening depends on duration of anesthesia. The panels depict model calculations of P_{alv} and P_{CNS} normalized to MAC during washout at 10 L/min FGF following anesthesia at approximately 1.2 × MAC-immobility for 30 minutes *(solid lines)* or 4 hours *(dashed lines).* The MAC-awake (approximately 0.34 × MAC-immobility) is shown to indicate the threshold below which typical patients regain perceptive awareness after general anesthesia. Although P_{alv} drops earlier than P_{CNS}, the clinically relevant endpoint (return of consciousness) is predicted when P_{CNS} falls below MAC-awake. **A,** Washout using a pharmacokinetic model for isoflurane (orange is P_{alv}, purple is P_{CNS}). The 30-minute isoflurane uptake was 990 mL of vapor, and the 4-hour isoflurane uptake was 3420 mL of vapor. Prolonged anesthesia with isoflurane dramatically increases the time required to wash out sufficient drug to achieve awakening. After a 30-minute anesthetic, P_{CNS} drops to MAC-awake in 9 minutes, whereas it takes more than 20 minutes of wash-out to reach the same P_{CNS} following a 4-hour anesthetic. **B,** Washout using a desflurane model (*blue* is P_{alv}, *green* is P_{CNS}). The 30-minute desflurane uptake was 1530 mL of vapor, and the 4-hour desflurane uptake was 4600 mL of vapor. The predicted times to awakening (5.2 versus 6.3 minutes) are much closer following different durations of desflurane anesthesia, because of its low blood solubility. Clinical studies demonstrate that emergence and recovery (time to extubation) following isoflurane anesthesia nearly doubles when exposure increases from 20 minutes to 75 minutes, while extubation is achieved in less than 10 minutes following desflurane anesthesia from 20 to 100 minutes' duration. P_{alv}, Alveolar anesthetic partial pressure; P_{CNS}, partial pressure in the central nervous system; *CO,* Cardiac output; FGF, fresh gas flow; *MAC,* minimum alveolar concentration; *MV,* minute ventilation; P_{alv}, alveolar anesthetic partial pressure; P_{CNS}, partial pressure in the central nervous system; P_{MV}, anesthetic partial pressure in mixed venous blood.

directly exposed to air, and under these circumstances, anesthetic losses via direct transfer and air movements are larger than those via skin, but are still a small fraction of total clearance.[60]

Effect of the Anesthetic Circuit

As mentioned earlier, circuit components, including tubing, connectors, manual ventilation bag, and CO_2-absorbent material, absorb inhaled anesthetics, effectively creating another compartment that fills while anesthetic is flowing and needs to be emptied during washout.[19] Low-level release of anesthetic gases from these components can continue for a considerable time.

Clearance via Metabolism of Anesthetics

Metabolism of inhaled anesthetics in tissues, particularly liver, contributes to a variable degree to drug clearance. Metabolism of inhaled anesthetics is reviewed in detail in the second part of this chapter (see Metabolism and Toxicity). Methoxyflurane, a drug that is no longer in clinical use, and halothane, an older drug that is rarely used in the United States, are highly metabolized inhaled anesthetics. Methoxyflurane undergoes extensive metabolism in humans, with only 19% of an inhaled dose recovered in exhaled gases.[61] Approximately 20% to 25% of inhaled halothane is metabolized through biotransformation in the liver. A high rate of metabolism will reduce the anesthetic partial pressure in tissues, resulting in reduced P_{MV} and increased rates of overall anesthetic clearance. Tissue-dependent breakdown contributes less to clearance of newer inhaled anesthetics.

Additional Considerations and Possibilities

Modern inhaled anesthetics such as sevoflurane and desflurane have low blood solubility, and therefore provide a distinct advantage for both anesthetic induction and recovery from anesthesia. However, they present no advantage over older drugs such as isoflurane for maintenance of anesthesia during long cases. What if anesthesia is induced with one drug, followed by a switch to isoflurane during the maintenance period and then back to the more soluble drug, such as desflurane, for a period preceding emergence? This might allow for rapid induction and wake-up. Although a fast wake-up can be achieved by allowing sufficient time for near total washout of isoflurane and its replacement with desflurane, this type of crossover requires significant lead-time and high fresh gas flows. As an illustration, Neumann and colleagues[62] compared 2-hour anesthetics at 1.25 × MAC (2 L/min FGF) with isoflurane alone, desflurane alone, or isoflurane with a crossover to desflurane during the last half hour. Although subjects awoke faster with desflurane alone, the crossover strategy did not result in acceleration of wake-up compared with isoflurane alone.

Diffusion Hypoxia

Diffusion hypoxia is an additional sequelae of rapid outgassing from the tissues of patients anesthetized with N_2O. During the initial 5 to 10 minutes after discontinuation of anesthesia, the flow of N_2O from blood into the alveoli can be several liters per minute, resulting in dilution of alveolar oxygen.[63] Another effect of rapid outgassing is dilution of alveolar P_{CO_2}, which can also reduce respiratory drive.[64] If the patient does not receive supplemental oxygen during this period, then the combined effects of respiratory depression from anesthesia, reduced alveolar P_{CO_2}, and reduced alveolar P_{O_2} can result in hypoventilation and oxyhemoglobin desaturation. This outcome is routinely avoided by providing supplemental O_2 for the first 1 to 10 minutes of recovery, together with vigilant attention to respiration.

METABOLISM AND TOXICITY OF INHALED ANESTHETICS

This portion of the chapter focuses on adverse effects that are attributable to inhaled anesthetics, excluding most of the acutely reversible pharmacodynamic effects of inhaled anesthetics on various physiologic systems (see Chapters 27, 28, and 29).

The inhaled anesthetics are a unique group of drugs that can enter and leave the body unchanged through the lungs. Thus, chemical transformation of inhaled anesthetics is unrelated to their therapeutic activities, such as amnesia, hypnosis, and immobilization. Nonetheless, the carbon-halogen and other bonds of volatile alkanes and ethers can break down under certain conditions: biotransformation by enzymes in various tissues, reactions with strong bases in CO_2 adsorbents, and exposure to ultraviolet radiation in the environment. Anesthetic breakdown resulting from decomposition in tissues or the breathing circuit can produce toxic reactive intermediates, which in sufficient amounts can harm patients directly or indirectly. N_2O gas is not biotransformed but selectively reacts with and inactivates vitamin B_{12} and perturbs B_{12}-dependent biochemical pathways. The breakdown of waste anesthetics in the atmosphere also has potential environmental and health consequences. There are potential long-term neurotoxic effects of anesthetic exposure that are not associated with chemical breakdown.

BIOTRANSFORMATION OF INHALED ANESTHETICS

The extent and location of inhaled anesthetic metabolism depends on multiple chemical factors. Inhaled anesthetics undergo varying degrees of biotransformation (Table 26-3) in various tissues. Methoxyflurane undergoes by far the greatest metabolism, estimated at 70%, and experiments indicate that only a small fraction of drug taken up into body tissues is exhaled.[61] Given the remarkable lipophilicity of methoxyflurane, respiratory clearance of this drug from muscle and fat extends over a period of days (see Tables 26-1 and 26-2). Halothane is the next most lipophilic drug and ranks second in metabolic clearance (see Table 26-3). Thus, prolonged residence in body tissues is an important factor in biotransformation of inhaled anesthetics. Chemical stability is another important factor. Isoflurane is an isomer of enflurane, and the two drugs display comparable respiratory uptake, distribution, and respiratory clearance. Nonetheless, isoflurane is metabolized only one tenth as much as enflurane. Although sevoflurane and desflurane represent another pair of anesthetics, both characterized by rapid uptake, distribution, and respiratory clearance, 5% of sevoflurane is biotransformed versus 0.02% of desflurane.

Of the major organs involved in anesthetic biotransformation, the liver and kidneys are exposed to the highest metabolite concentrations and thus are most susceptible to damage from toxic metabolites. Clinically significant hepatotoxicity is primarily associated with exposure to halothane, and nephrotoxicity is associated with methoxyflurane.[90] Investigations into the mechanisms of these toxicities have influenced drug development and provided important insights into human toxicology.[91]

Biotransformation in Liver

The liver is the major site of metabolism for most drugs, particularly lipophilic drugs, which typically are transformed into hydrophilic metabolites that are more readily excreted. The liver is large and contains high concentrations of many drug-metabolizing enzymes. Other organs that contribute to drug metabolism and clearance include the gastrointestinal tract, kidneys, and the lungs.[92,93] Drug biotransformation reactions include oxidation, hydrolysis, and conjugation. A single drug can be transformed into several metabolites, depending on the relative rates of various enzyme reactions, the drug concentration in different tissues expressing relevant enzymes, competition at enzyme sites with other drugs or endogenous substances, and other factors. Oxidation and hydrolysis are also known as *phase 1 reactions,* and they result in introduction or exposure of a polar group on the drug. The phase 1 enzymes that metabolize inhaled anesthetics in the liver are various cytochrome P450 (CYP) isoforms in the endoplasmic reticulum of hepatocytes. These enzymes catalyze oxidation reactions, such as dehalogenation, N- and O-dealkylation, N- and S-oxidation, and deamination. These reactions require oxygen and reduced nicotinamide adenine dinucleotide phosphate (NADPH)-dependent cytochrome P450 reductase as cofactors. Under hypoxic conditions, some P450 enzymes can also catalyze reductive reactions. More than 50 CYP isoforms are active in humans, and CYP3A4 and CYP3A5 are the most abundant. Conjugations are also known as phase 2 reactions, and they often append highly polar groups such as glucuronic acid, sulfate, or glycine to polar groups on phase 1 metabolites. The resulting hydrophilic products are readily excreted in urine via the kidneys or in bile via the gastrointestinal tract. *N*-Acetylation reactions are an exception that result in metabolites that are less water soluble than the parent drug.

Many factors affect hepatic drug metabolism, including concomitant drugs, disease, age, and genetics.[57] Induction and inhibition of enzymes are associated with exposure to certain drugs or other exogenous substances. Induction of specific CYP isoforms is a gene-mediated response to chronic exposure to substrates of the enzyme, resulting in accelerated enzyme production or slowed turnover. For example, phenobarbital use results in increased production of CYP3A4 and NADPH-cytochrome P450 reductase, leading to dramatically increased metabolism of all CYP3A4

TABLE 26-3 METABOLISM OF HALOGENATED VOLATILE ANESTHETICS

substrates. Enhanced metabolism can reduce drug efficacy (and therefore is one mechanism of drug tolerance) or, in cases of pro-drug transformation to active metabolites, increase efficacy. If metabolites are toxic, as is the case with volatile anesthetics, enhanced metabolism may increase toxicity. Conversely, CYP inhibition leads to enhanced activity of parent drugs and reduced metabolite effects. CYP enzyme inhibition is associated with hepatic disease and exposure to certain substances. An important example is CYP3A4 inhibition by grapefruit juice.[94] Regarding volatile anesthetics, the major oxidative enzyme CYP2E1 is inducible by ethanol and isoniazid and is inhibited by disulfiram.[95] Diseases such as hepatitis, various cirrhotic diseases, and hepatocarcinoma can also reduce enzymatic activity, as can cardiac failure with reduced hepatic perfusion.

Neonates have different dominant CYP isoforms compared with adults (see Chapters 93 and 94). Impaired hepatic metabolism is common in premature and full-term infants, notably in bilirubin glucuronidation, leading to hyperbilirubinemia of the newborn.[96,97] Pharmacogenomics is a growing area of pharmacologic research that has linked variable drug metabolism to genetic variability. A well-established example in anesthesiology is homozygous inheritance of atypical butyrylcholinesterase, resulting in slow hydrolysis of succinylcholine.[98] Genetic variations in CYP2D6 have clarified the basis for widely varying efficacies and toxicities of codeine, metoprolol, nortriptyline, dextromethorphan, and other substrate drugs.[99]

Hepatic CYP2E1 is particularly important in the oxidative metabolism of halogenated inhaled anesthetics (see Table 26-3). Under conditions of hypoxia or decreased blood flow, or in liver regions of low P_{O_2}, CYP2A6 and CYP3A4 catalyze the breakdown of volatile anesthetics via reductive pathways. Halothane metabolism is primarily oxidative, and under normal conditions, approximately 1% of halothane undergoes reductive metabolism. Oxidative metabolism of halothane results in release of chloride and bromide ions, resulting in trifluoroacetyl chloride, which reacts with water to form trifluoroacetic acid (Fig. 26-14). Reductive metabolism of halothane results initially in loss of bromide, and the intermediate either reacts with a hydrogen donor to form 2-chloro-1,1,1-trifluoroethane or captures an electron, further reducing the carbon-carbon bond to form 2-chloro-1,1-difluoroethylene (see Fig. 26-14). Halothane reduces hepatic blood flow and can cause hepatocellular hypoxia in some regions in the liver, potentially leading to an increase in its reductive metabolism.[90] All the ether anesthetics undergo similar oxidative metabolism catalyzed by CYP2E1 (see Table 26-3, Fig. 26-15). Oxidative metabolism of these drugs results in the release of fluoride (F^-) and chloride (Cl^-) ions and the formation of reactive intermediates that react with water to form carboxylic acids. Isoflurane and desflurane both produce trifluoroacetic acid, whereas enflurane forms 2-difluoromethoxy-2,2-difluoroacetic acid. Oxidative metabolism of methoxyflurane can follow several paths, releasing Cl^- or F^- in sequential steps and producing methoxy-difluoroacetic acid, dichloroacetic acid, and acetic acid (see Table 26-3).

Halothane Hepatotoxicity

The first modern halogenated volatile anesthetic, halothane, was introduced in 1955. Clinical exposure to halothane is associated with two distinct types of hepatic injury.[100,69,101] Subclinical hepatotoxicity occurs in 20% of adults who receive halothane. It is characterized by mild postoperative elevations in alanine aminotransferase and aspartate aminotransferase, but is reversible and innocuous. Anaerobic halothane reduction by CYP2A6 to a 2-chloro-1,1,1-trifluoroethyl radical (see Fig. 26-14) is thought to mediate this mild hepatic injury.[65] The fulminant form of hepatotoxicity, commonly known as halothane hepatitis, is characterized by elevated alanine aminotransferase, aspartate aminotransferase, bilirubin, and alkaline phosphatase levels, and massive hepatic

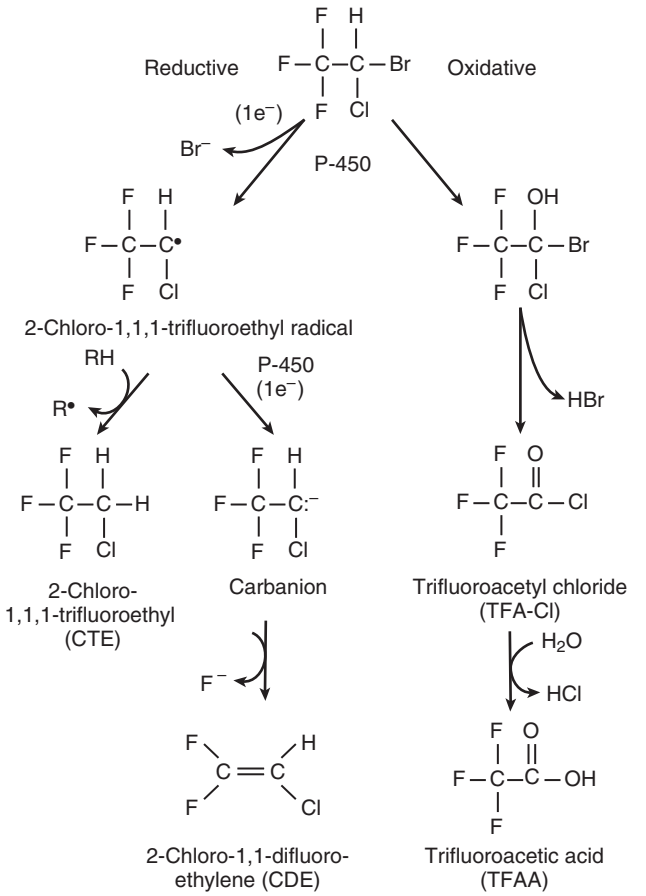

Figure 26-14. Oxidative and reductive metabolism of halothane. Major products of hepatic CYP2E1 catalyzed halothane metabolism are shown. Under normal conditions, 24% of halothane undergoes oxidative metabolism, and 1% undergoes reductive metabolism.

necrosis following the administration of halothane. Halothane hepatitis is rare (1 in 5000 to 35,000 administrations in adults), but is fatal in 50% to 75% of these cases. Because of the potential for fatal hepatitis, halothane is no longer used in adult patients in many countries.

Halothane hepatitis is caused by a hypersensitivity reaction associated with oxidative metabolism of halothane. The highly reactive trifluoroacetyl chloride metabolite of halothane oxidation can react with nearby liver proteins (see Table 26-3). In most patients who developed hepatic necrosis after halothane anesthesia, antibodies against TFA-modified proteins were detected, suggesting that the hepatic damage is linked to an immune response against the modified protein, which acts as a neoantigen (see Figure 26-16). Accordingly, patients who develop halothane hepatitis often have a history of prior exposures to halothane or other volatile anesthetics, together with symptoms suggestive of immune reactivity, such as fever, rash, arthralgia, and eosinophilia.[66] A current hypothesis is that TFA-protein adducts induce a cytotoxic T cell reaction in sensitized individuals, which leads to liver damage.[69] However, the immune responses observed in halothane hepatitis might not mediate liver injury.

Hepatotoxicity and massive hepatic necrosis has occurred after halothane anesthesia in pediatrics (see Chapter 93). However, two large retrospective studies have demonstrated that the clinical syndrome of halothane hepatitis is even more rare in the pediatric population (1 in 80,000 to 200,000) than in adults.[102-104] Halothane is metabolized to a similar degree in adults and children. The children are immune competent from birth. Pediatric cases of halothane hepatitis are also associated with multiple anesthetic exposures, suggesting a mechanism similar to that in adults. Why the incidence of halothane hepatitis is more frequent in the adult population is not known.

Other volatile anesthetics including enflurane, isoflurane, and desflurane have also been associated with fulminant hepatic necrosis,[82,105-109] but compared with halothane, the incidence of this potentially fatal toxicity is rare after administration of these newer volatile anesthetics. The mechanism of severe hepatitis following enflurane, isoflurane, and desflurane may be the same as for halothane, because all these drugs are oxidatively metabolized to highly reactive intermediates that can covalently modify hepatic proteins (Fig. 26-16). As with halothane, case investigations usually reveal that patients have had prior exposure to volatile anesthetics, and antibodies to modified hepatic proteins can be detected. The extremely infrequent incidence of severe hepatitis for modern volatile anesthetics is likely due to their lower degree of oxidative metabolism and subsequent immune sensitization. In fact, hepatitis was also commonly reported soon after introduction of methoxyflurane, another highly metabolized anesthetic that is metabolized to highly reactive acidic intermediates.[70,110] Unlike all other volatile anesthetics, sevoflurane is oxidized at the fluoromethoxy C-H bond and forms hexafluoroisopropanol and inorganic F^- (see Table 26-3; Fig. 26-17).[111,112] Hexafluoroisopropanol is relatively stable, and modified liver proteins are not formed after sevoflurane anesthesia. Cases of hepatitis and rapid death after sevoflurane anesthesia have been reported, but there was no evidence of an immune-mediated mechanism.[86]

Biotransformation in Kidneys

The kidneys are large organs that receive high blood flow. Renal physiologic activities include glomerular filtration of water-soluble metabolites, reabsorption of water and essential metabolites, urinary excretion of waste, and regulation of hormones involved in vascular tone (renin) and water balance (aldosterone). The kidneys clear most of the water-soluble metabolites resulting from biotransformation of inhaled anesthetics. Kidneys also contain CYP enzymes, including CYP2E1, that catalyze both phase 1 and phase 2 reactions and are therefore additional sites where inhaled anesthetic metabolism occurs. As in the liver, various CYPs in renal parenchyma can undergo induction or inhibition by exogenous substances.[113-116]

Fluoride-Associated Nephrotoxicity

The first modern halogenated ether anesthetic, methoxyflurane, was introduced in 1959. Methoxyflurane causes polyuric renal insufficiency, and it is no longer used in clinical practice.[117] The nephrotoxic effect of methoxyflurane is attributed to inorganic fluoride (F^-) released during its metabolism. Investigations have provided significant insights into potential nephrotoxic mechanisms by fluorinated volatile anesthetics and have influenced the development of subsequent halogenated anesthetic agents.

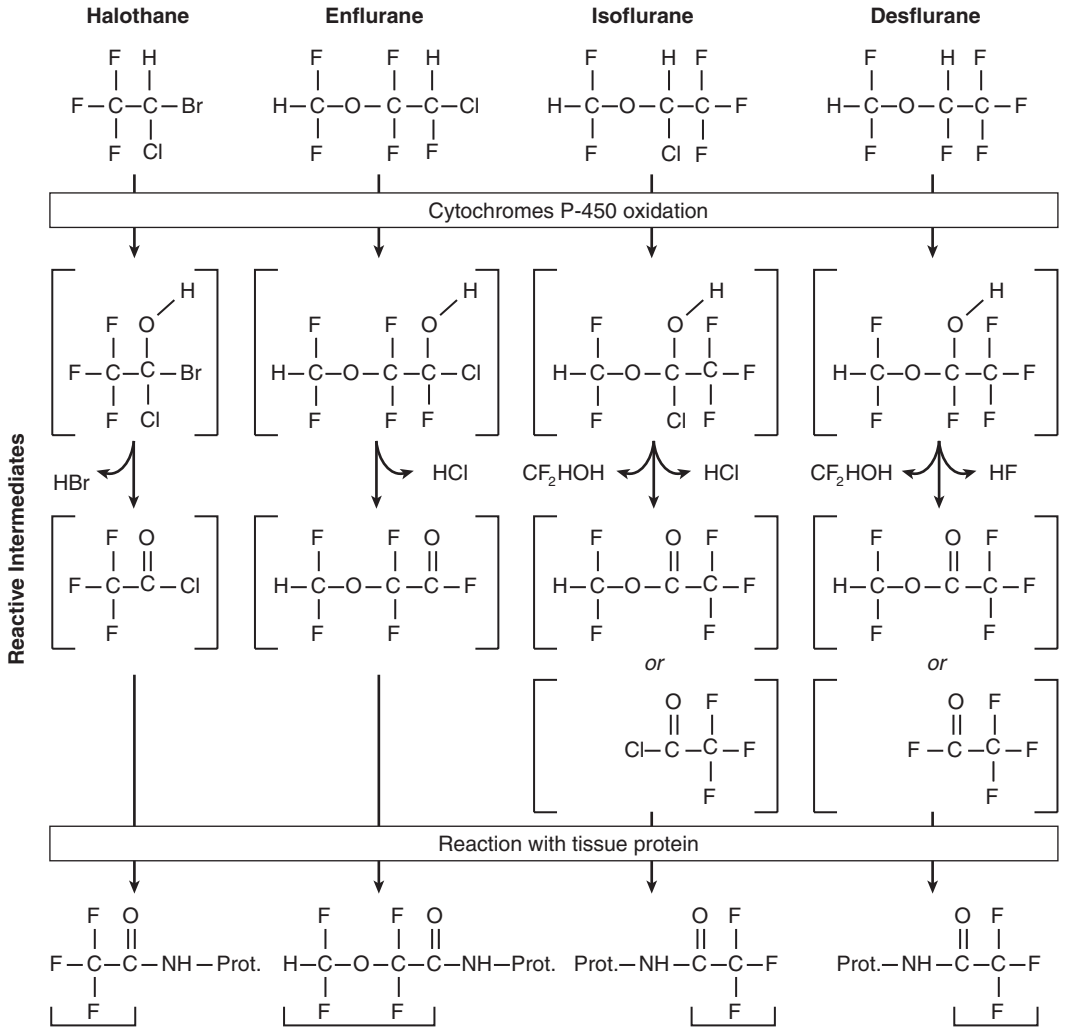

Figure 26-15. Proposed pathways for inhaled anesthetic metabolism to reactive intermediates. CYP2E1 catalyzes oxidative metabolism of halothane, enflurane, isoflurane, and desflurane to a variety of reactive intermediates that can form adducts with hepatocellular proteins. Trifluoroacetylated proteins are identical after halothane, isoflurane, and desflurane, whereas adducts following enflurane are immunologically similar.

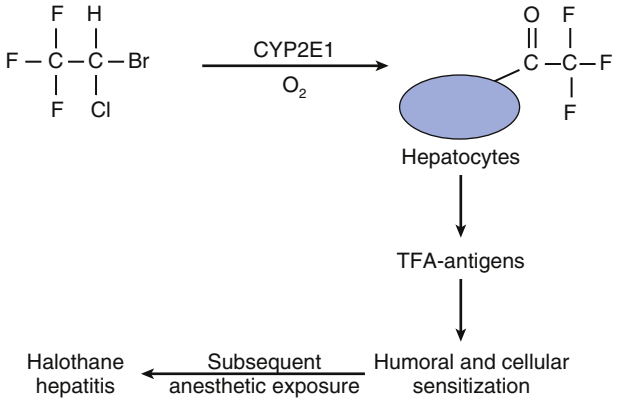

Figure 26-16. Pathways generating the immune response after exposure to inhaled anesthetics. Halothane is metabolized to a reactive trifluoroacetyl intermediate that forms an amide bond with hepatocellular proteins. The altered protein triggers an immune response, which on subsequent exposure to anesthetic results in hepatocellular damage and necrosis. A similar process may ensue after exposure to other fluorinated drugs metabolized to similar halo-acyl intermediates. *(Modified from Njoku D, Laster MJ, Gong DH, et al: Biotransformation of halothane, endflurane, isoflurane and desflurane to trifluoroacetylated liver proteins: association between protein acylation and liver injury,* Anesth Analg *84:173-178, 1997.)*

Absorbed methoxyflurane undergoes extensive biotransformation,[61] including cytochrome-catalyzed oxidation that releases inorganic fluoride ions (F^-) into blood. Animal studies provide clear evidence of the nephrotoxicity of methoxyflurane, which includes a strong relationship between methoxyflurane dose and renal injury,[118] increased nephrotoxicity with induction of CYP enzymes,[119,120] and decreased nephrotoxicity with inhibition of methoxyflurane metabolism.[75,121] Clinical data further indicate that severity of nephrotoxicity and mortality are associated with high plasma fluoride concentrations after methoxyflurane anesthesia.[122,123] Patients with serum inorganic fluoride levels below 50 μM had no evidence of renal injury, whereas patients with post-methoxyflurane serum F^- greater than 50 μM suffered high rates of renal dysfunction and increased mortality.[72,124] Moreover, serum F^- concentrations were significantly higher after the administration of methoxyflurane than with other halogenated volatile anesthetics, which are not associated with nephrotoxicity (Fig. 26-18). Inorganic fluoride released during methoxyflurane metabolism likely causes renal injury, and the nephrotoxic threshold for plasma F^- is approximately 50 μM. Individual variability among patients in the degree of apparent

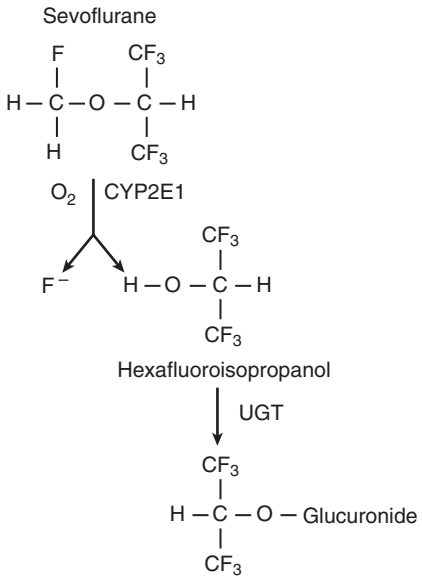

Figure 26-17. Metabolic oxidation of sevoflurane. CYP2E1 catalyzes phase 1 defluorination of sevoflurane, forming hexafluoroisopropanol. Phase 2 glucuronidation is catalyzed by uridine 5′-diphosphate glucuronosyltransferase.

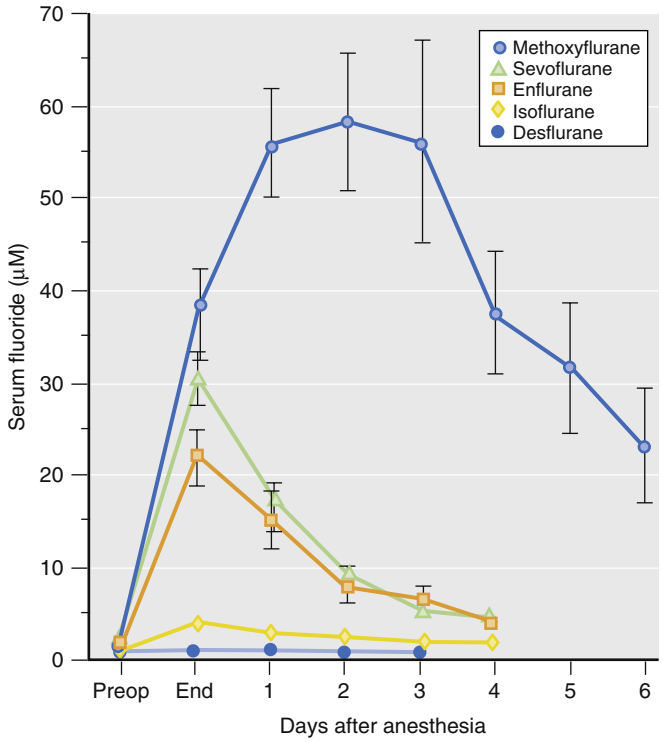

Figure 26-18. Serum inorganic fluoride (F^-) exposure before and after methoxyflurane anesthesia is much greater than with other anesthetics. Points represent serum F^- measurements (mean ± SD) from multiple subjects. After 2 to 3 MAC-hours of methoxyflurane anesthesia, F^- rises during and after drug administration ends, peaks above 60 μmol/L on postanesthesia days 2 and 3, then declines slowly, remaining elevated for more than 1 week. Sevoflurane anesthesia (3.7 MAC-hours) produces an early peak F^- concentration averaging 31 μmol/L, which declines over 3 to 4 days. Enflurane anesthesia (2.7 MAC-hours) results in an early average peak of 22 μmol/L which declines in 3 to 4 days. Isoflurane and desflurane result in small and negligible rises in serum F^- concentrations. Only methoxyflurane is associated with fluoride-associated renal toxicity. MAC, minimum alveolar concentration.

renal injury after methoxyflurane exposure was observed. Genetic heterogeneity, drug interactions, and preexisting renal disease probably account for these differences.

Since the introduction of methoxyflurane, all prospective halogenated anesthetic drugs have been extensively tested experimentally and clinically for their degree of defluorination and the resulting serum F^- concentrations. However, experience with newer drugs, particularly with sevoflurane, has caused investigators to reexamine the classical fluoride-induced nephrotoxicity hypothesis. Sevoflurane was initially synthesized in the 1970s, but because of its relatively large defluorination rate (2% to 5%), its introduction into clinical practice was delayed. It was first used widely in Japan in 1990. Subsequent clinical studies demonstrated no clinically significant nephrotoxicity after the administration of sevoflurane, even when high peak F^- concentrations greater than 50 μM were confirmed.[111] Typical peak fluoride concentrations after 2 to 3 MAC-hours of sevoflurane anesthesia are 20 to 30 μM, and less than 5 μM after isoflurane and desflurane (see Fig. 26-18). Enflurane metabolism also often results in peak F^- concentrations greater than 20 μM. Isoflurane and desflurane are metabolized minimally, and they produce lower plasma fluoride concentrations. However, none of these anesthetics is associated with clinically significant renal toxicity, suggesting that methoxyflurane is unique in its ability to harm kidneys. One difference between methoxyflurane and the current volatile anesthetics is its extreme lipophilicity and extremely long residence time in tissues. This results in prolonged elevated F^- concentrations in blood (see Fig. 26-18), suggesting that the length of F^- exposure is a key risk factor. However, prolonged, moderate increases of plasma fluoride (25 to 38 μM) during several days of isoflurane anesthesia have occurred without adverse renal effects.[125,126] Thus, neither the peak level nor the duration of high plasma fluoride concentration entirely explains the nephrotoxic effects by the halogenated anesthetics. It is also not clear whether the integrated concentration multiplied by time exposure to inorganic F^- represents the key risk factor; however, methoxyflurane is metabolized significantly within kidney parenchyma, producing high intrarenal inorganic fluoride concentrations (likely much higher than those measured in blood), which are proposed to cause renal injury.[71,73] Thus, compared with methoxyflurane, the absence of renal toxicity with current volatile anesthetics likely derives from a combination of factors: (1) their lower tissue solubilities, particularly in kidney (see Table 26-2), resulting in lower intrarenal fluoride production; (2) lower rates of biotransformation; and (3) more rapid respiratory clearance from the body.

ANESTHETIC DEGRADATION IN CARBON DIOXIDE ABSORBENTS

Sevoflurane, Compound A, and Renal Toxicity

Halogenated anesthetics can undergo chemical breakdown while interacting with CO_2 absorbents that contain strong bases such as sodium hydroxide (NaOH) and potassium hydroxide (KOH), which are present in soda lime and Baralyme.[127] Strong bases extract a proton from

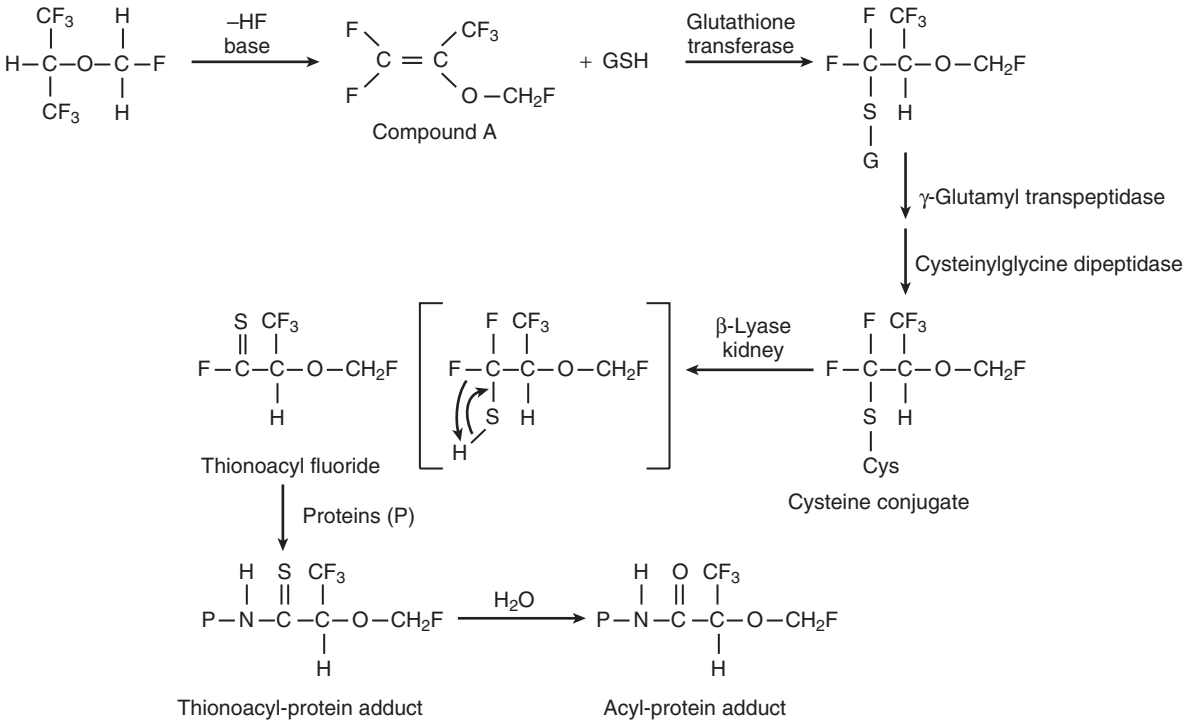

Figure 26-19. Proposed pathway mediating nephrotoxic effects of compound A in rodents. Sevoflurane degrades to compound A in the presence of strong base in some CO_2 absorbent materials. Compound A itself is not nephrotoxic but undergoes hepatic S-conjugation with glutathione. In the kidney, additional metabolic steps produce an S-cysteine compound A conjugate, which is metabolized by β-lyase to a reactive thionoacyl fluoride that is proposed to damage proteins essential for kidney function. Humans have very low β-lyase activity, which is hypothetically the basis for the lack of reported nephrotoxicity in patients. *GSH,* Glutathione; *HF,* hydrofluoric acid. *(Adapted from Martin JL, Kandel L, Laster MJ, et al: Studies of the mechanism of nephrotoxicity of comound A in rats,* J Anesth *11:32-37, 1997.)*

the isopropyl group of sevoflurane, primarily forming a haloalkene (fluoromethyl-2,2-difluoro-1-[trifluoromethyl] vinyl ether), known as *compound A* (Fig. 26-19). Compound A is volatile and can be absorbed via alveolar gas exchange. Compound A exposure is nephrotoxic in laboratory animals, causing proximal tubular necrosis and, with sufficient exposure, death. In rats, renal injury is observed with cumulative exposure to compound A above 150 parts per million (ppm)-hours (e.g., 50 ppm inhalation for 3 hours).[128,129] Moderately severe but reversible histopathologic damage was found in rats after 200 ppm-hour exposure, associated with increased blood urea nitrogen (BUN), creatinine, and other measures of renal damage. Compound A exposure greater than 1000 ppm-hours is lethal in half of exposed rats.

Patients given sevoflurane anesthesia are routinely exposed to compound A in rebreathing circuits, and the inhaled concentration is dependent on the fresh gas flow rate and the type of CO_2 absorbent present. Fresh gas flows of 1 L/min result in maximal compound A concentrations of approximately 20 ppm with soda lime and 30 ppm with Baralyme.[130] Higher FGF rates result in a smaller accumulation of compound A in the breathing circuit. However, compound A exposure is not associated with clinically significant nephrotoxicity in humans. There is no threshold exposure level known to cause more than subclinical renal damage. Numerous studies in which human subjects or patients were exposed to greater than 200 ppm-hours of compound A have reported that clinical measures of renal function (BUN, creatinine, urinary protein or glucose, and urine concentrating ability) and laboratory tests for subtle renal damage (*N*-acetyl-β-glucoaminidase, alanine aminopeptidase, γ-GTP, and β_2-microglobulin) remain unchanged.[74,131-134] Kharasch and colleagues[135] compared the effects of low-flow sevoflurane and isoflurane anesthesia in patients with stable renal insufficiency and found no significant difference in postoperative renal function tests. Other studies have reported normal BUN and creatinine, but transient reversible abnormalities in other renal function test values following prolonged sevoflurane anesthesia at low FGF (>330 ppm/hr compound A exposure in one study).[136-139]

The evidence of nephrotoxicity in rats compared with the remarkably benign results in humans suggests that mechanisms of sevoflurane metabolism and toxicity differ between these species. The difference in the nephrotoxic effects of compound A between humans and rats may be attributed to the doses of compound A, interspecies differences in metabolic toxification, and sensitivity of the proximal tubular cells to compound A cytotoxicity.[90] Detailed studies show that in rats, compound A undergoes S-conjugation to cysteine, and that the resulting cysteine conjugate is metabolized by renal β-lyase to form a reactive thionoacyl fluoride intermediate that acylates proteins and has been proposed to mediate the nephrotoxic effect[127,140] (see Fig. 26-19). Human kidneys have far lower β-lyase activity than rat kidneys, accounting for the differential toxicity of compound A in the two species. Inhibition of β-lyase using aminooxy-acetic

†Baralyme was withdrawn from the market in 2004.

acid (AOAA) protects rats from compound A nephrotoxicity,[141] whereas others have found no protective effect of AOAA or other inhibitors in the proposed pathway.[142] Alternative mechanisms underlying compound A toxicity have been proposed, including formation of reactive sulfoxides catalyzed by CYP3A isozymes,[143] which are also more active in rat than in human kidneys.

Although the mechanism underlying compound A toxicity in experimental animals remains uncertain, the clinical data are reassuring concerning the lack of significant sevoflurane nephrotoxicity in humans. Compound A exposure can be limited by careful selection of fresh gas flows, vaporizer output, and CO_2 absorbent materials. The use of 2 L/min fresh gas flows ensures that for the vast majority of patients, exposure to compound A will be below the most conservative threshold for nephrotoxicity. Although clinical studies indicate that sevoflurane is most likely safe even in patients with preexisting renal dysfunction, the drug should be administered in accordance with the approved package labeling guidelines.

Like sevoflurane, halothane degrades in the presence of CO_2 absorbents to form a reactive intermediate, bromochlorodifluoroethylene (BCDFE),[127] which has also been investigated as a possible nephrotoxin. Eger and colleagues[144] found that in comparison with compound A, BCDFE accumulates twentyfold to fortyfold less in breathing circuits and is fourfold less reactive.[144] Thus, the risk of BCDFE nephrotoxicity is negligible.

Carbon Monoxide and Heat

In the presence of strong bases in dry CO_2 absorbents (water content < 5%), some halogenated volatile anesthetics undergo degradation, resulting in the formation of CO, trifluoromethane (CF_3H), and hydrogen fluoride (HF).[127] The factors that determine the amount of CO produced include the chemical makeup of CO_2 adsorbent (KOH > NaOH >> $Ba(OH)_2$, $Ca(OH)_2$), dryness of the adsorbent material, the concentration of volatile agent, and its chemical structure.[145] Baralyme contains 4.6% KOH, whereas soda lime contains 2.5% KOH and 1.5% NaOH and reacts less vigorously with halogenated anesthetics. The relatively weak bases $Ba(OH)_2$ and $Ca(OH)_2$ are other major constituents in CO_2 absorbents, and do not catalyze CO formation (Table 26-4). The anesthetics that contain a difluoromethyl group (difluoromethyl-ethyl ethers) are most susceptible to this degradation and for this group CO production correlates with anesthetic concentration in the breathing circuit (desflurane > enflurane > isoflurane)[146] (Fig. 26-20). Sevoflurane, methoxyflurane, and halothane also degrade in the presence of strong bases, but do not produce CO. Production of CO appears to require nearly complete desiccation (i.e., removal of absorbent moisture) of the CO_2 absorbent, and typically occurs after high flow flushing of the breathing circuit for 1 to 2 days. Soda lime contains 15% water by weight, and Baralyme contains 13% water by weight (see Table 26-4). CO production is observed when water content of soda lime or Baralyme falls below 1.4% and 5%, respectively.[147] High ambient temperatures also accelerate desiccation of CO_2 absorbent materials and may increase the rate of CO producing reactions. As noted with compound A, CO accumulation in the breathing circuit is inversely related to the fresh gas flow.

Anesthetic degradation in the breathing circuit has resulted in CO poisoning during clinical anesthesia.[148,149] CO has 250-fold greater affinity for hemoglobin than O_2 does; therefore, the formation of carboxyhemoglobin reduces blood oxygen carrying capacity and tissue oxygen delivery, and is difficult to reverse. The detrimental effects and signs of CO toxicity are well known; however, with general anesthesia, signs of patient exposure to CO are masked, and hypoxia may be difficult to detect, because some pulse oximetry equipment cannot distinguish between carboxyhemoglobin and oxyhemoglobin.

The degradation of volatile anesthetics by bases in CO_2 absorbents is an exothermic reaction that results in the production of heat. Sevoflurane produces the most heat production when it is used with desiccated CO_2 absorbent. The absorbent canister and anesthetic circuit can reach extremely high temperatures, which can lead to explosion or fire, or both (see Chapter 109).[150,151]

Current recommendations to minimize anesthetic degradation to CO and heat include machine maintenance measures to avoid desiccation of CO_2 absorbent and the use of absorbents that contain less KOH and NaOH. Newer CO_2 absorbents (see Table 26-4) contain

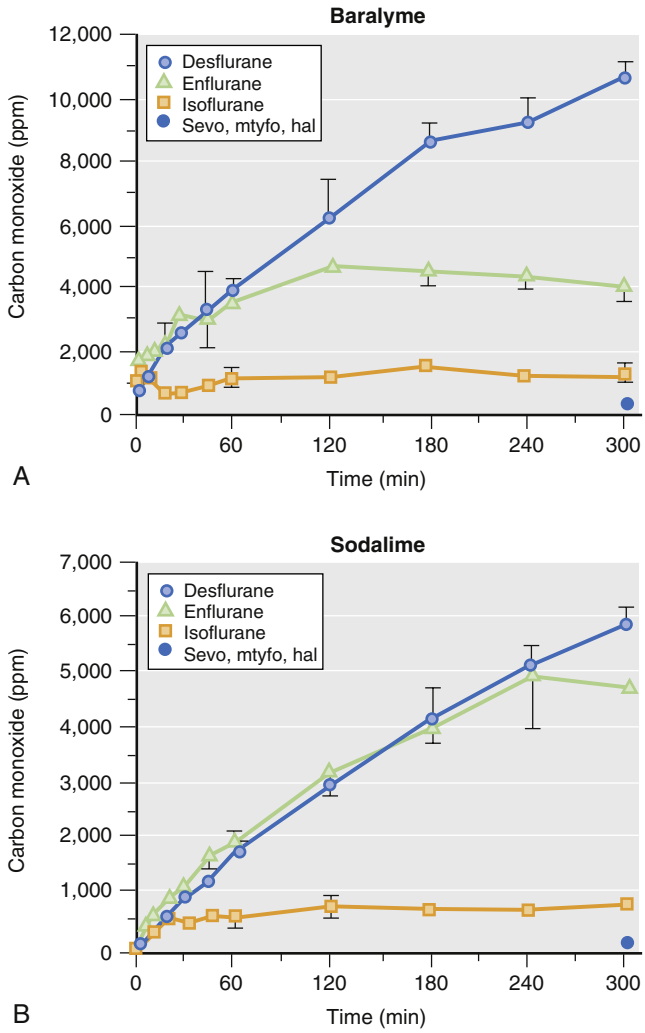

Figure 26-20. Inhaled anesthetic degradation and carbon monoxide production. Points represent mean ± SD of three measurements with equivalent anesthetic doses (1.5 × MAC) in the presence of dry CO_2 absorbents at identical fresh gas flows. **A,** Degradation and CO production with Baralyme. **B,** Degradation and CO production with soda lime. Degradation and CO production was observed with anesthetics containing difluoromethoxy groups (desflurane, enflurane, and isoflurane), but not halothane (hal) or those with monofluoromethoxy groups such as sevoflurane (sevo) and methoxyflurane (mtyfo). *MAC,* Minimum alveolar concentration. *(Adapted from Baxter PJ, Garton K, Kharasch ED: Mechanistic aspects of carbon monoxide formation from volatile anesthetics,* Anesthesiology *89:929-941, 1998).*

little or no strong base and do not degrade volatile anesthetics, regardless of hydration status.[130,152,153] The use of the newer CO_2 absorbents also reduces production of compound A during sevoflurane anesthesia.[154-156]

NITROUS OXIDE, VITAMIN B_{12}, AND HOMOCYSTEINE

N_2O is unique among anesthetics in irreversibly inhibiting cobalamins (vitamin B_{12}) by oxidizing the Co (I) ligand. Cobalamins are ingested or produced by bacteria in the gut, and they are critical cofactors together with 5-methyltetrahydrofolate in the activity of methionine synthase (Fig. 26-21). Methionine synthase catalyzes methylation of homocysteine to methionine, while also demethylating 5-methlytetrahydrofolate to produce tetrahydrofolate. Methionine, converted to S-adenosylmethionine, is the major substrate for methylation in biochemical pathways involved in the synthesis of DNA, RNA, myelin, and catecholamines.[157] Chronic vitamin B_{12} deficiency (as in pernicious anemia) results in hematologic and neurologic dysfunction. Long-term N_2O exposure, typically among individuals who frequently inhale it as a recreational drug, can also cause megaloblastic anemia, myelopathy, neuropathy, and encephalopathy, sometimes presenting as psychosis.[79,158,159] Risk factors that increase susceptibility to N_2O toxicity include pernicious anemia or other gastrointestinal malabsorption syndromes, extremes of age, alcoholism, malnutrition, a strict vegetarian diet, and inborn deficiencies in cobalamin or tetrahydrofolate metabolism.[79] Inhibitors of folate metabolism, such as methotrexate, can also enhance sensitivity to N_2O toxicity.[160]

In healthy surgical patients, megaloblastic changes in the bone marrow are rare, and reported only after a prolonged period of exposure (>12 hours) to N_2O. However, in seriously ill patients or those with risk factors noted earlier, shorter (or repetitive) periods of N_2O exposure can lead to significant subacute pathology. Megaloblastic bone marrow changes can be induced after a short period (2 to 6 hours) of N_2O exposure.[161] Vitamin B_{12} deficiency or reduced methionine synthase activity can also lead to subacute myelinopathy and neuropathy.[162-165] A case highlighting the potential importance of inborn metabolism was reported by Selzer and associates.[166] In this case, a 4-month-old child developed an irreversibly and ultimately fatal seizure disorder several weeks after receiving N_2O during anesthesia. Autopsy revealed widespread brain atrophy and demyelination, and biochemical investigations revealed reduced methyltetrahydrofolate reductase (MTHFR) activity, which eventually were linked to several mutations in the gene encoding MTHFR.

Another consequence of reduced methionine synthase activity is accumulation of its substrate, homocysteine (see Fig. 26-21). Homocystinuria caused by severe inborn deficiency of methionine synthase activity is associated with extremely increased blood homocysteine levels, early atherosclerosis of coronary and cerebral arteries, and premature death.[167] These observations led to the "homocysteine hypothesis," which postulates that homocysteine stimulates inflammation and atherosclerosis, and is a key modifiable factor in vascular morbidity and mortality. Increased homocysteine levels are an independent risk factor for cardiac and cerebrovascular morbidity,[168,169] but the association between homocysteine levels and atherothrombotic disease is weak.[170] Moreover, studies in which diet and vitamin supplementation were used to reduce homocysteine levels demonstrate improvement in some markers of vascular risk, but do not reduce the rate of myocardial infarction and atherosclerotic stroke.[170,171] Thus, the importance of chronic, moderate increases in homocysteine to cardiovascular outcomes is tenuous, or perhaps only pertinent to limited patient populations.

Do the rapid increase of homocysteine levels during N_2O anesthesia influence the risk of cardiovascular

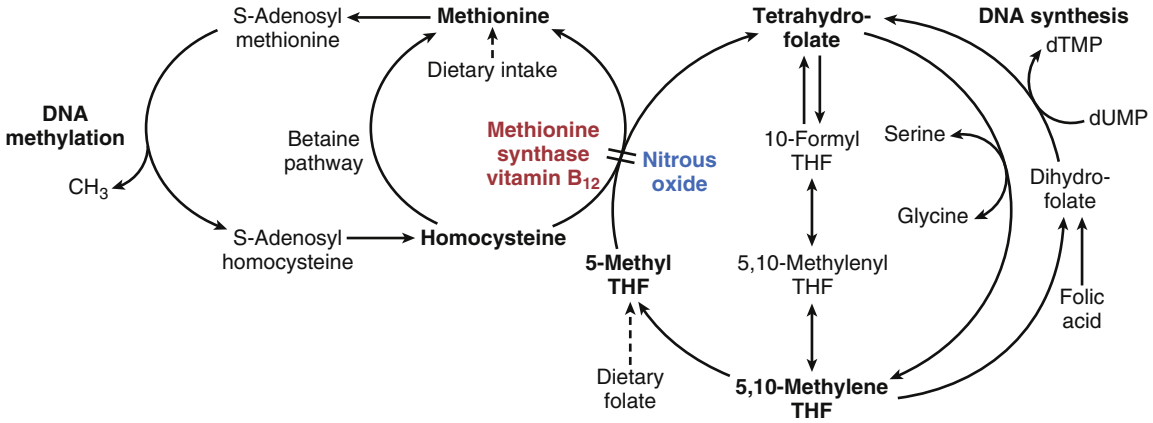

Figure 26-21. Nitrous oxide inhibition of methionine synthase. Biochemical cycles involved in methylation reactions are shown. Methionine synthase *(red)* catalyzes methylation of homocysteine with 5-methyl tetrahydrofolate as the donor, producing methionine and tetrahydrofolate (THF). Both vitamin B_{12} and folate are essential cofactors for methionine synthase. Nitrous oxide *(blue)* inhibits methionine synthase by oxidizing the cobalt of cobalamin (vitamin B_{12}). Methyl transfer pathways are important in synthesis of protein and DNA.

and neurovascular morbidity following surgery and anesthesia? Badner and colleagues[172] reported that N_2O administration significantly increased homocysteine levels and increased myocardial risk in carotid endarterectomy patients. The Evaluation of Nitrous Oxide in a Gas Mixture for Anaesthesia (ENIGMA) trial in over 2000 patients reported that avoidance of N_2O combined with increased inspired oxygen concentration during anesthesia decreased the incidence of a variety of complications after major surgery but found no reduction in death, myocardial infarction, stroke, or hospital length of stay.[173] A follow-up study of the ENIGMA trial patients reported that those exposed to N_2O for more than 2 hours were at increased risk (odds ratio, 1.6; 95% confidence interval, 1.01 to 2.5) of myocardial infarction up to 5.7 years after enrollment (ENIGMA-II).[174] No difference in rates of death or stroke were found. Unfortunately, diagnosis of myocardial infarction in ENIGMA-II was often based on data obtained in telephone interviews, rather than established diagnostic criteria. A recent post hoc study of 5133 enrollees in the Perioperative Ischemic Evaluation (POISE) trial[175] found no increase in rates of death, myocardial infarction, or stroke in approximately 1500 patients who received N_2O.

Homocysteine elevation following N_2O inhalation is a useful marker for assessing the sensitivity of methionine synthase and related biochemical pathways to N_2O inhibition. Nagele and colleagues[176] studied a small group of surgical patients with common mutations in the gene encoding MTHFR, and found that those with 667C→T and 1298A→C mutations were at risk of developing abnormally high homocysteine levels after N_2O exposures of at least 2 hours. However, a common gene variant (66A→G) associated with reduced methionine synthase reductase activity did not result in abnormally high homocysteine levels after anesthesia with N_2O.[177] Preoperative infusions of vitamin B_{12} and folate do not prevent the normal increases in homocysteine observed following anesthesia with N_2O.[178]

The continued value of N_2O, first used as an anesthetic in the early nineteenth century, has been questioned by some.[179,180] Given the ambivalence of currently available data, we recommend that anesthesia providers carefully screen patients to identify the few most likely to suffer N_2O side effects, and to avoid the drug in these cases.

INHALED ANESTHETICS AND NEUROTOXICITY

The ability of general anesthetics to ablate consciousness reversibly has benefitted millions of patients and enabled dramatic advances in health care. Although inhaled anesthetics were the first class of anesthetics and continue to be used in the vast majority of cases, the potential of long-lasting neurotoxic effects of inhaled and other general anesthetics does exist in patients of extreme ages[181-183] (see Chapters 80 and 93). The greatest concern surrounds the effects of general anesthetics in the youngest patients during periods of rapid brain development.[184] In a seminal study, Jevtovic-Tetrodovic and coworkers[185] demonstrated widespread neuronal apoptosis in the brains of 7-day-old rats after exposure to midazolam, isoflurane, and N_2O. Additional findings in these animals included long-lasting (up to 4.5 months) deficits in hippocampal long-term potentiation (a neurophysiologic correlate of learning and memory), and performance deficits in spatial learning tests. Subsequent animal studies in various species, including nonhuman primates, demonstrate that during sensitive periods of early brain development, exposure to most general anesthetics is associated with accelerated neuronal cell death (apoptosis) and degeneration.[186-190] Prolonged exposure to anesthetics can lead to neuroapoptosis and neurocognitive problems.[187,189] However, other studies suggest that even low nonapoptotic concentrations of general anesthetics may inhibit normal synapse formation and damage developing neuronal networks.[191] Mechanisms underlying neurodevelopmental toxicity are potentially linked to the same ion channels hypothesized to mediate general anesthesia. General anesthetic actions are attributed in part to both antagonism of *N*-methyl-D-aspartate receptor and potentiation of GABAA receptor signal transduction, and drugs with either or both of these activities damage developing brains.[183,192,193]

Early preclinical studies of neurodevelopmental toxicity of anesthesia demanded investigation of potential neurobehavioral correlates in humans. Current epidemiologic data (2013) are inconclusive. Clinical studies within the United States point to a possible association between anesthetic exposure in early childhood and the impairment of neurocognitive development,[181,194] in particular with cumulative anesthetic exposure.[195] In contrast, studies from Europe on the effects of a single exposure to anesthesia in early life that used combined data from national health data bases and educational registries within Denmark[196] found that early inguinal hernia repair was not associated with poor cognitive outcome; rather it is suggested that the poor academic performance of a subgroup of these children may be due to their being developmentally disadvantaged compared with the background population. In another study in sibling pairs in which one sibling received anesthesia before age 3 years, comparable test scores were reported for verbal, performance, and global intelligence between exposed and unexposed siblings.[197] Although some of the findings from the United States are concerning, potentially significant confounding factors were not controlled in these retrospective studies and firm conclusions cannot yet be drawn regarding the neurocognitive risks of general anesthesia in young children. Ongoing prospective clinical trials are expected to provide more definite information regarding this important issue[181,198] (see Chapter 93).

For updated recommendations to health care providers and parents regarding exposure to anesthesia and surgery in early life, please consult http://www.smarttots.org/resources/consensus.html or http://www.esahq.org. For a comprehensive description of the long-term impact on the adult brain, see Chapter 99.

INHALED ANESTHETICS AND ENVIRONMENTAL EFFECTS

Anesthetic gases in the workplace and in the outdoor environment have the potential to cause harm. Three potential sequelae have been investigated: global warming, ozone depletion, and health effects from workplace exposure (Table 26-5).

Global Warming Effects

Atmospheric trapping of thermal radiation from the earth's surface is known as the *greenhouse effect,* which the Intergovernmental Panel on Climate Change[203] deems a major contributor to global warming. Inhaled anesthetics are recognized greenhouse gases.[204,205] Isoflurane, sevoflurane, and desflurane, the most widely used current inhaled anesthetics, are minimally metabolized in the body, and are substantially eliminated through exhalation. Most anesthesia waste scavenging systems transfer these gases directly and unchanged into the atmosphere. Recently, attention to the ecotoxicologic properties of inhaled anesthetics has grown. The global warming potential takes into account the heat-trapping efficiency and lifespan of atmospheric gases (time for removal by chemical reaction with radicals, photolysis, and deposition). The global warming potential of volatile anesthetics ranges from 1230-fold (isoflurane) to 3714-fold (desflurane) that of an equal mass of CO_2. Recently Ryan and Nielsen[201] suggested that the most common volatile anesthetics can significantly influence global warming, with the greatest impact produced by atmospheric desflurane.

The global warming potential of N_2O is approximately 300-fold greater than that of an equal mass of CO_2.[206,207] N_2O is used in large quantities relative to volatile anesthetic gases and is remarkably stable, with an atmospheric lifespan of approximately 120 years.[208] Atmospheric N_2O is produced by natural sources in soil and water as well as human sources including agriculture (nitrogen-based fertilizers) and combustion of fossil fuels. Sherman and Cullen[209] first reported that N_2O could contribute to global warming and estimated that approximately 1% of man-made N_2O production was for anesthesia. More recently, the anesthetic use of N_2O may contribute 3.0% of total N_2O emissions in the United States.[205] Although the use of N_2O is declining in many countries, data on the worldwide medical use of N_2O are not available.

Ozone Depletion

The ozone layer of the earth's atmosphere, which has been declining 4% per decade since the 1970s, absorbs damaging ultraviolet B light (wavelengths 280 to 315 nm). The biologic consequences of increasing ultraviolet B radiation include increases in skin cancer, cataracts, damage to plants, and reduction of oceanic plankton populations. Halogenated volatile anesthetics are similar to chlorofluorocarbons (CFCs), which are major ozone depleting pollutants. Ozone depletion by halocarbons depends on molecular weight, number, and type of halogen atoms, and atmospheric lifespan.[210] The atmospheric lifespan of halogenated anesthetics is much shorter (4.0 to 21.4 years)[211] than that of many CFCs (up to 100 years). Fluorination is associated with longer atmospheric lifespan because of the stability of carbon-fluorine (C-F) bonds. Chemicals with a lifetime of more than 2 years are believed to reach the stratosphere in significant quantities. There they are exposed to intense ultraviolet radiation that can break carbon-halogen bonds, creating halogen radicals that catalytically destroy ozone. Chlorine-containing anesthetics such as halothane, isoflurane, and enflurane may be more destructive to the ozone layer than newer anesthetics, such as sevoflurane and desflurane, which contain only C-F bonds. Carbon-hydrogen bonds are susceptible to attack by hydroxyl radicals (OH·) in the troposphere,[212] making them less likely to reach the stratosphere. However, even compounds with a lifetime of a few months may potentially contribute to ozone destruction.[213] Contributions to total stratospheric ozone depletion were estimated as 1% for halothane and 0.02% for enflurane and isoflurane.[211]

N_2O is the primary source of stratospheric nitrogen oxides, NO and NO_2, and both destroy ozone. Because only 10% of N_2O is converted to NO_X, its ozone depleting potential is lower than that of an equal mass of CFCs. However, N_2O emission is the single largest ozone depleting human emission, and is expected to remain so for the rest of this century.[199] The use of N_2O could actually contribute additional environmental harm when used with halogenated anesthetics.

TABLE 26-5 ATMOSPHERIC LIFETIMES AND ENVIRONMENTAL EFFECTS OF INHALED ANESTHETICS

Compound		Lifetime (yr)	Ozone-Depleting Potential	Global Warming Potential (20 yr)	Global Warming Potential (100 yr)
CFC-12	CCl_2F_2	100	1	11,000	10,900
Carbon dioxide	CO_2	5-200	—*	1	1
Nitrous oxide	N_2O	114	0.017[199]	289	298
Halothane	$CF_3CHBrCl$	7[200]	0.36	—	218†
Isoflurane	$CHF_2OCHClCF_3$	2.6-3.6[201]	0.01	1230-1401[201]	350
Sevoflurane	$CH_2FOCH(CF_3)_2$	1.2-5.2 [201]	0	349-1980 [201]	575
Desflurane	$CHF_2OCHFCF_3$	10[201]	0	3714[201]	—

Ozone-depleting potential is the ratio of integrated perturbations to total ozone relative to an equal emission of CFC-12. Global warming potential is defined as the cumulative radiative retention integrated over a period of time from the emission of gas relative to reference gas (CO_2). The data are based on the Intergovernmental Panel on Climate Change Fourth Assessment Report [248] unless otherwise indicated.

*CO_2 unlikely reacts and depletes ozone; however, CO_2 producing the greenhouse effect in the troposphere is predicted to reduce stratospheric temperatures and cause further ozone depletion.[202]

†Computed value for halothane relative to global warming potential for CFC-12.

The environmental impact of all inhaled anesthetics could be reduced by up to 80% to 90% if closed-circuit anesthesia were widely employed, and to a lesser degree if low carrier gas flow rates were used routinely (see Fig. 26-13). Technologies that trap anesthetics in waste gas flows have the potential to reduce emissions into the environment, and can reduce drug costs by reusing (after redistillation) the trapped drugs.[214] Physician education warning that the medical use of N_2O can significantly contribute to both the greenhouse effect and ozone depletion should be maintained. Avoiding N_2O when it provides no clinical advantage is suggested as a more environmentally sound anesthetic practice.[204]

Exposure to Waste Anesthetic Gases

Health care personnel can be exposed to waste anesthetic gases both in and out of the operating room environment. Possible adverse health effects by chronic exposure to trace concentrations of inhaled anesthetics have caused concern among health care professionals for many years.[215,216] Laboratory studies suggest reproductive abnormalities in animals exposed to high concentrations of N_2O (1000 ppm or greater).[217,218] However, neither animal nor epidemiologic studies have shown any evidence for adverse effects attributable to the low levels of anesthetic gases in operating room air. A long-term prospective study found no causal relationship between adverse health effects and exposure to waste anesthetic gases with or without a scavenging system.[219] All inhaled anesthetics cross the placental-fetal exchange barrier. Teratogenicity, which has been demonstrated in animal fetuses chronically exposed to N_2O,[220,221] is of particular concern in pregnant health care workers, but there is no evidence of harm in humans. Furthermore, there is no evidence of harm to fetuses of women anesthetized while pregnant,[222] although general anesthesia is associated with neuroapoptosis during critical phases of brain development (see earlier, Inhaled Anesthetics and Neurotoxicity) warrant further clinical study of outcomes after anesthetic exposure during late-term pregnancy.[223] Currently, the U.S. Occupational Safety and Health Administration (OSHA) recommends that no worker should be exposed to concentrations of halogenated anesthetic greater than 2 ppm for a period not to exceed 1 hour during anesthesia administration (http://www.osha.gov/dts/osta/anestheticgases/index.html). OSHA also recommends that no worker should be exposed to 8-hour time-weighted average concentrations greater than 25 ppm. The recommended exposure level for N_2O is 25 ppm during anesthetic administration.

Potential postoperative exposure of health care workers to exhaled anesthetic gases in postanesthesia care units, intensive care units, and other patient care areas should also be recognized. Studies have documented excessive levels of waste anesthetic gases in poorly ventilated postanesthesia care units[224-226]; however, no studies have documented significant adverse health.

Xenon and Other Noble Gases

Current inhaled anesthetics represent vast improvements over earlier inhaled anesthetics, with N_2O representing the longest surviving widely used anesthetic. The noble gas xenon was first shown to produce general anesthesia in 1951,[227] and subsequent studies have revealed that it approaches the ideal closer than any other inhaled anesthetic.[228-230] It is most comparable to N_2O, but superior in a number of ways. Xenon is present as a minor constituent of air (50 parts per billion), and it is isolated by distillation of liquefied air, liquefied nitrogen, and oxygen. Xenon is entirely unreactive in the biosphere; therefore, it is the only inhaled anesthetic that is not an environmental pollutant, although its distillation from air uses considerable energy and thus creates CO_2 and other pollutants as byproducts.[205] It is odorless, tasteless, and nonflammable, and it has a limitless shelf-life. Its solubility in blood ($\lambda_{b/g}$ = 0.14) and body tissues is lower than that of any other inhaled anesthetic, including N_2O. As a result, it has extraordinarily rapid onset and respiratory clearance, with emergence times twofold to threefold faster when it replaces N_2O in clinical settings.[231,232] It undergoes no biotransformation or reactions with CO_2 absorbents or ultraviolet light. Moreover, xenon has favorable pharmacodynamic effects in comparison with most inhaled anesthetics. It produces minimal cardiovascular depression, and it is not arrhythmogenic.[233-235] As with N_2O, xenon has analgesic activity, and it reduces intraoperative opioid requirements.[236] It does not trigger malignant hyperthermia or produce any known toxicity.[237] In fact, xenon has cardioprotective and neuroprotective activities in preclinical models,[228,230] although clinical trials have

not demonstrated a reduction in postoperative delirium in high-risk patients receiving xenon.[238,239]

Given all these advantages, why is xenon not a commonly used inhaled anesthetic? The main reason is its cost.[240] At more than $15 per liter in the gas form, xenon is greater than 100-fold more expensive than N_2O and is far more expensive per patient than either desflurane or sevoflurane, which are currently the most expensive volatile anesthetics. Xenon has a MAC-immobility of 0.61 atm, and even with a strict closed-circuit technique, greater than 10 L is needed to anesthetize a typical patient. To perform closed-circuit anesthesia with xenon–oxygen also requires lengthy preanesthetic denitrogenation to prevent N_2 from accumulating in the rebreathing circuit.[241] Transitioning from 100% oxygen during denitrogenation to closed-circuit xenon–oxygen anesthesia is another slow process because xenon is added to the circuit as oxygen is metabolized in the patient at 200 to 250 mL/min. High-flow xenon is otherwise necessary to make this transition short. To make xenon a more affordable anesthetic, specialized anesthesia machines have been designed to enable its efficient delivery,[242] and new waste-scavenging systems are being introduced with cryogenic traps that can condense xenon in a liquid form from waste gases.[243] This process allows relatively inexpensive recycling of xenon after it has been redistilled to a pure form.

In addition to cost, xenon presents a few other downsides. Xenon gas has a much higher density (5.9 g/L) than either N_2O (1.5 g/L) or air (1.0 g/L), resulting in increased flow resistance and work of breathing.[244] Thus, it may be a poor choice for patients with compromised respiratory function. As with N_2O, high xenon partial pressures needed for anesthesia cause expansion of trapped air spaces and vascular air emboli.[245] Compared with propofol infusion, xenon anesthesia results in approximately twofold the incidence of nausea and vomiting.[246]

Currently, xenon remains an experimental anesthetic, with current research focusing on its potential as a clinical neuroprotectant and development of technologies to reduce its cost. Shifting the cost-benefit balance toward more xenon use in patients will depend on whether clinical studies ultimately support xenon's potential organ protection efficacy. Other noble gases also share some of xenon's neuroprotective actions in experimental model systems, and they are under investigation as potential clinical drugs.[247]

Chapter 27

Inhaled Anesthetics: Pulmonary Pharmacology

NEIL E. FARBER • ECKEHARD A.E. STUTH • ASTRID G. STUCKE • PAUL S. PAGEL

Acknowledgment: The editors and publisher would like to thank Dr. David C. Warltier for contributing a chapter on this topic to the prior edition of this work. It has served as the foundation for the current chapter.

Key Points

- Inhaled anesthetics affect every facet of pulmonary physiologic function.
- Bronchodilatory actions of volatile anesthetics occur through decreases in intracellular calcium (ICa^{2+}) concentration and/or a reduction in calcium (Ca^{2+}) sensitivity. Volatile anesthetics attenuate increases in pulmonary airway resistance attributable to chemical or mechanical stimuli.
- Inhaled anesthetics diminish the rate of mucous clearance and alter type II alveolar cell function, which may play a role in postoperative pulmonary complications.
- Volatile anesthetics cause biphasic responses in pulmonary vascular smooth muscle that are mediated at multiple sites of a Ca^{2+}-mediated signaling pathway. Volatile anesthetic–induced inhibition of hypoxic pulmonary vasoconstriction (HPV) is small but may worsen hypoxemia.
- Components of the respiratory system include peripheral and central chemoreception, a central pattern generator, and motoneuronal output. Inspiratory efforts are closely coordinated with upper airway patency. Anesthetics depress these systems through a reduction of chemodrive and direct inhibition of neurotransmission, leading to a risk of respiratory depression and upper airway obstruction.
- During volatile anesthesia, maintenance of spontaneous ventilation is dependent on the carbon dioxide (CO_2)–mediated excitatory central chemoreceptor inputs to the central respiratory pattern generator. Peripheral chemoreceptor inputs and hypoxic arousal reflexes are severely impaired even during sedative levels of volatile anesthesia.
- Volatile anesthetics reduce tidal volume and minute ventilation and cause tachypnea in a dose-related fashion.
- Diaphragmatic function is relatively well preserved during volatile anesthesia, whereas inspiratory rib cage muscles are significantly depressed. Abdominal expiratory muscle activation contributes to less-coordinated respiratory muscle activation, which is pronounced during CO_2-stimulated breathing.
- Upper airway patency can be rapidly compromised during volatile anesthesia. Upper airway obstruction can even occur at sedative concentrations of volatile anesthetics in susceptible patients.
- Volatile anesthetics vary in their ability to irritate airways and enhance defensive airway reflexes. Sevoflurane is the anesthetic of choice for inhaled induction of anesthesia in infants and children (also see Chapter 93).
- Volatile anesthetics are immunomodulatory. In some models, they are proinflammatory. Yet, volatile anesthetics may reduce inflammation and improve both chemical and pulmonary physiologic function.
- Nitrous oxide may cause adverse pulmonary effects.
- The high-density and low blood-gas coefficient of xenon result in improved gas exchange and a *fast on and off action* without causing diffusion hypoxia.

INTRODUCTION

This chapter describes the pulmonary pharmacology of modern inhaled anesthetics (including isoflurane, desflurane, and sevoflurane), nitrous oxide, and the anesthetic noble gas, xenon. Comparison with older volatile anesthetics (e.g., halothane, enflurane, ethers) is made only when necessary because these drugs are no longer available in the developed world. The lungs are unique in their exposure to a wide variety of physical forces including ventilation, blood flow, and surface tension. The actions of inhaled anesthetics on airway tone, pulmonary vascular resistance (PVR), mucociliary function, surfactant production, ventilatory control, and acute lung injury are examined in detail.

INHALED ANESTHETICS

BRONCHOMOTOR TONE

Transient increases in airway resistance may be caused, at least in part, by an increase in bronchiolar smooth muscle tone. Asthma is one of the most common chronic airway diseases worldwide with an estimated annual death rate of 250,000 (also see Chapter 103). Patients without recent symptoms of asthma have a relatively low frequency of perioperative respiratory complications, yet perioperative bronchospasm develops in approximately 9% of patients with asthma.[1] Prospective studies have demonstrated 1.7% of patients with asthma experience a poor respiratory outcome[2] and 25% wheezed after the induction of anesthesia.[3] Of the 40 cases of bronchospasm resulting in settled malpractice claims reported by the American Society of Anesthesiologists Closed Claims Project,[4] 88% involved brain damage or death and only one-half of these patients had a history of asthma or chronic obstructive pulmonary disease (COPD). Adverse respiratory events accounted for 28% of claims dealing with anesthesia-related brain damage and death in the United States and are associated with the highest mean cost per closed claim. In France, 7% of anesthesia-related deaths were attributed to bronchospasm.[5] Of the 4000 reported adverse incidents in Australia, 3% (103) were related to perioperative bronchospasm.[6] Additionally, an allergic mechanism was far less frequently involved (21%) than a nonallergic mechanism (79%). Although bronchospasm caused by airway irritation occurred more frequently in patients who had one or more predisposing factors such as asthma, heavy tobacco smoking, or bronchitis, a history of asthma was only present in 50% and 60% of patients with nonallergic and allergic bronchospasm, respectively.

Pharmacology of Bronchial Smooth Muscle

Airway smooth muscle extends as far distally as the terminal bronchioles and is affected by autonomic nervous system activity. Nonadrenergic, noncholinergic mechanisms, activated by the stimulation of the afferent bronchopulmonary sensory C fibers, may play a role in airway smooth muscle constriction to tachykinins, vasoactive intestinal peptide, adenosine, and calcitonin gene-related peptides. However, this pathway may be less important in humans than in other animal models. Bronchiolar constriction associated with asthmatic exacerbations are complex and involve airway nerves, smooth muscle, epithelium, and inflammatory cells. Reflex-mediated bronchoconstriction, on the other hand, caused by upper airway irritation, is modulated by afferent sensory pathways in the nucleus of the solitary tract, projecting to vagal preganglionic neurons. The excitatory neurotransmitter glutamate modulates stimulation of the nucleus tractus solitarii (NTS) and vagal preganglionic neurons, whereas the inhibitory neurotransmitter gamma-aminobutyric acid (GABA) project from the nucleus of the solitary tract to the vagal preganglionic neurons. The efferent pathway from the vagal preganglionic neurons back to the airway is via the vagus nerve and involves acetylcholine release, predominantly on M_3 muscarinic receptors of airway smooth muscle to induce airway constriction.

Parasympathetic nerves originating in the vagal centers within the central nervous system also mediate baseline airway tone. Changes in intracellular calcium (ICa^{2+}) levels and Ca^{2+} influx may be caused by alterations in cyclic nucleotides within bronchial smooth muscle. Agonist-induced contraction is mediated by an increase in myosin light-chain kinase activity, phosphorylation of the 20-KD regulatory myosin light chain, or an increase in Ca^{2+} sensitivity.[7] Ca^{2+}/calmodulin–dependent myosin light-chain kinase is a critical component of tonic smooth muscle contraction.[8] Exogenous administration of acetylcholine or the stimulation of the vagus nerve increases the relative amount of cyclic guanosine monophosphate (cGMP), compared with cyclic adenosine monophosphate (cAMP), and results in bronchial smooth muscle contraction. Agonist activation of bronchial smooth muscle cells also involves the second messenger, cyclic adenosine diphosphate ribose (cADPR), which results in inositol triphosphate (IP_3)–mediated release of Ca^{2+} from the sarcoplasmic reticulum (SR) by activating ryanodine channels.[9] This release is followed by activation of store- and receptor-operated nonselective cation channels, which, in turn, leads to sodium (Na^+) influx. This localized increase in Na^+ may switch the Na^+/Ca^{2+} exchanger into reverse mode, leading to even more Ca^{2+} influx and greater constriction. Several different cAMP signaling compartments exist in airway smooth muscle that are selectively responsive to different hormones and neurotransmitters.[10] The mechanical stretch of human bronchial smooth muscle cells also causes contraction via an influx of Ca^{2+} through unique stretch-activated nonselective cation channels.[11] Adenosine indirectly contracts airway smooth muscle via the release of contractile agents from mast cells and nerves by directly stimulating adenosine type I (A1) receptors on airway smooth muscle, thereby rapidly mobilizing ICa^{2+} stores through G proteins and IP_3 signaling.

Agonist-induced stimulation of particulate guanylyl cyclase relaxes bronchial smooth muscle by decreasing Ca^{2+} current. In contrast, stimulation of soluble guanylyl cyclase by substances such as nitric oxide (NO) reduces ICa^{2+} concentration and Ca^{2+} sensitivity.[12] In addition to Ca^{2+}, potassium (K^+) also plays a significant role in resting membrane potentials. The two-pore domain,

acid-sensitive K^+ (TASK-1) channel is a voltage-independent K^+ channel found in human pulmonary artery (PA) smooth muscle cells that helps set their resting membrane potential and plays a role in their sensitivity to a variety of vasoactive factors, including hypoxia, pH, G-protein coupled pathways, and volatile anesthetics.

Release of histamine in the airway or various forms of mechanical or chemical stimulation increases afferent vagal activity to produce reflex bronchoconstriction. This increase in bronchomotor tone is attenuated by the cholinergic antagonist atropine. M_2 and M_3 muscarinic receptors on airway smooth muscle mediate bronchoconstriction by increasing Ca^{2+} sensitivity.[13] Presynaptic M_2 muscarinic receptors have also been identified that inhibit acetylcholine release and thus drugs that preferentially inhibit M_2 receptors (e.g., ipratropium bromide) may paradoxically produce bronchoconstriction.[14] This effect is not commonly observed in patients. The histamine-degrading enzyme, histamine N-methyltransferase, has been localized to human airway epithelium and may play a protective role against histamine-mediated bronchoconstriction.[15] Cholinergic stimulation acting on muscarinic receptors primarily creates a central airway constriction, whereas antigen challenges usually provoke greater changes in the lung periphery.[16]

Adrenergic receptors in bronchial smooth muscle are classified into α and β_2 types. Although α-receptors have been characterized in the human bronchial tree, their clinical importance has not been demonstrated. In contrast, the β_2-receptor subtypes play an important role in bronchiolar smooth muscle responsiveness. Stimulation of β_2 adrenoceptors causes cAMP-mediated relaxation via activation of protein kinase A and subsequent Ca^{2+} efflux out of the cell and into the SR. Notably, asthma, as well as allergy- and methacholine-induced bronchospasm, do not appear to be genetically linked to a dominant β_2-adrenoceptor gene.[17]

Respiratory epithelium releases substances that modulate bronchial smooth muscle tone. Removal of the epithelium enhances contractile responses to acetylcholine, histamine, or serotonin in large airways and decreases relaxation responses to isoproterenol in small airways. These actions are analogous to the effect of endothelial damage on vascular smooth muscle tone. Notably, cardiopulmonary bypass does significantly affect porcine bronchiolar epithelium-mediated bronchomotor activity, in contrast to vascular endothelium-mediated smooth muscle dysfunction.[18] Although endogenous epithelial factors have been identified, NO may play an important vasodilatory role in respiratory epithelium similar to that of vascular endothelium. Endothelin-1 is also a potent endogenous bronchoconstrictor that functions by activation of the IP_3 pathway.[19] Endothelin-1 is a more potent constrictor of vascular than bronchial smooth muscle and has greater efficacy in the pulmonary than the systemic circulation.

Effects of Inhaled Anesthetics

Volatile anesthetics are all bronchodilators, but some controversy remains concerning which volatile anesthetic exerts the most potent bronchodilation. In animal models, halothane appears to have the most pronounced effect of relaxing airway smooth muscle. Eliminating indirect effects of arterial carbon dioxide (CO_2) tension is important when examining the actions of volatile anesthetics on bronchial tone, especially during spontaneous ventilation, as hypercapnia-induced bronchodilation and hypocapnia-induced bronchoconstriction are both attenuated by isoflurane.[20] What may be interpreted as a dose-dependent effect of deepening the level of volatile anesthetics may actually be attributable to an indirect action by a progressive increase in CO_2 tension. The structure of the respiratory epithelium changes from pseudostratified columnar cells of the large airways to thinner, cuboidal cells of the bronchioles, and thus a relatively large amount of histologic heterogeneity exists between these regions. Although all volatile anesthetics cause bronchodilation, their specific effects on the bronchioles depend on the location in and the structure of the respiratory tree. In vitro, isoflurane preferentially relaxes the bronchioles rather than the bronchi.[21] Park and colleagues[22] demonstrated that isoflurane and halothane dilate fourth order bronchi at equivalent minimum alveolar concentration (MAC) values. Isoflurane, sevoflurane, and desflurane at concentrations of up to 1 MAC similarly attenuated methacholine-induced bronchoconstriction in open-chest, pentobarbital-anesthetized rats.[23] Isoflurane and sevoflurane also appear to have greater inhibitory effects on bronchial contraction as compared with tracheal smooth muscle contraction.[24] Similarly, halothane, desflurane, and isoflurane relax distal airways (e.g., bronchioles) to a greater extent than proximal airways (e.g., bronchi).[25] These differential effects appear to be related to the type of voltage-dependent Ca^{2+} (VDC) channels that are present in these regions.

Inhalation of 1 or 2 MAC halothane, enflurane, sevoflurane, and isoflurane did not alter baseline pulmonary resistance and dynamic pulmonary compliance, but these anesthetics significantly attenuated increases in pulmonary resistance and decreases in dynamic pulmonary compliance in response to intravenous histamine. Halothane was most effective in altering indices of bronchodilation, whereas responses to isoflurane, enflurane, and sevoflurane were nearly identical.[26] In contrast, desflurane produced bronchodilation at 1 MAC but increased airway resistance at 2 MAC.[27] Halothane, enflurane, and sevoflurane are equivalent at dilating third- or fourth-generation bronchi as directly measured with a fiberoptic bronchoscope in vivo.[28]

A controversy remains regarding the role of desflurane in promoting or inhibiting airway constriction. Desflurane and sevoflurane (1 MAC) block the increases in central airway resistance after a cholinergic challenge to equivalent degrees in rabbits. However, neither anesthetic protected against the increases in tissue damping (a measure of heterogeneous deterioration of the peripheral airways), which occurred after the cholinergic stimulus. Both anesthetics inhibited basal bronchial tone by approximately 30% to 40%. This finding was consistently observed in the presence or absence of allergic inflammation of the airways and bronchial hyperresponsiveness.[29] When the mechanism of constriction is centrally mediated, such as with a cholinergic challenge,[23,30,31] desflurane appears to play a beneficial role in attenuating deleterious effects

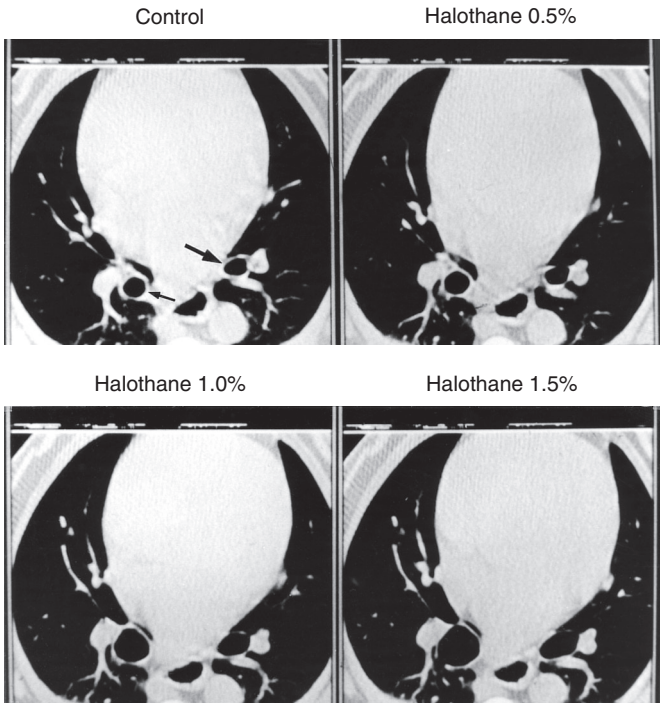

Figure 27-1. High-resolution computed tomography scans from one dog. *Upper left:* Control. *Upper right:* During 0.5% halothane. *Lower left:* During 1.0% halothane. *Lower right:* During 1.5% halothane. Note the progressive dilation of the airways as indicated by the arrows. *(Reproduced from Brown RH, Mitzner W, Zerhouni E, et al: Direct in vivo visualization of bronchodilation induced by inhalational anesthesia using high-resolution computed tomography,* Anesthesiology *78:295, 1993. Used with permission.)*

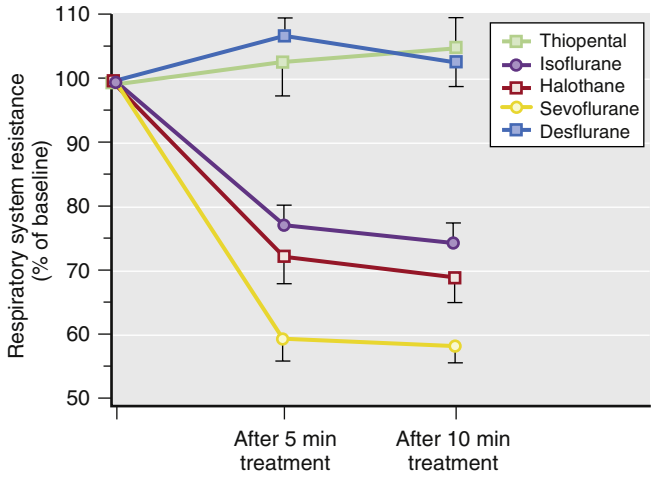

Figure 27-2. Percent change in respiratory system resistance in patients after 5 and 10 minutes of maintenance anesthesia with either 0.25 mg/kg/min thiopental plus 50% nitrous oxide or 1.1 minimum alveolar concentration (MAC) sevoflurane, halothane, or isoflurane or approximately 1 MAC desflurane. All volatile anesthetics except desflurane decreased resistance. Sevoflurane decreased resistance more than isoflurane. *(Modified from Rooke GA, Choi JH, Bishop MJ: The effect of isoflurane, halothane, sevoflurane, and thiopental/nitrous oxide on respiratory system resistance after tracheal intubation,* Anesthesiology *86:1294, 1997; and Goff MJ, Arain SR, Ficke DJ, et al: Absence of bronchodilation during desflurane anesthesia: a comparison to sevoflurane and thiopental,* Anesthesiology *93:404, 2000. Used with permission.)*

of bronchoconstriction. However, when the mechanism of airway constriction is from nonadrenergic, noncholinergic activation such as tachykinins, desflurane may augment and worsen constriction.[32,33] Clinically, anesthesiologists tend to avoid using desflurane in patients with reactive airway disease.

Effects of Inhaled Anesthetics on Bronchomotor Tone in Humans

Using computed tomography (CT), Brown and colleagues[34] showed that halothane causes greater bronchodilation than does isoflurane at low concentrations (Figure 27-1). Sevoflurane (1 MAC) reduced respiratory system resistance (determined using an isovolume technique) by 15% in patients undergoing elective surgery. In contrast, desflurane did not significantly alter resistance.[35] Rooke and associates[36] compared the bronchodilating effects of halothane, isoflurane, sevoflurane, and thiopental–nitrous oxide in 66 healthy patients undergoing induction of anesthesia and tracheal intubation (Figure 27-2). In contrast to thiopental–nitrous oxide, all volatile anesthetics significantly reduced respiratory resistance. An equivalent MAC value of sevoflurane and halothane decreased resistance to similar degrees, whereas isoflurane produced substantially less bronchodilation in vivo.

The work of breathing (expressed in joules) is defined as pressure or force multiplied by the tidal volume during inspiration. Respiratory work of the lung is further broken down into elastic work (required to overcome the recoil of the lung) and resistive work (required to overcome airway flow resistance and viscoelastic resistance of pulmonary tissues). The work of breathing is usually derived from transpulmonary pressure volume curves. Volatile anesthetics increase the work of breathing in adults and children. Some animal studies have suggested that volatile anesthetics *reduce* pulmonary compliance mediated at the lung periphery rather than at the airway level, thereby increasing viscoelastic and elastic pressures in the lung.[37] This finding was histologically supported by the observation of increased areas of alveolar collapse alternating with hyperinflation. In contrast, in a murine model of chronic asthma, sevoflurane anesthesia significantly decreased resistance in central and distal airways and also lowered resistance in the lung periphery. These data suggested that sevoflurane exerts a beneficial action in the presence of chronic airway obstruction and implied that volatile anesthetics reduce the work of breathing (Figure 27-3).[38] Indeed, most studies in humans demonstrate that low (small) concentrations of volatile anesthetics significantly reduce upper and lower respiratory system resistance (Figure 27-4).[39]

Expiration is passively affected by the recoil characteristics of the lung during normal breathing. In anesthetized patients, the ventilatory response to expiratory resistance is reduced to a greater extent than is the response to inspiratory resistance. Conscious and anesthetized humans exhibit decreases in respiratory rate during expiratory resistive loads, but only anesthetized subjects develop rib cage–abdominal wall motion dyssynchrony that causes less effective ventilation and increases

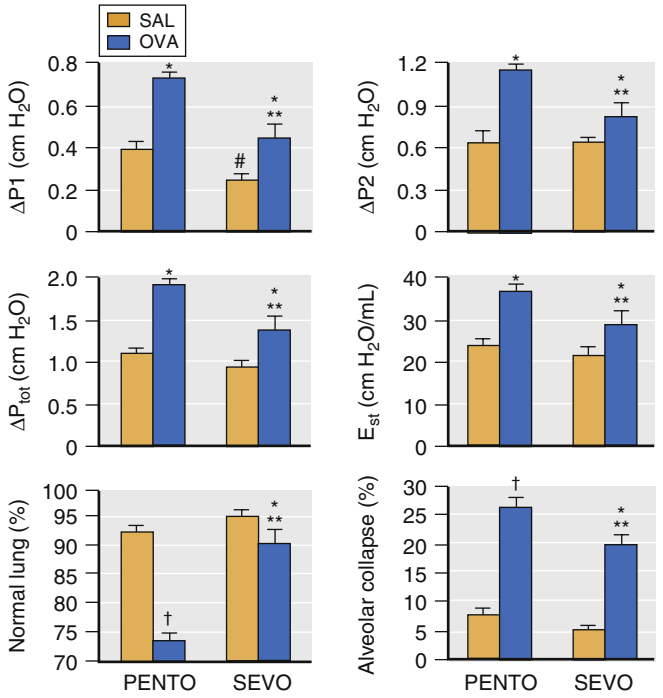

Figure 27-3. Mean ± standard error of the mean (SEM) for pressure to overcome airway resistance (ΔP1), viscoelastic lung properties (ΔP2), total of ΔP1 and ΔP2 (ΔP_{tot}), and static lung elastance (E_{st}). Also shown are the percent of normal area and the percent of alveolar collapse in mice repeatedly challenged with intratracheal instillation of saline (SAL) or ovalbumin (OVA). Animals were anesthetized with pentobarbital sodium (PENTO) or sevoflurane (SEVO), 1 minimum alveolar concentration (MAC). *, $P < 0.05$ versus corresponding SAL group; **, $P < 0.001$ versus OVA-PENTO group; #, $P < 0.05$ versus SAL-PENTO group; †, $P < 0.01$ versus the SAL-PENTO group. *(Modified from Burburan SM, Xisto DG, Ferreira HC, et al: Lung mechanics and histology during sevoflurane anesthesia in a model of chronic allergic rhinitis,* Anesth Analg *104:631, 2007. Used with permission.)*

in arterial CO_2 tension. This concept may be particularly important in spontaneously breathing, anesthetized patients who demonstrate expiratory obstruction, such as may be observed during partial breathing circuit occlusion, asthma, emphysema, or airway secretions.

Previously described experimental studies demonstrating the equal potency of sevoflurane and isoflurane and the relatively greater potency of halothane for bronchodilation must be extrapolated with caution because Ascaris- or histamine-mediated experimental bronchospasm may not precisely mimic tracheal intubation–induced bronchospasm in humans. In contrast to the findings in experimental animals, Arakawa and colleagues[40] showed that similar inspired concentrations of halothane, isoflurane, and sevoflurane produced nearly identical reductions in airway resistance in a patient with status asthmaticus. Indeed, volatile anesthetics may be an effective method of treating status asthmaticus when conventional therapy has failed.[40]

The use of β-adrenoceptor agonists may be beneficial for the treatment of acute bronchospasm in patients anesthetized with halothane,[41,42] but its use may not be beneficial with other volatile anesthetics. The β_2-adrenergic agonist, fenoterol, lowered respiratory system resistance after endotracheal intubation but did not further reduce resistance when administered in the presence of 1.3% isoflurane.[43] These data should be interpreted with caution because the technique used to determine respiratory system resistance incorporates alterations in lung and chest wall resistance, as well as tissue viscosity. The most important functional change that occurs in the presence of lung disease is increased resistance. Resistance to airflow is typically thought of as being determined by contraction and relaxation of airway smooth muscle. However, nonmuscle elements, such as lung inflammation, airway thickening, altered lung volumes, lung recoil, airway wall remodeling, mucous hypersecretion, and loss of lung elastance, also play a clinically significant role in the amount of airway narrowing.[44] The role of volatile anesthetics in altering many of those non–smooth-muscle elements responsible for airway resistance has not yet been studied.

The actions of volatile anesthetics on bronchomotor tone are also dependent on the substance used to elicit contraction in vitro.[45] Relaxation of tracheal smooth muscle by halothane and isoflurane is greatest in the presence of the endogenous mediator, serotonin, (potentially representing anaphylactoid or immunologic reactions) compared with acetylcholine (representing the neutrally derived mediator of reflex bronchospasm). Inhaled anesthetics may remain effective bronchodilators, even in the presence of severe serotonin- or histamine-induced bronchospasm that is refractory to β_2-adrenoceptor therapy. It is important to note that volatile anesthetic–induced decreases in bronchomotor tone and neurally mediated airway reflexes may be partially opposed by a simultaneous reduction in functional residual capacity (FRC) in the anesthetized patient. The well-known increased risk for morbidity and mortality in patients with asthma may be at least partially attributed to these FRC-mediated increases in airway resistance. Exposure of airway smooth muscle to low temperatures may abolish the inhibitory effects of volatile anesthetics on carbachol-induced contraction,[46] suggesting that intraoperative hypothermia also may attenuate volatile anesthetic–induced bronchodilation.

Bronchospasm may occur in respiratory diseases other than asthma. For example, healthy patients undergoing surgical stimulation of pulmonary parenchyma or airways (including tracheal stimulation by an endotracheal tube) are at risk of developing bronchospasm. The choice of preoperative medication, sedative-hypnotic, neuromuscular blocker, and volatile anesthetic are all important factors in determining the clinical appearance of bronchospasm in patients with known reactive airway disease. Iwasaki and colleagues[47] demonstrated that sevoflurane-induced relaxation of airway smooth muscle and VDC channels were dependent on the type of hyperreactive airway model. Sevoflurane had smaller effects in a model of chronic tobacco smoking (enlarged alveolar ducts and less muscarinic hyperreactivity), compared with an antigen-acute asthmatic (ovalbumin-sensitized) model. The morphologic changes in the peripheral airway may be responsible to some degree for a decrease in the efficacy of volatile anesthetics as bronchodilators in tobacco smokers, but sevoflurane and isoflurane decrease respiratory system resistance in patients with COPD.[48] In contrast to an acute asthmatic model that is characterized

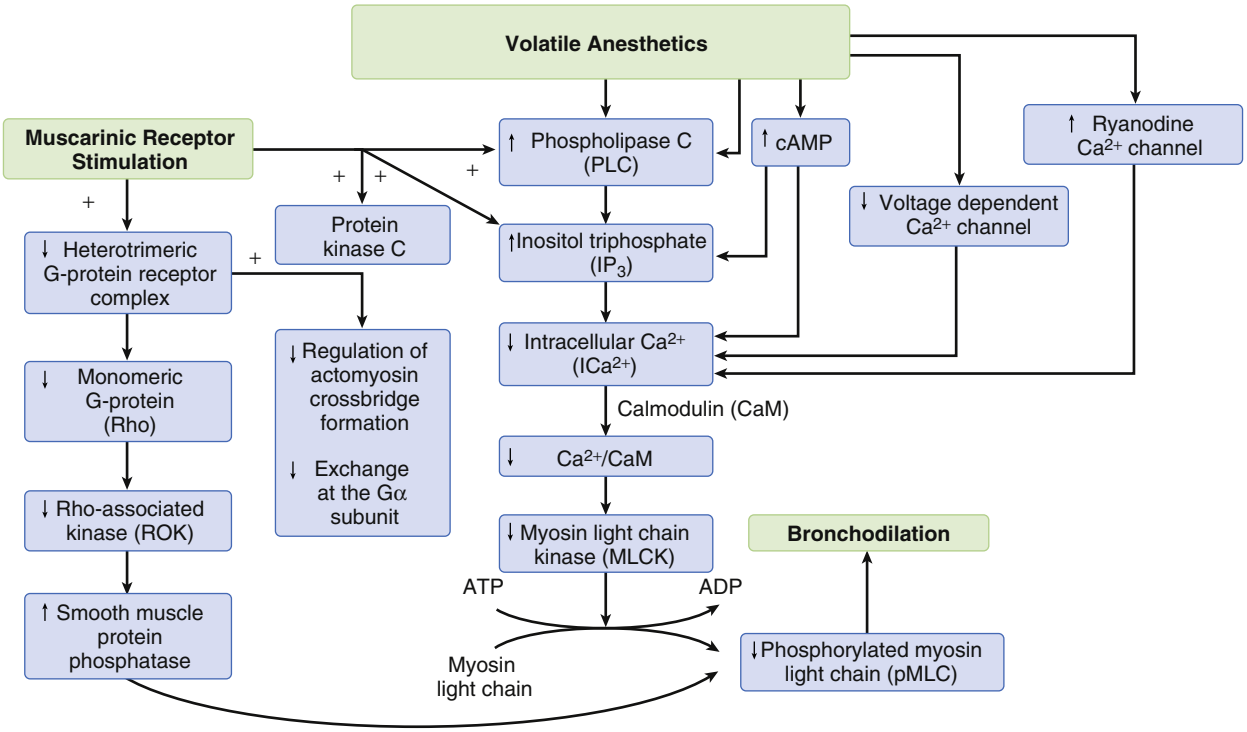

Figure 27-4. Isoflurane (ISO) at 0.6% reduced respiratory system elastance (E in cm H_2O/L) and resistance (R in cm H_2O/L/sec). *Total* represents the total respiratory system (lung and chest wall). Values are mean ± standard deviation (SD). No further reductions with increasing concentrations of isoflurane were observed. *, $P < 0.05$ versus baseline; *ADP*, adenosine diphosphate; *ATP*, adenosine triphosphate; *cAMP*, cyclic adenosine monophosphate. *(Modified from Ruiz P, Chartrand D: The effect of isoflurane 0.6% on respiratory mechanics in anesthetized-paralyzed humans is not increased at concentrations of 0.9% and 1.2%,* Can J Anaesth *50:67, 2003. Used with permission).*

by eosinophilic inflammation and airway wall changes, inflammation in chronic asthma involves many other cell types, including mast cells, macrophages, epithelial cells, and bronchial smooth muscle cells. In addition, chronic inflammation is associated with remodeling of bronchial epithelium to produce smooth muscle hypertrophy, gland hyperplasia, and neovascularization.

The administration of volatile anesthetics to children undergoing elective imaging studies was characterized by progressive reductions in the cross-sectional area of upper airway musculature, resulting in pharyngeal airway collapse[49] (also see Chapter 93). As observed with isoflurane in animal models, the effects of sevoflurane in children were not uniformly distributed along the upper airway. In healthy children, sevoflurane slightly decreased airway resistance, but desflurane had the opposite effect, presumably via reduced airway dimensions.[50] Children with documented airway susceptibility, such as those diagnosed with asthma or a recent upper respiratory tract infection, exhibited significant increases in respiratory system mechanical parameters such as respiratory impedance and elastance. In contrast to the beneficial effects of administering sevoflurane in these children, administration of desflurane caused greater deleterious changes in airway mechanics including an elevation in airway resistance, tissue damping, and elastance.[50]

Mechanisms of Action

Volatile anesthetics relax airway smooth muscle by directly depressing smooth muscle contractility. This action is the result of the anesthetics' direct effects on bronchial epithelium and airway smooth muscle cells, combined with the indirect inhibition of reflex neural pathways. The mechanisms responsible for the direct relaxation effects involve decreases in both ICa^{2+} concentration and Ca^{2+} sensitivity. Several intracellular mediators responsible for Ca^{2+} mobilization are potential sites for the action for volatile anesthetics. Inhibition of cell membrane-associated VDC channels by volatile anesthetics reduces Ca^{2+} entry into the cytosol.[47] Volatile anesthetic–induced increases in cAMP concentrations cause decreases in intracellular-free Ca^{2+} by stimulating Ca^{2+} efflux and increasing Ca^{2+} uptake into the SR. In addition, a volatile anesthetic–induced decrease in Ca^{2+} sensitivity attributable to the inhibition of protein kinase C activity,[51] inhibition of G-protein function, and attenuation of Rho and Rho-kinase signaling pathways also play important contributory roles.[52,53] Volatile anesthetics may differentially alter pulmonary resistance by affecting the density of the gas mixture (Figure 27-5).[51] In an experimental lung model of fixed pulmonary resistance, high concentrations of volatile anesthetics increased the density of the gas mixture and the calculated resistance, with desflurane producing the largest increase at all MAC values studied.

The effects of volatile anesthetics on proximal compared with distal airways may be related to the differential effects on VDC channels and the relative distribution of these channels. Long-lasting (L-type) VDC channels appear to be the predominant mechanism for Ca^{2+} entry in tracheal smooth muscle, whereas both transient

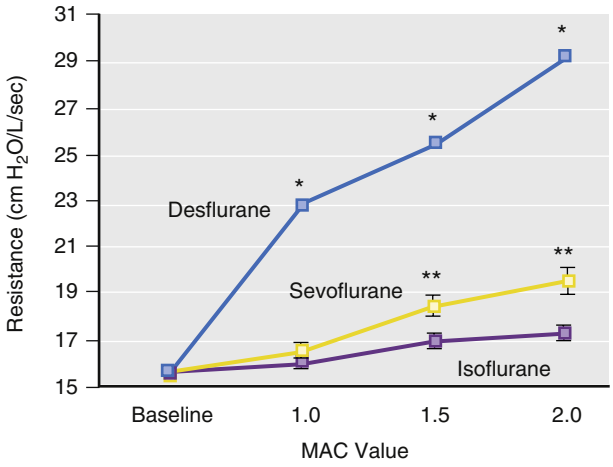

Figure 27-5. Comparison of the effect of different volatile anesthetics at equivalent concentrations on total pulmonary resistance. At 1 minimum alveolar concentration (MAC), only desflurane significantly increased pulmonary resistance, compared with isoflurane and sevoflurane. At 1.5 and 2 MAC, sevoflurane significantly increased total pulmonary resistance, compared with isoflurane, whereas desflurane caused a more pronounced increase than the other two agents. *, Increased pulmonary resistance in comparison with sevoflurane and isoflurane; **, increased pulmonary resistance in comparison with isoflurane. *(Reproduced from Nyktari VG, Papaioannou AA, Prinianakis G, et al: Effect of the physical properties of isoflurane, sevoflurane, and desflurane on pulmonary resistance in a laboratory lung model,* Anesthesiology *104:1202, 2006. Used with permission.)*

(T-type) and L-type VDC channels are present in bronchial smooth muscle.[24,54] Yamakage and coworkers[24] demonstrated that isoflurane and sevoflurane inhibit both types of VDC channels in a dose-dependent fashion, but their effects on T-type VDC channels in bronchial smooth muscle were substantially more pronounced (Figure 27-6). The differential effects of volatile anesthetics on tracheal smooth muscle, compared with bronchial smooth muscle, may also be related to actions on Ca^{2+}-activated chloride channel activity[55,56] or differential sensitivities of K^+ channel subtypes.[55]

The proposed signaling pathways underlying volatile anesthetic–induced bronchodilation are depicted in Figure 27-7. Volatile anesthetic–induced reductions in ICa^{2+} result from the inhibition of both VDC and receptor-gated Ca^{2+} channels. In addition, volatile anesthetics deplete SR Ca^{2+} stores by increasing Ca^{2+} leakage. Ca^{2+} influx occurring in response to depleted SR Ca^{2+} stores is known as store-operated Ca^{2+} entry (SOCE). By depleting SR Ca^{2+} stores, volatile anesthetics may be expected to enhance SOCE. Nevertheless, clinically relevant concentrations of volatile anesthetics (isoflurane more than sevoflurane) also inhibit SOCE in airway smooth muscle to further reduce available Ca^{2+}.[57] The cyclic nucleotides, cAMP and cGMP, also have similar inhibitory effects on SOCE in airway smooth muscle, and these effects are additive in the presence of isoflurane. In contrast, sevoflurane augments only the effects of cGMP on SOCE.

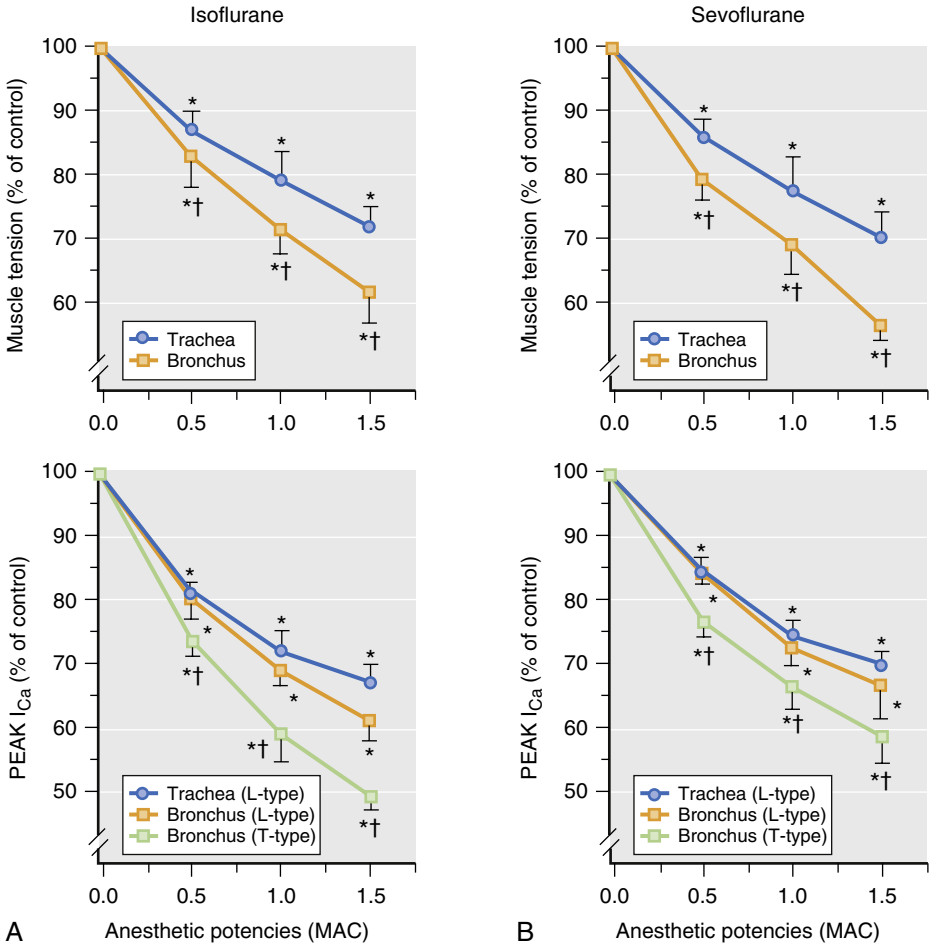

Figure 27-6. Effect of isoflurane and sevoflurane on porcine tracheal versus bronchial smooth muscle tension or inward calcium (Ca^{2+}) current intercellular calcium (ICa^{2+}) through T- and L-type voltage-dependent Ca^{2+} (VDC) channels. No differences were observed in the inhibition of L-type VDC channels. Both anesthetics had greater inhibitory effects on T-type VDC channels in bronchial smooth muscle. Symbols represent mean ± standard deviation (SD). **A,** *, $P < 0.05$ versus 0 minimum alveolar concentration (MAC). †, $P < 0.05$ versus tracheal smooth muscle. **B,** †, $P < 0.05$ versus L-type VDC channels. *(Reproduced from Yamakage M, Chen X, Tsujiguchi N, et al: Different inhibitory effects of volatile anesthetics on T- and L-type voltage dependent Ca^{2+} channels in porcine tracheal and bronchial smooth muscles,* Anesthesiology *94:683, 2001. Used with permission.)*

Volatile anesthetic–induced reductions in SR Ca^{2+} appear to occur through enhancement of IP_3 and ryanodine-receptor channel activities.[58] Kai and co-workers[52] demonstrated that halothane attenuates acetylcholine-induced Ca^{2+} sensitization in canine tracheal smooth muscle to a greater extent than does sevoflurane, whereas isoflurane showed no effect at concentrations equivalent to 2 MAC. These findings were analogous to the differential effects of volatile anesthetics on relaxing airway smooth muscle. This effect appears to be mediated, at least in part, by an increase in smooth muscle protein phosphatase,[59] modulation of G proteins (specifically G_q and G_I that exert actions on cGMP),[52,60] or modulation of the Rho and Rho-kinase signaling pathways. Volatile anesthetics interact with the muscarinic receptor–heterotrimeric G protein complex to prevent agonist-promoted nucleotide exchange at the Gα subunit of the G protein.[61,62] Perhaps volatile anesthetics, through this mechanism, inhibit signaling proteins such as phospholipase C, protein kinase C, and ion channels. Halothane, sevoflurane, and, minimally, isoflurane exert potent direct effects on muscarinic receptor–mediated contraction of isolated airway smooth muscle.[62] The inhibitory effects of volatile agents on the biochemical coupling between the M_3 muscarinic receptor and the $G\alpha_q$ heterotrimeric G protein is completely reversible with time. Isoflurane-induced relaxation of precontracted bronchial smooth muscles is significantly augmented by pretreatment with a Rho-kinase inhibitor, whereas sevoflurane-inhibited guanosine-5′-triphosphate (GTP) gamma S-stimulated contraction and membrane translocation of both Rho and Rho-kinase in a concentration-dependent manner. These latter actions play important roles in Ca^{2+} sensitization.[53] The final pathway in airway smooth muscle contraction is the generation of force and shortening of smooth muscles regulated by myosin crossbridge number and kinetics. Isoflurane modulates both crossbridge number and cycling rates of isolated rat airway smooth muscle.[63]

Volatile anesthetics are allosteric effectors of the action of GABA at the neuronal GABA A ($GABA_A$) channels. Thus the bronchodilatory action of volatile anesthetics is mediated by $GABA_A$ channels in the brainstem or GABA B ($GABA_B$) receptors on preganglionic

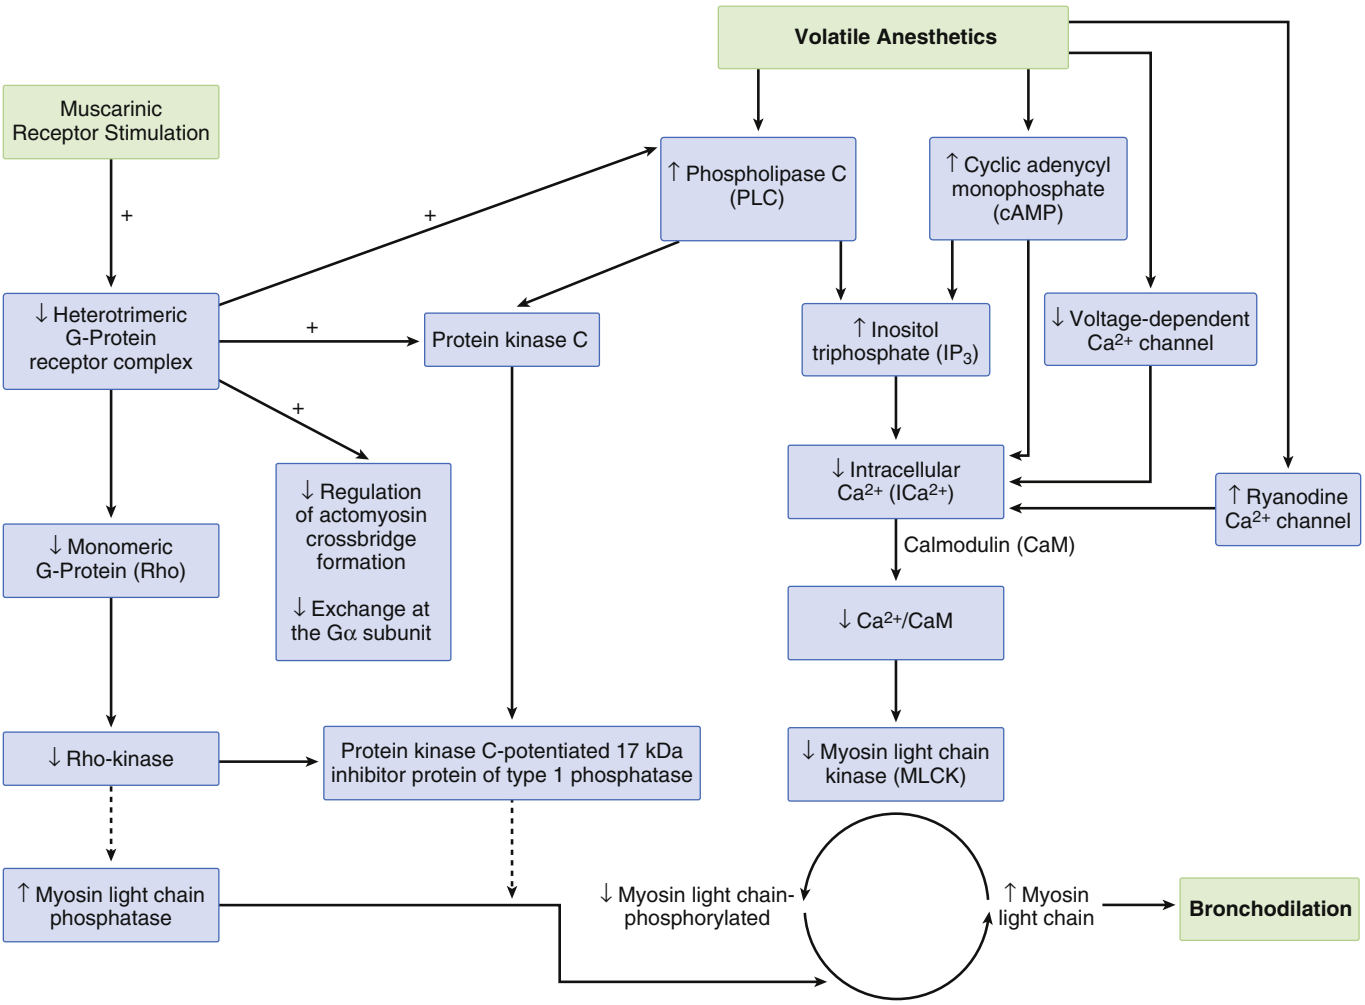

Figure 27-7. Proposed signaling pathways underlying volatile anesthetic-induced bronchodilation and/or inhibition of muscarinic agonist–induced contraction of airway smooth muscle. +, Excitatory action of muscarinic-receptor agonist. ↑, Activation or increase attributable to the volatile anesthetic. ↓, Inhibition or decrease attributable to the volatile anesthetic. Volatile anesthetics play a role in decreasing intracellular calcium (ICa^{2+}) levels and decreasing calcium (Ca^{2+}) sensitivity.

cholinergic nerves in the lung similar to the observations with propofol.[64] Indeed, $GABA_A$ and $GABA_B$ receptors, as well as glutamic decarboxylase (enzyme responsible for GABA synthesis), are located in airway epithelial and smooth muscle cells. Further, GABA levels increase and localize to airway smooth muscle after contractile stimuli in upper airways, and augmentation of cholinergic-induced tracheal ring contraction by GABA antagonism was shown to be reversed by a GABA agonist. These data suggest that volatile anesthetic–induced bronchodilation may also be mediated by the GABAergic airway system.[64,65]

The bronchoconstricting effects of low inhaled concentrations of CO_2 were attenuated by inhaled but not intravenous halothane, suggesting that the volatile anesthetic exerts a direct action on airway muscle tone or local neural reflex arcs rather than centrally controlled reflex pathways. Consistent with this hypothesis, halothane-, isoflurane-, sevoflurane-, and desflurane-induced dilation of distal bronchial segments is partially dependent on the presence of bronchial epithelium.[22,66] A prostanoid (e.g., prostaglandin E_2 or I_2) or NO may be responsible for the bronchodilatory effects of volatile anesthetics under these conditions. For example, isoflurane-mediated bronchodilation appears to be more dependent on NO than prostanoids, whereas the converse is true for halothane. Focal epithelial damage or inflammation may occur in small airways in patients with asthma or allergen exposure, and, as a consequence, the bronchodilatory response to volatile anesthetics may be reduced.[67] Nevertheless, the most pronounced bronchodilatory action of volatile anesthetics in patients with chronic reactive airway disease primarily occurs in the proximal rather than distal airways.

Direct stimulation of intrinsic airway nerves in vitro produces a contractile response that is inhibited by atropine. Volatile anesthetic–induced bronchodilation also occurs by modulation of this airway cholinergic neural transmission mediated through prejunctional and postjunctional mechanisms.[68,69] The combination of atropine and halothane did not increase airway caliber over that attained with either drug alone, suggesting that halothane dilates airways by blocking vagal tone during unstimulated conditions.[70] The release of histamine and the nonadrenergic, noncholinergic bronchodilatory neural reflex (believed to be mediated by NO[71]), do not appear to play a significant role in low-dose halothane-induced bronchodilation. Potent tracheal constriction also occurs in response to the endogenously produced endothelin-1. Isoflurane administration at a clinically relevant dose (2%) depressed endothelin-1–induced airway smooth muscle contraction in rat tracheal rings, suggesting another potential mechanism for airway smooth muscle relaxation.[72]

MUCOCILIARY FUNCTION AND SURFACTANT

Normal Mucociliary Function

The upward clearance of mucus from the tracheobronchial tree acts as a primary pulmonary defense mechanism to remove foreign particulate matter, microorganisms, and dead cells. Ciliated respiratory epithelium cells are present throughout the respiratory tract distally to the terminal bronchioles, but the density of ciliated respiratory epithelium progressively decreases from the trachea to the terminal bronchioles. Cilia are hairlike appendages, consisting of hundreds of proteins organized around a microtubular architecture. They are anchored to the apical cytoplasm by a basal body and extend from the cell surface into the extracellular space.[73,74] Cilia have historically been classified as either motile or immotile (primary). Motile cilia were thought to be responsible for generating extracellular fluid movement or propelling individual cells, whereas primary cilia were believed to be vestigial. However, primary cilia are actually important environmental sensors. Primary cilia localized to human bronchial smooth muscle play key roles in sensing and transducing extracellular mechanochemical signals and are also capable of identifying smooth muscle injury.[75] Indeed, ciliopathies are responsible for a variety of pediatric disorders such as primary ciliary dyskinesia and autosomal recessive polycystic kidney disease and research in ciliary physiologic function, morphologic structure, and pathologic disorders has rapidly evolved as a result.[73,76] The effects of volatile anesthetics on this complex primary ciliary physiologic function are currently unknown.

Ciliary motion consists of a rapid stroke in a cephalad direction, followed by a slower caudal recovery stroke. Movements of cilia are closely coordinated in a proximal-to-distal direction to move matter efficiently toward the trachea in a wave motion known as *metachronism*. Each motile cilium is organized in nine peripheral microtubule pairs surrounding a central pair (9 + 2). During a beat, dynein arms undergo an adenosine triphosphate (ATP)–dependent attachment, retraction, and release cycle with the adjacent doublet, which results in a sliding motion. The basal bodies of the motile cilia are anchored to the microtubules, nexin links, and radial spokes and are further restricted by the ciliary membrane. This anatomic constraint converts the sliding motion into a bend.

The quantity and physical properties of the mucous layer may also promote the coordination of ciliary beats. Mucus is a mixture of water, electrolytes, and macromolecules (e.g., lipids, mucins, enzymes) secreted by goblet cells and mucosal glands. Thicker layers of mucus slow the removal of surface particles from the airway, whereas low-viscosity mucus promotes more rapid ciliary transport. Mucociliary function may be assessed using high-speed videomicroscopy to examine the ciliary beat frequency. In vivo techniques in experimental animals have used a tracheal window model. In contrast, the velocity of mucous movement is typically measured with radioactive markers or fiberoptic bronchoscopy in humans. Impaired mucociliary function in the upper airways correlates with low levels of nasal NO, but the clinical significance of this finding is unclear.[77] Direct nervous system control of ciliary coordination has not been demonstrated in vertebrates, but mucociliary clearance is closely related to autonomic nervous system activity, most likely related to changes in physical characteristics of respiratory secretions[78] (also see Chapter 103).

Postoperative atelectasis and hypoxemia are common causes of perioperative morbidity. Many factors affect mucociliary function in the patient who is mechanically ventilated, and these factors contribute to the above complications. Poorly humidified inspired gases reduce ciliary movement and desiccate mucus. The flow rate of mucous movement was maintained within the normal range during a 40-minute exposure to inspired dry air at a temperature higher than 32° C in dogs. However, 3 hours of inhalation of dry air caused a complete cessation of the flow of tracheal mucus, which was restored by the subsequent use of inspired gases with 100% relative humidity at 38° C. Several anesthesia-related factors also reduce the rate of mucous movement, including the administration of high-inspired oxygen (O_2) concentrations and of adjuvant medications (e.g., corticosteroids, atropine, beta-adrenoreceptor antagonists) that affect bronchial tone, the presence of a cuffed endotracheal tube, and positive-pressure ventilation.[79]

Effects of Inhaled Anesthetics on Mucociliary Function

Volatile anesthetics and nitrous oxide diminish the rates of mucous clearance by decreasing ciliary beat frequency, disrupting metachronism, and altering the physical characteristics or quantity of mucus. Halothane, enflurane, isoflurane, and sevoflurane, in contrast to many intravenous anesthetics,[80,81] reduced ciliary movement and beat frequency in vitro.[80-84] Among the volatile anesthetics, sevoflurane exhibited the weakest cilioinhibitory effects in rat cultured tracheal epithelial cells in vitro (Figure 27-8).[84]

Gamsu and colleagues[85] compared the rate of tantalum (a powder that adheres to airway mucus) clearance from the lungs of postoperative patients who received general anesthesia for either intraabdominal or lower extremity surgical procedures. Tantalum retention was closely correlated with the retention of mucus (Figure 27-9) and was shown for as long as 6 days after intraabdominal surgery, with an average retention time three times greater than that observed in patients who underwent lower extremity surgery. Teflon discs placed on the tracheal mucosa and observed with fiberoptic bronchoscopy were used to examine tracheal mucous velocity in young women undergoing gynecologic surgery.[86] The administration of halothane (1% to 2%) and nitrous oxide (60%) rapidly decreased the rate of mucous movement. Little or no mucous motion was observed after 90 minutes of halothane–nitrous oxide inhalation. Inspired gases were humidified, but the use of high-inspired concentrations of O_2, a cuffed endotracheal tube, and positive-pressure ventilation were important confounding factors in this study. Bronchial mucosal transport velocity was also determined using radiolabeled albumin microspheres distally deposited in the mainstem bronchi using a fiberoptic bronchoscope in healthy patients.[87] In contrast to the findings of the study with halothane, mucous velocity was unchanged during the administration of 1.5 MAC isoflurane. Whether this relative lack of effect of isoflurane on mucous transport was specifically related to the type of volatile anesthetic was unclear. However, mucous pooling has been observed during and after anesthesia,

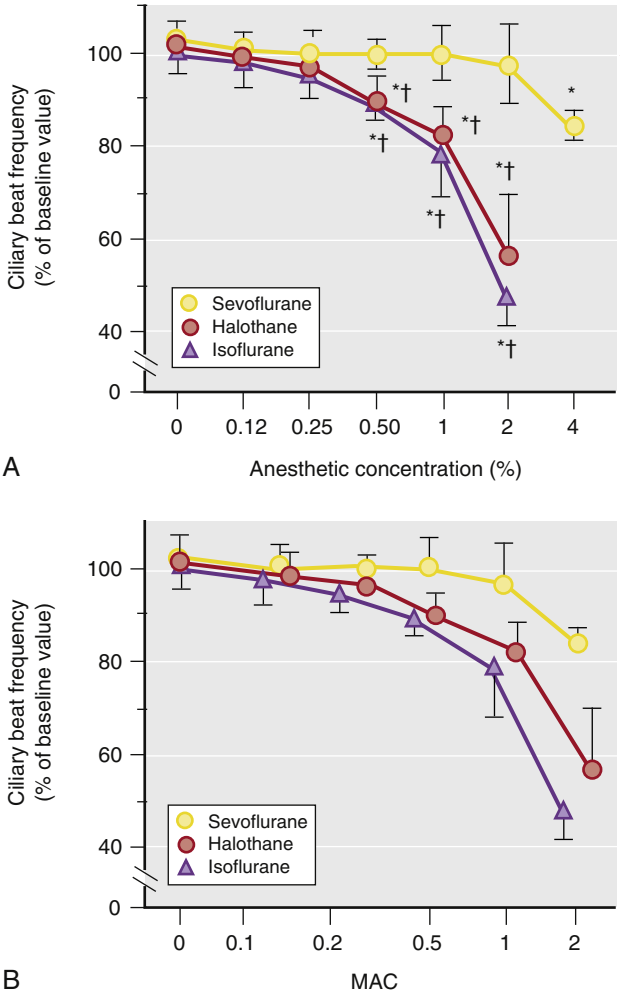

Figure 27-8. Effects of sevoflurane, halothane, and isoflurane on ciliary beat frequency (CBF) in cultured rat tracheal epithelial cells. CBF was measured at baseline and 30 minutes after exposure to various anesthetic concentrations. Values represent mean ± standard deviation (SD). **A**, Plot of percent baseline CBF versus anesthetic concentration. *, $P < 0.05$ versus 0% vehicle. †, $P < 0.05$ versus sevoflurane at the same concentration. **B**, Percent baseline CBF versus minimum alveolar concentration (MAC). *(Modified from Matsuura S, Shirakami G, Iida H, et al: The effect of sevoflurane on ciliary motility in rat cultured tracheal epithelial cells: a comparison with isoflurane and halothane,* Anesth Analg *102:1703, 2006. Used with permission.)*

and impaired bronchial mucous transport velocity is clearly associated with increased postoperative pulmonary complications.

The effects of sevoflurane and remifentanil on bronchial mucous transport were compared with total intravenous anesthesia (consisting of propofol and remifentanil) in patients undergoing general surgery.[88] In contrast to in vitro results,[84] bronchial mucous transport velocity was significantly reduced in patients receiving sevoflurane 30 minutes after endotracheal intubation. Desflurane is considered more irritating to the airways than sevoflurane, but both sevoflurane and desflurane, in combination with fentanyl, produced equivalent reductions in bronchial mucous transport velocity in patients undergoing general surgery. Unfortunately, velocity measurements were only obtained at a single time point 30 minutes

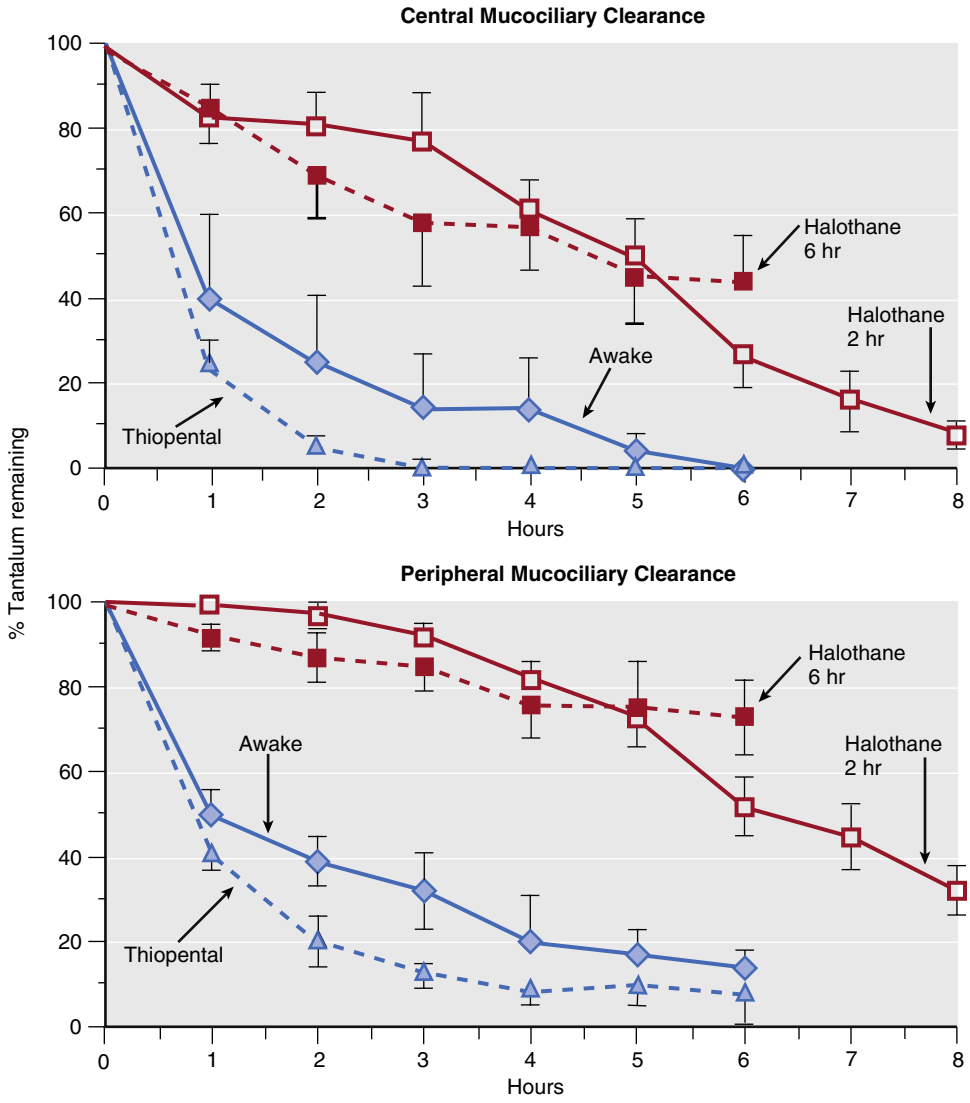

Figure 27-9. Mucociliary clearance measured as tantalum clearance in patients undergoing surgery with either general or local anesthesia (awake). Note the decrease in mucociliary clearance in both peripheral and central airways during halothane anesthesia. *(Modified from Forbes AR, Gamsu G: Mucociliary clearance in the canine lung during and after general anesthesia,* Anesthesiology *50:26, 1979. Used with permission.)*

after endotracheal intubation and a wide range of volatile anesthetic concentrations (0.8 to 1.5 MAC) were used in this study. These design deficiencies certainly limit interpretation of the results.

Impairment of ciliary beat frequency, mucociliary clearance, and bronchial mucous transport are associated with a high risk for pulmonary complications, including retention of secretions, atelectasis, and lower respiratory tract infection.[89] A reduction in bronchial mucous transport of as little as 3.5 mm per minute was associated with an increase in pulmonary complications in patients who were mechanically ventilated for 4 days in the intensive care unit (ICU). Thus pulmonary therapy directed at enhancing clearance of secretions from the airways may be beneficial in the immediate postoperative period, regardless of the type of volatile anesthetic chosen.

Tobacco smokers have significantly slower bronchial mucous transport velocities and more frequent pulmonary complications than nonsmokers undergoing major abdominal or thoracic surgery.[90] The specific effects of volatile anesthetics on mucous movement in smokers has not been well studied, but one may presume that an additive or synergistic negative effect on mucous transport may be present under these circumstances. Impairment of mucociliary function also occurs after lung transplantation. The mechanism for this dysfunction may be related to alterations in the surface properties of mucus and significant impairment of mucociliary transport distal to bronchial transection and reanastomosis.[91] The effects of volatile anesthetics on mucous transport in patients who underwent lung transplantation have not been described, but the baseline reductions in mucociliary movement would certainly be expected to predispose these patients to postoperative respiratory complications.

Effects of Inhaled Anesthetics on Surfactant

Pulmonary surfactant decreases the work of breathing by reducing surface tension at the fluid-gas interface. Surfactant is a mixture of proteins and phospholipids synthesized by alveolar type II cells. Similar to mucus, surfactant plays a role in removing foreign particles from airways while also enhancing the bactericidal actions of alveolar macrophages. Halothane[92] and isoflurane[93] transiently reduced phosphatidylcholine synthesis (a component of surfactant) by alveolar cells, in a dose-dependent manner during a 4-hour exposure. High concentrations of

halothane also disrupted the energy metabolism of cultured alveolar cells as indicated by reduced ATP content and enhanced glycolytic metabolism. Halothane and isoflurane potentiated hydrogen peroxide–mediated reduction of phosphatidylcholine content in alveolar type II cells[93,94] by affecting cell energetics. Halothane decreased the Na^+/K^+–adenosine triphosphatase (Na^+/K^+-ATPase), and Na^+ channel activity in alveolar type II cells, probably related to alterations in ICa^{2+} or ATP depletion.[95] A similar decrease in type II alveolar cell Na^+/K^+-ATPase occur after the administration of isoflurane.[96] Transepithelial Na^+ transport helps regulate alveolar fluid balance, and, as a result, impairment of this transport system may contribute to alveolar edema. This observation may be especially relevant in patients during surgery because volatile anesthetics decrease alveolar epithelial fluid clearance.[97]

The phospholipid makeup of surfactant is critical to its functional integrity. Another crucial component of surfactant is the hydrophobic surfactant-associated protein C. This protein is exclusively synthesized by alveolar type II cells, confers the properties of rapid surface adsorption and surface-tension reduction to phospholipids, facilitates the adsorption and spreading of phospholipids to form the surfactant monolayer, and enhances the lipid uptake into alveolar type II cells. Exogenous surfactants that contain surfactant-associated protein C are also effective at decreasing the rates of barotrauma and mortality in vivo. Clinically relevant concentrations of halothane increase surfactant-associated protein C messenger ribonucleic acid (mRNA) in vitro but cause the opposite effect in mechanically ventilated rats.[98] In contrast, thiopental administration increased the content of surfactant-associated protein C mRNA in both in vitro and in vivo models.[98] Extrapolation of these findings to patients undergoing anesthesia should be approached with caution, but these results may suggest that halothane and mechanical ventilation play a potentially additive and deleterious role on surfactant production and homeostasis of the alveolar space, particularly in the presence of acute lung injury. The actions of desflurane and sevoflurane on pulmonary surfactant metabolism have yet to be evaluated.

The specific roles of depressed mucociliary function and alterations in type II alveolar cells on pulmonary complications remain unclear, but impairment of ciliary motility, bronchial mucous transport, and surfactant production would certainly be expected to play significant roles in perioperative morbidity. As discussed in the following text, volatile anesthetics are also important immunomodulators of type II alveolar cell function during lung injury. Prolonged administration of volatile anesthetics may produce mucous pooling and adversely alter alveolar cell surfactant metabolism. These actions may result in adverse effects on pulmonary function including atelectasis and infection. Those at greatest risk appear to include patients with excessive or abnormal mucous or surfactant production or those with acute lung injury (e.g., chronic bronchitis, asthma, cystic fibrosis, chronic mechanical ventilation) (also see Chapter 103). Nevertheless, controlled studies of the effects of volatile anesthetics on mucociliary function, surfactant metabolism, and immunomodulation in patients with or experimental models of compromised pulmonary function have not been performed to date.

PULMONARY VASCULAR RESISTANCE

Determinants of Pulmonary Vascular Tone

The pulmonary vascular bed is a low-pressure, high-flow system. Normal PA pressure is approximately one-fifth of the systemic arterial pressure. As a result, calculated PVR is lower than systemic vascular resistance. The main PA and its major branches have a thinner medium and less vascular smooth muscle than the aorta and proximal arterial great vessels. PVR is increased with small (i.e., shorter, narrower, more tortuous alveolar blood vessels) or large lung volumes (compression of extraalveolar vessels), whereas PVR is lowest at a lung volume equivalent to the FRC. Changes in PA pressure and PVR exert important effects on pulmonary gas or fluid exchange. An increase in PVR occurs in conjunction with a corresponding increase in PA pressure and promotes interstitial fluid transudation. PVR is also increased by positive end-expiratory pressure (PEEP), alveolar hypoxia, hypercarbia, acidosis, and critical closing pressure. Hypoxia and acidosis have a synergistic effect on PVR. Clinically, the use of positive inotropic medications (e.g., milrinone) or expanded blood volume passively decreases PVR by increasing flow (cardiac output). Volatile anesthetics may also have indirect effects on PVR through a reduction in lung volumes during spontaneous ventilation.

Direct changes in pulmonary vascular smooth muscle tone alter PVR by affecting the slope of pressure-flow relation. Such direct changes may be produced by a rapid rise in ICa^{2+} or by alterations in sympathetic nervous system activity, arterial O_2 and CO_2 tension, acid-base balance, or plasma catecholamine concentrations. Hypercapnia at constant pH (i.e., isohydria) does not alter isolated PA tone, but normocapnic acidosis relaxes isolated PAs by an endothelium-independent mechanism.[99] Nevertheless, PA endothelial dysfunction potentiates hypercapnia-induced vasoconstriction.[100]

Activation of two primary endothelial-related enzymes affects pulmonary vascular tone: NO synthase and cyclooxygenase. Inducible, endothelial, and neuronal NO synthases are widely distributed in the lung, extensively involved in vascular homeostasis, and intimately linked to the pulmonary O_2 environment. NO synthase appears to play little role in the regulation of PVR in the healthy, normoxic lung,[101,102] but this enzyme and its metabolite NO are critical mediators of PVR during hypoxia.[103] In addition to producing vasodilation in ventilated, normoxic pulmonary regions during one-lung hypoxia, NO may also release an endogenous inhibitor of NO synthase that vasoconstricts nonventilated, hypoxic regions.[104] NO may be beneficial in the treatment of high-altitude pulmonary edema[105] and neonatal pulmonary hypertension resulting from a variety of congenital heart diseases, hypoplastic lung, and meconium aspiration. NO is also beneficial in the treatment of acute adult pulmonary hypertension, provided that the PVR is not *fixed* by remodeling and hypertrophy of pulmonary vascular smooth muscle. Thus NO may be useful in the management of severe mitral regurgitation, left ventricular dysfunction after myocardial infarction, and during heart or lung transplantation. Notably, NO inhalation during acute bronchospasm may paradoxically worsen

hypoxemia.[106] Whether this adverse action is mediated by direct bronchodilatory actions on less constricted peripheral airways or by worsening intrapulmonary shunt is unclear. Pulmonary endothelial dysfunction after cardiopulmonary bypass impairs endothelium-dependent vasodilation.[107] Nevertheless, the use of NO in pediatric and adult patients during cardiac surgeries has become a common means of reducing PVR in this setting (also see Chapters 67, 94, and 104). Similar to NO, carbon monoxide stimulates guanylyl cyclase and increases cGMP levels in pulmonary arterial vascular smooth muscle cells to regulate vascular tone. Inhaled carbon monoxide also attenuates hypoxemia-induced increases in PVR through this mechanism.[108]

Prostacyclin is another endogenous vasodilatory substance released from the endothelium that elicits smooth muscle relaxation through adenylyl cyclase stimulation and production of cAMP. Prostacyclin is clinically used as an inhaled or injected pulmonary vasodilator (Flolan or treprostinil). A role for endothelium-derived hyperpolarizing factor (EDHF) was identified as a third pathway for endothelium-mediated vasorelaxation.[109] EDHF produces relaxation by hyperpolarizing vascular smooth muscle in a process involving K^+ channel activation. EDHF production may be elicited by endothelial agonists (e.g., bradykinin, substance P) or alterations in wall shear stress.[109] EDHF may be an important regulator of pulmonary arterial blood flow, but its role in determining changes in PVR has not been well defined. Alterations in PVR may certainly be transient and occur in response to changes in acid-base balance and arterial blood gas tension. In contrast, the development of chronic pulmonary hypertension involves: (1) *endothelial dysfunction* with a resultant vasoconstriction, smooth muscle proliferation, and platelet aggregation; (2) *vascular remodeling*, attributable to a failure to eliminate endogenous vasoconstrictors (thromboxane A2, angiotensin 2, and endothelin-1), vascular smooth muscle hypertrophy, and protein kinase C–mediated fibroblast proliferation with collagen deposition; and (3) *formation of plexiform lesions* (i.e., complex vascular formations) that irreversibly obliterate pulmonary arterioles. Another pulmonary vasodilator, sildenafil citrate, acts by inhibiting cGMP-specific phosphodiesterase type 5 (an enzyme that promotes degradation of cGMP) and is clinically used to treat patients with refractory PA hypertension.

Mechanism of Hypoxic Pulmonary Vasoconstriction

Regional changes in PVR simultaneously affect the regional distribution of blood flow within the lung, produce changes in ventilation-perfusion matching, and gas exchange. The distribution of pulmonary arterial blood flow and ventilation in the lung is mainly a gravity-dependent phenomenon **(**also see Chapter 19) that is primarily mediated by the asymmetric branching of airways and blood vessels, thereby establishing regional heterogeneity.[110] An increase in PVR occurring within an area of atelectasis contributes to localized tissue hypoxia but also optimizes overall gas exchange (i.e., decreases the partial alveolar-arterial O_2 tension gradient [P_AO_2-PaO_2]) by shifting blood flow away from the atelectatic segment to well-ventilated regions of the lung. This phenomenon is termed hypoxic pulmonary vasoconstriction (HPV) and is unique to the pulmonary circulation because other vascular beds (e.g., coronary, cerebral) dilate (and do not constrict) in response to hypoxia. Thus HPV maintains oxygenation, and medications (including volatile anesthetics) that interfere with HPV may adversely affect gas exchange. HPV plays an especially important role in the presence of atelectasis, pneumonia, reactive airway disease, adult respiratory distress syndrome (ARDS), and one-lung ventilation. It usually does not contribute to pulmonary blood flow heterogeneity under normal conditions in supine humans.[111]

HPV is a locally mediated phenomenon that occurs independent of the autonomic nervous system control. HPV may be observed when alveolar O_2 tension falls below approximately 60 mm Hg and is maximal when O_2 tension is approximately 30 mm Hg. HPV was first identified in 1894, but the precise mechanisms underlying HPV remain unclear, despite many years of intensive research. Specialized O_2-sensing cells modulate respiratory and circulatory function to maintain a normal O_2 supply. Hypercapnia-induced acidosis increases PVR in intact animals and in isolated, perfused lungs. Acidosis-induced increases in PVR are relatively small at normal alveolar O_2 tensions but are dramatically enhanced during alveolar hypoxia. Local acidosis and increases in alveolar CO_2 tension may augment HPV and further improve arterial oxygenation in healthy lungs. High CO_2 concentrations reduce NO levels,[112] but whether this action is responsible for hypercarbia-induced improvements in the ratio of ventilation to perfusion is unclear.[113]

Although the hypoxia-mediated endothelial-derived vasoconstrictor has yet to be identified,[114] hypoxia clearly releases Ca^{2+} from smooth muscle SR via ryanodine receptors,[115] enhances Ca^{2+} sensitization,[114-116] and modulates voltage-gated K^+ channels in smooth muscles.[117] Heme oxygenase-2, hydrogen sulfide, CO, reactive O_2 species, and adenosine monophosphate–activated protein kinase (AMPK) have all been proposed as mediators of the hypoxic-response coupling.[116,118] Direct phosphorylation and regulation of O_2-sensitive ion channels by AMPK through inhibition of mitochondrial oxidative phosphorylation may also be responsible for hypoxia-response coupling.[116]

Inhaled Anesthetics and Hypoxic Pulmonary Vasoconstriction

All volatile anesthetics vasodilate the pulmonary vascular bed. Akata[119] presents a thorough review of the mechanisms by which inhaled anesthetics produce this vasodilation, including a reduction in free cytosolic Ca^{2+} and inhibition of myofilament Ca^{2+} sensitivity. Nevertheless, the pulmonary vasodilator effect of volatile anesthetics is relatively small in normal lungs, and the small decreases in PVR produced by volatile anesthetics are frequently offset by a concomitant reduction in cardiac output in vivo. The net effect of these hemodynamic changes result in little, if any, change in PA pressure concomitant with a small decrease in total pulmonary blood flow. In contrast to their action as direct pulmonary vasodilators, volatile anesthetics also attenuate K_{ATP} channel- and

Used with permission).*

endothelin-mediated pulmonary vasodilation in chronically instrumented dogs.[120-122] The inhibition of pulmonary vasodilation is not a uniform observation during the administration of volatile anesthetics under all conditions. For example, isoflurane and halothane, but not enflurane, enhance isoproterenol-mediated vasodilation.[123,124] Unlike the findings with other volatile anesthetics, K_{ATP} channel–mediated pulmonary vasodilation in response to lemakalim is preserved during sevoflurane anesthesia.[122] Indeed, evidence suggests that halothane, enflurane, and isoflurane, but not sevoflurane, differentially modulate pulmonary vascular tension through Ca^{2+}-activated or voltage-sensitive K^+ channels, at least in isolated rabbit lungs.[125] Halothane- and enflurane-induced constriction of pulmonary vessels were potentiated by voltage-gated potassium (Kv) channel inhibition in isolated lungs. In contrast, isoflurane did not affect pulmonary vessels when Kv channels were inhibited. Further, sevoflurane dilated pulmonary vessels and this dilation were not unaffected by K^+ channel subtype inhibitors (Figure 27-10). Isoflurane also attenuated hypotension-induced pulmonary vasoconstriction.[126] PA smooth muscle TASK-1 channels also appear to contribute to volatile anesthetic–induced PA dilation.[127] Rather than causing immediate vasodilation, volatile anesthetics produced a paradoxical initial dose-dependent increase in force in isolated pulmonary arterial strips as a result of Ca^{2+} release from intracellular stores (Figure 27-11). Subsequently, a decrease in force (associated with a Ca^{2+}/calmodulin–dependent protein kinase II activation) occurs.[128,129] Extrapolation of these results to humans in vivo must be approached with caution, but these studies suggest that vasodilatory responses of volatile anesthetics may be more profound in patients with reduced SR Ca^{2+} stores (e.g., neonates) or those with depressed protein kinase activity (e.g., primary pulmonary hypertension).

Several mechanisms contribute to the diminished FRC, reduced oxygenation, and increased alveolar-arterial O_2 gradient during anesthesia. Volatile anesthetics contribute to this process by affecting HPV. The effects of volatile anesthetics on HPV are multifactorial and involve direct actions on the pulmonary vasculature, combined with indirect effects mediated by systemic hemodynamics, the autonomic nervous system, and local humoral regulation. In general, in vitro studies have demonstrated that all volatile anesthetics attenuate HPV to some degree in isolated perfused lungs or in an in situ preparation with constant perfusion (Figure 27-12), whereas most intravenous anesthetics do not.[118] The combined administration of a Ca^{2+}-channel blocker and a volatile anesthetic further reduces HPV by an additional 35% to 40%, compared with either drug alone, suggesting that these medications inhibit HPV through differing mechanisms. Indeed, the mechanism of the direct inhibitory action of volatile anesthetics on HPV is unclear but may be related to an enhancement of arachidonic acid metabolism[130] or other endothelial-derived vasodilating factors.[131] Conversely, other evidence suggests that anesthetic-induced inhibition of HPV may occur independent of the presence of pulmonary vascular endothelium, NO, or guanylate cyclase.[132-134] Volatile anesthetics also disrupt Ca^{2+} homeostasis in vascular smooth muscle and thereby interfere with pulmonary vasoconstriction. Halothane and isoflurane attenuated endothelium-dependent vasodilation by inhibiting the accumulation of cGMP[134] and a K_{ATP} channel-mediated interaction between NO and prostacyclin in isolated canine PA rings.[135] In contrast, isoflurane modulated the HPV response, at least in part, through Ca^{2+}-activated and voltage-sensitive K^+ channels. Attenuation of HPV by sevoflurane occurred independent of K^+-channel function.[136]

The relative efficacy of volatile anesthetics on HPV in vivo is difficult to ascertain, in part, because of several factors that are known to impair HPV, including species, temperature, pH, CO_2 tension, relative degree of hypoxia, size of the hypoxic area, surgical trauma, and administration of medications. During one-lung ventilation, the direct inhibitory effects of volatile anesthetics on HPV may

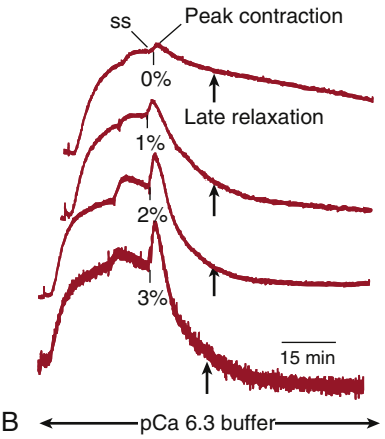

Figure 27-11. A, Proposed signaling pathways underlying volatile anesthetic-induced contraction and relaxation in pulmonary artery smooth muscle. Intracellular calcium (ICa^{2+}) may be increased by release from the sarcoplasmic reticulum (SR), by the inhibition of voltage-sensitive potassium (K_v) or calcium-activated potassium (K_{ca}) channels, or by receptor-operated Ca^{2+} channels (ROCC). Increased ICa^{2+} results in an initial dose-dependent increase in force (associated with activation of protein kinase C [PKC] and increased mitogen-activated protein kinase, [MAPK]). Volatile anesthetics also decrease ICa^{2+} by activating adenosine triphosphate–regulated potassium (K_{ATP}) channels, thereby inhibiting Ca^{2+} influx via voltage-operated Ca^{2+} channels (VOCC), decreasing SR-induced release of Ca^{2+}, inhibiting the phosphatidylinositol (Pi) cascade, and enhancing SR-mediated reuptake of Ca^{2+}. The resultant decrease in force is associated with activation of Ca^{2+}-calmodulin-dependent protein kinase II (CaMKII). It is important to note that there are many agent-specific effects of volatile anesthetics on each component of these pathways. *pERK,* Phosphorylated extracellular signal-regulated kinase. **B**, Example of a biphasic (contraction/relaxation) effect of halothane on pulmonary arterial smooth muscle. *0%, 1%, 2%, and 3%,* Halothane concentrations; *ss,* control force at steady state before halothane. increase perfusion in the nonventilated lung and worsen hypoxemia. However, volatile anesthetics may also affect HPV, lung perfusion, and oxygenation by indirect actions on cardiac output and mixed venous O_2 saturation.[137] Thus the direct effects of anesthetics on HPV, compared with indirect actions mediated through alterations in pulmonary perfusion, must be appreciated. The efficacy of HPV inversely varies with pulmonary arterial blood flow, and a direct inhibition of HPV by volatile anesthetics may be opposed by a simultaneous reduction in cardiac output such that HPV may appear to be unaffected. As a result, the net HPV response to volatile anesthetics

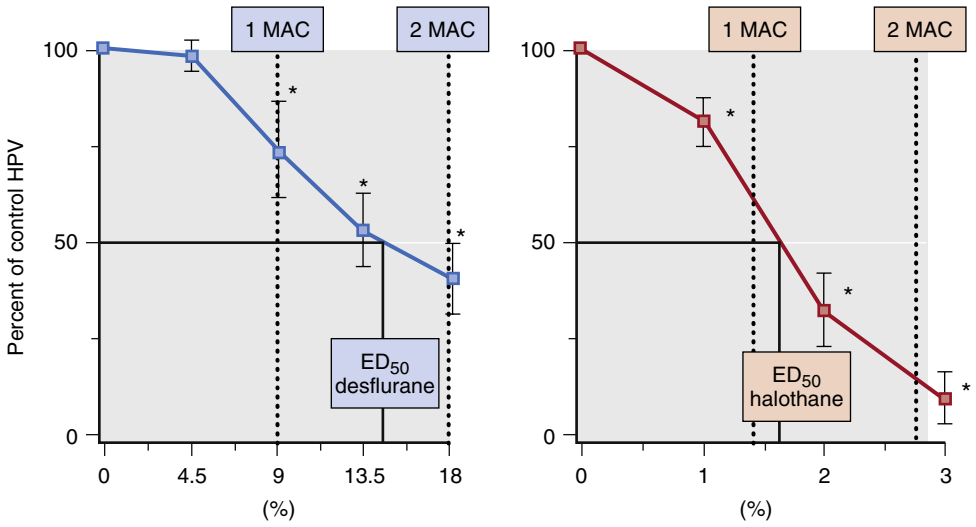

Figure 27-12. Concentration-dependent inhibition of hypoxic pulmonary vasoconstriction (HPV) in isolated rabbit lungs by desflurane *(blue squares)* and halothane *(red squares)*. Used with permission.)*

is unchanged when the cardiac output is reduced, but it may be fully intact or only minimally attenuated when pulmonary arterial blood flow is preserved. A reduction in cardiac output also decreases mixed venous oxygenation, which may enhance pulmonary vasoconstriction. These data emphasize the flow dependence of HPV during the administration of a volatile anesthetic. Baseline pulmonary arterial blood flow and pressure also modulate the effects of HPV. Elevated PA pressures may cause passive distension of constricted vascular beds and thereby reverse HPV. Alternatively, reflex pulmonary and systemic vasoconstriction in response to hypotension may increase PVR in healthy lung segments, leading to a favorable shift of pulmonary blood flow to hypoxic areas of lung.

Early studies suggested that nitrous oxide attenuates HPV in animal models in vivo. As opposed to the findings with isoflurane,[130] inhibition of HPV was not observed during sevoflurane or desflurane anesthesia (Figure 27-13)[138] in chronically instrumented dogs subjected to gradual occlusion of the right main PA. Nitrous oxide,[139] desflurane, and isoflurane,[140] but not xenon,[139] reduced the mixed venous O_2 saturation, cardiac output, and arterial oxygenation during one-lung ventilation in pigs. However, nitrous oxide,[139] xenon,[139] desflurane,[140,141] and isoflurane[140,142] did not alter perfusion of the nonventilated lung or reduce the shunt fraction during one-lung ventilation. In animals with a preexisting gas exchange defect attributable to a pneumoperitoneum, sevoflurane, but not isoflurane, caused more pronounced abnormalities in gas exchange than did propofol.[143] Thus although reductions in HPV by volatile anesthetics have been relatively small in vivo, coexisting pulmonary disease may worsen anesthetic-induced gas exchange abnormalities.

Effects of Volatile Anesthetics on Pulmonary Vasculature in Humans

In general, anesthesia is associated with some deterioration in pulmonary gas exchange. Attributing alterations in ventilation or perfusion to specific effects of volatile anesthetics is tempting. However, many other factors including gravity, posture, atelectasis, differences in vessel

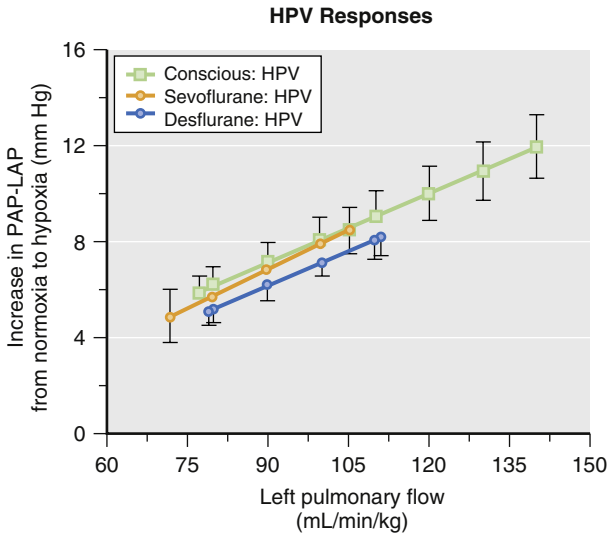

Figure 27-13. Composite hypoxic pulmonary vasoconstriction (HPV) responses (increase in pulmonary artery pressure [PAP] minus left atrial pressure [LAP] as a function of left pulmonary flow in the same seven chronically instrumented dogs in the conscious state and during sevoflurane and desflurane anesthesia. Neither anesthetic affected the magnitude of HPV when compared with the response in the conscious state. *(From Lesitsky MA, Davis S, Murray PA: Preservation of hypoxic pulmonary vasoconstriction during sevoflurane and desflurane anesthesia compared to the conscious state in chronically instrumented dogs,* Anesthesiology *89:1501, 1998. Used with permission)*

conductance between lung regions, intrathoracic pressure, and HPV may affect the distribution of pulmonary blood flow during the administration of volatile anesthetics. Alterations in regional ventilation are regulated by variations in alveolar compliance, inspiratory rate, flow rate, pleural pressures, and ventilatory strategies.[144]

In spontaneously breathing healthy volunteers, sevoflurane (1 MAC for 20 minutes) administered via a facemask did not alter the relative distribution of either ventilation or perfusion in a ventral to dorsal (front to back) direction measured by single photon–emission CT.[144] Similarly, no change in the distribution of ventilation (measured using electrical impedance tomography)

occurred in spontaneously breathing adults scheduled for elective orthopedic surgery given 0.7 MAC of sevoflurane via a laryngeal mask airway (LMA) (with higher tidal volumes and lower respiratory rates).[145] Interestingly, sevoflurane reduced regional heterogeneity of the perfusion distribution and widened the ventilation/perfusion ($\dot{V}/\dot{Q}$) ratio regional heterogeneity with a tendency toward lower ratios in spontaneously breathing volunteers.[144] This alteration may contribute to less effective pulmonary gas exchange, but these findings were relatively small compared with alterations in $\dot{V}/\dot{Q}$ distribution that occur during mechanical ventilation.[145,146] Whether the mode of ventilation is pressure-controlled or pressure-supported, sevoflurane caused similar ventral redistributions of ventilation.[145]

Isoflurane does not substantially alter pulmonary shunt in healthy patients even at concentrations that produce systemic hypotension.[147] Most clinical thoracic surgeries are usually undertaken in the lateral position with an open chest and dramatically affect the relative distribution of ventilation and perfusion. Under these circumstances, a diseased nondependent lung may affect the pulmonary vascular response to hypoxia, as may surgical manipulation of the lung itself. Most observations in experimental animals or patients undergoing single-lung ventilation fail to demonstrate clinically significant attenuation of HPV during the administration of a volatile anesthetic. Differences in shunt fraction, PVR, or oxygenation between isoflurane and sevoflurane anesthesia in patients undergoing one-lung ventilation for lobectomy for lung cancer do not appear to be significant.[148] Two studies demonstrated that shunt fraction is similar in patients receiving propofol or either isoflurane[149] or sevoflurane[150,151] during single-lung ventilation. No significant differences in shunt fraction or arterial O_2 tension were observed when pulmonary gas exchange was compared during intravenous infusions of ketamine (which does not inhibit HPV) and the administration of enflurane. In contrast, isoflurane[152,153] and sevoflurane[153] impaired oxygenation and decreased shunt fraction more than an intravenous infusion of propofol during single-lung ventilation in humans. However, the differences in oxygenation observed in these studies were small and clinically insignificant. Interpretation of the differences in oxygenation between intravenous and volatile anesthetics in these studies may be complicated by the relative depth of anesthesia. In contrast, when doses of propofol and sevoflurane were chosen based on similar depth of anesthesia (based on a bispectral index [BIS] monitor), similar reductions in arterial oxygenation were observed in patients undergoing one-lung ventilation.[151] Similar and rather modest changes in shunt fraction and oxygenation were shown to occur with halothane,[154] isoflurane,[148,154,155] desflurane[155] and sevoflurane[148] in patients undergoing thoracotomy and single-lung ventilation (Figure 27-14).

Convincing evidence suggests that all volatile anesthetics may be safely used in patients undergoing thoracotomy and single-lung ventilation (also see Chapter 66). The increase in shunt and the decrease in oxygenation caused by halothane or isoflurane[154] were consistent with an approximately 20% inhibition of HPV at

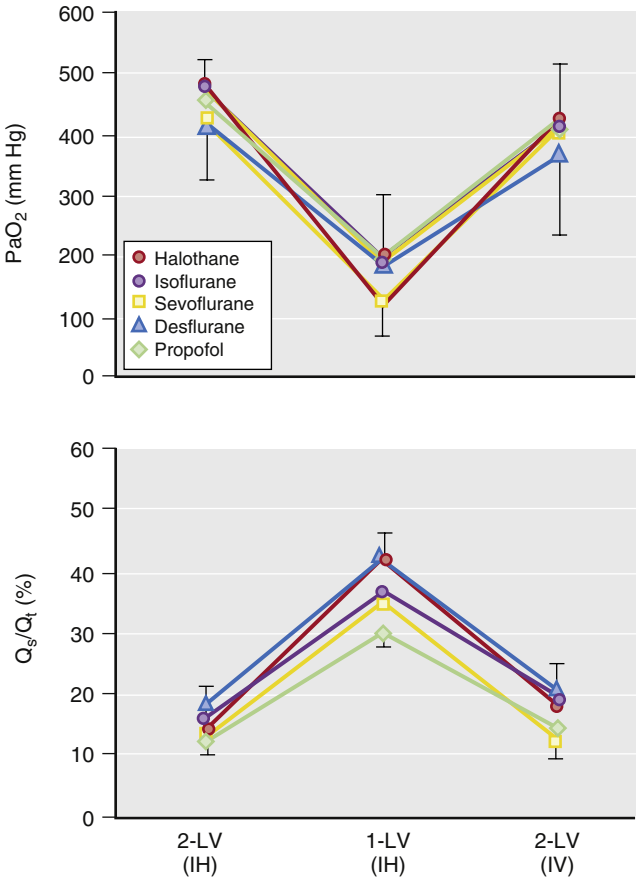

Figure 27-14. Partial arterial pressure of oxygen (PaO_2) and intrapulmonary shunt fraction (Q_s/Q_t) in patients with both lungs ventilated (2-LV) or with one lung ventilated (1-LV). Patients received an inhaled agent (IH) halothane, isoflurane, sevoflurane, or desflurane or the intravenous (IV) anesthetic propofol. Note the minimal effect on PaO_2 and shunt fraction that occurs in changing from a volatile anesthetic to an IV agent. *(Data modified from Abe and colleagues,[148,153] Benumof and colleagues,[154] and Pagel and colleagues.[155])*

1 MAC. Instead of the expected 50% reduction in pulmonary blood flow in a hypoxic lung in the absence of a volatile anesthetic, blood flow decreases by 40% during hypoxia in the presence of 1 MAC isoflurane. This change in flow corresponds to an increase in pulmonary shunt by approximately 4% of the cardiac output. Carlsson and colleagues[156] applied multiple inert gas elimination techniques to measure the true shunt fraction in humans anesthetized with volatile anesthetics and demonstrated a 2% to 3% increase in shunt fraction corresponding to approximately 20% HPV inhibition at 1.5% isoflurane. In addition, no significant effects on arterial oxygenation occurred with clinically relevant concentrations of isoflurane or enflurane. Indeed, the use of total intravenous anesthesia with propofol and alfentanil did not decrease the risk of hypoxemia during single-lung ventilation, compared with a volatile anesthetic.[149] Not only does isoflurane appear safe to use during single-lung ventilation, but the administration of isoflurane before pulmonary ischemia may also protect against ischemia-reperfusion injury. For example, isoflurane attenuated increases in PVR and blunted reductions in the coefficient of filtration

and the wet-to-dry ratio in isolated rabbit lungs subjected to ischemia and reperfusion.[157]

Isoflurane did not affect the pulmonary vasoconstrictor response to sympathetic α-adrenoreceptor activation or influence pulmonary vascular tone in the presence of increased PVR mediated by endothelin-mediated receptor activation[158] after single-lung transplantation.[159] These findings may have important implications for the intraoperative anesthetic management of patients with similar abnormalities in pulmonary vasoregulation because volatile anesthetics may produce smaller reductions in PVR than expected. The precise actions of volatile anesthetics on HPV and pulmonary shunt in patients with preexisting pulmonary disease remain to be defined, but the action of these drugs on the lung vasculature itself must be considered when evaluating causes of hypoxemia during anesthesia.

Volatile anesthetics exert only mild, if any, inhibitory effects on HPV and oxygenation[160,161] (also see Chapter 66). This relatively minor inhibition of HPV by volatile anesthetics should not significantly influence clinical decision making, especially considering the efficacy of drugs such as the peripheral chemoreceptor agonist, almitrine[162] (which enhances HPV) and inhaled NO (which causes localized vasodilation and increases perfusion to adequately ventilated pulmonary regions). In addition, ventilatory strategies (e.g., nondependent lung continuous positive airway pressure [CPAP], permissive hypercapnia) and fiberoptic bronchoscopy to check proper double-lumen endotracheal tube positioning help alleviate hypoxemia (also see Chapter 66). Thus the net effect of volatile anesthetics on HPV is multifactorial and not only depends on the direct effects of these agents on pulmonary vasomotor tone, but it is also determined by indirect actions that commonly occur during anesthesia and surgery.

CONTROL OF RESPIRATION

COMPONENTS OF THE RESPIRATORY SYSTEM

The main components of the respiratory system are located in the brainstem and include the medulla oblongata, pons, and midbrain (Figure 27-15). The neuronal networks in these areas are sufficient to generate involuntary, *automatic* breathing, which may be superseded by cortical centers for voluntary efforts such as speech, swallowing, and coughing. Respiration is also modulated by reflex inputs from the upper airways, lungs, and carotid bodies. Connections to the lateral hypothalamus convey *wakefulness* drive to the respiratory center. The anesthesiologist must be familiar with the main features of the respiratory system. Both physiologic sleep and exposure to volatile anesthetics may alter respiratory function to the point that mechanical ventilatory support becomes necessary. The following section does not describe anatomic features in detail, as these have been previously reviewed.[163-165] Rather, the focus is the major functional components of the respiratory system and how they are influenced by sleep and volatile anesthetics (Figure 27-16).

The effects of volatile anesthetics on the control of breathing have been summarized.[166,167] In general, the degree to which fast neurotransmission to individual respiratory neurons is affected by volatile anesthetics depends on the neurotransmitter inputs to the neuron. Volatile anesthetics decrease glutamatergic excitatory drive to bulbospinal respiratory neurons and increase $GABA_A$ergic inhibitory mechanisms at the postsynaptic neuronal membrane.[168] In hypoglossal upper airway motor neurons, volatile anesthetics hyperpolarize neuronal membrane resting potential by activating K^+ leak channels that are linked to serotonin or norepinephrine receptors.[169,170] The magnitude of volatile anesthetic depression may also depend on the position of the neuron in the *neuronal hierarchy*, which extends from the neurons generating excitatory respiratory drive to the respiratory pattern generator and down to the phrenic and hypoglossal respiratory output motor neurons (see Figure 27-16). For example, *downstream* phrenic motor neurons, which innervate the diaphragm, are significantly more depressed by volatile anesthetics than *upstream* bulbospinal respiratory premotor neurons that innervate the phrenic motoneurons. This suggests that either there are cascading anesthetic effects on synaptic neurotransmission from the premotor to the motor neuron or that there is additional direct anesthetic inhibition of the phrenic motor neuron (e.g., via TASK channel activation by volatile anesthetics).[168,169,171] Consequently, volatile anesthetics, which strongly affect synaptic neurotransmission, will have a greater depressant effect on polysynaptic neuronal circuits that include many synapses, compared with those comprised of only few neurons (paucisynaptic). Most connections between the single components of the respiratory system seem to be paucisynaptic, which has been proposed to explain a relative resistance of automatic breathing to the depressant effects of volatile anesthetics. As an example for the cascading effect of anesthetics on neurotransmission, we will assume a depression of 20% per synapse as has been shown for respiratory premotor neurons.[168] If this depression occurred at three different steps of the neuronal hierarchy (e.g., from chemoreceptor neuron to pre-Bötzinger neuron, from pre-Bötzinger neuron to inspiratory premotor neuron, from premotor neuron to phrenic motoneuron), then this would mean a total decrease in excitatory drive to 80% × 80% × 80% = 51% of the original drive. This concept has also been suggested for Ca^{2+} channels by Lynch and Pancrazio.[172]

Most experimental data are derived from animal models and must be extrapolated to humans with caution. For example, the area of the pre-Bötzinger complex, which is an important respiratory pacemaker cell–containing region in in vitro preparations, has not been conclusively demonstrated in adult mammals in vivo[173,174] and is impossible to demonstrate using current technology in humans.[175,176] Feldman,[177] who was instrumental in establishing the role of the pre-Bötzinger complex in respiratory rhythm generation and more recently proposed the existence of an inspiratory and expiratory oscillator, now emphasizes that the oscillator model of respiration is a working hypothesis that may not

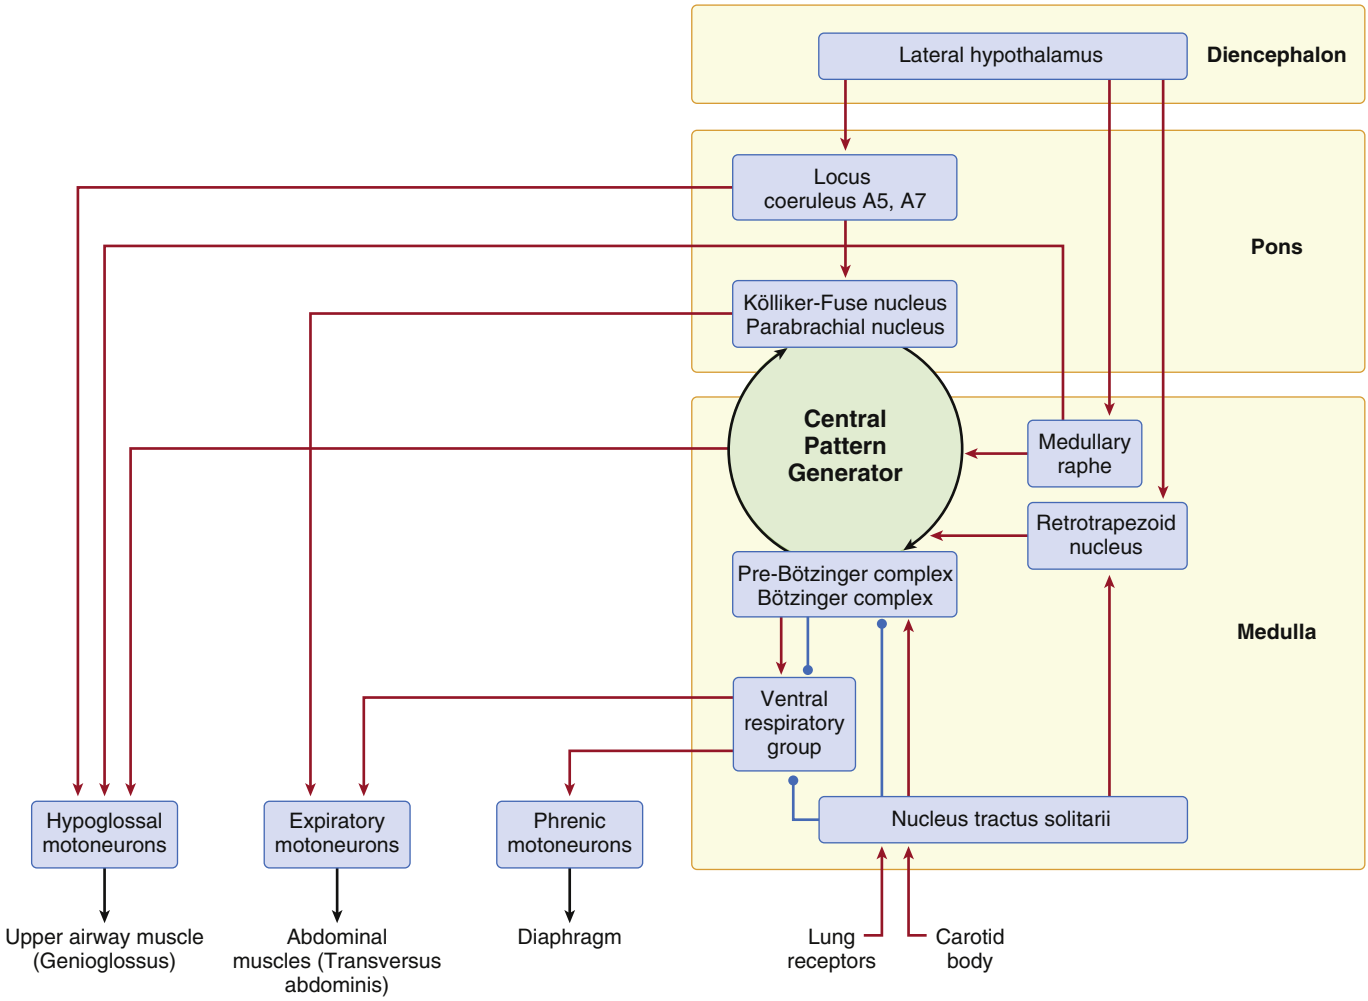

Figure 27-15. Anatomic components of the respiratory system and the main nuclei involved in the generation of respiration from chemoreception to motoneuron activation (see text for details). *Wakefulness drive* is derived from the lateral hypothalamus. The *central pattern generator*, where respiratory drive is converted into a respiratory pattern, is thought to consist of several nuclei in the medulla and pons. Potential sites of central chemoreception are the locus coeruleus, areas A5 and A7, in the pons, and the medullary raphé and retrotrapezoid nucleus in the medulla. Expiratory and inspiratory excitatory drive is relayed to premotor neurons (ventral respiratory group), which project to expiratory motoneurons and inspiratory motoneurons (e.g., phrenic nerve) in the spinal cord. These motor nerves innervate abdominal muscles (expiratory) and diaphragm (inspiratory). Respiratory pattern and chemoreception are influenced by afferents from the lungs and carotid bodies. Excitatory inputs *(red arrows)*; inhibitory inputs *(blue buttons)*.

reflect defined anatomical areas. Still, recent discoveries of genetic defects (e.g., in the pairedlike homeobox 2b (PHOX2B) transcription factor causing "Ondine's curse") suggest that important structural and functional defects in this area can increase sensitivity of patients (who remain undiagnosed) to anesthetic-induced depression of breathing.[178]

Animal data is presented first, as required for a basic understanding of respiratory function; then the focus of this chapter turns to the clinically applicable studies.

Central Chemoreception

In the healthy individual, automatic breathing under normoxic, normocapnic conditions depends on excitatory chemodrive, approximately two thirds of which results from stimulation of central chemoreceptors by CO_2 and pH and one third from peripheral chemoreceptors by O_2 and CO_2.[179] Although many brainstem nuclei contain neurons whose discharge responds to changes in extracellular pH, the locations of central chemoreceptors are still under intense debate.[180] In essence, chemoreceptors are thought to be neurons that (1) tonically and proportionally discharge to extracellular pH, (2) project to other areas of the respiratory system where they form excitatory synapses, and (3) are crucial to the function of the respiratory system (i.e., destruction of these neurons should decrease respiratory output).

Animal studies have pointed to multiple chemosensitive sites in the brainstem that fulfill these criteria[180] including the RTN, medullary raphé, locus coeruleus, NTS, lateral hypothalamus, and caudal ventrolateral medulla. Glial cells in these areas may also theoretically contribute to chemoreception through their effect on extracellular pH or by hypoxia- or CO_2-induced ATP release that may alter the function of *chemosensitive*

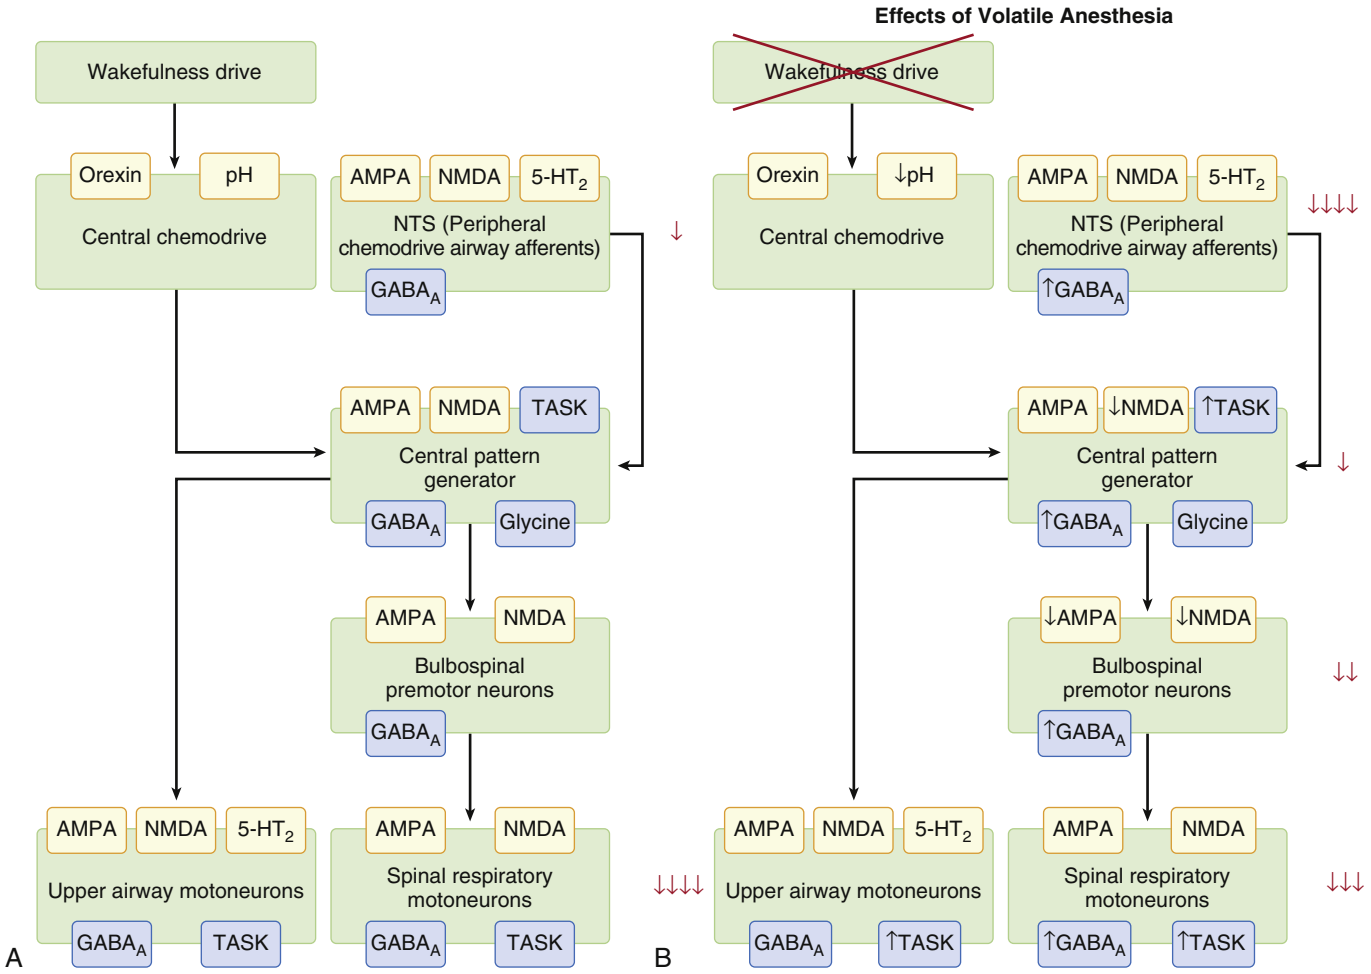

Figure 27-16. A, Ligand-gated receptors and ion channels on respiratory-related neurons. Excitatory receptors and channels are marked in *yellow*, inhibitory in *blue*. Opening of pH sensitive channels excites the neuron, whereas the opening of two-pore domain, acid-sensitive potassium (K^+) (TASK) channels causes membrane hyperpolarization and inhibition of neuronal discharge. **B**, Effects of volatile anesthetics on respiratory-related neurons. Volatile anesthetics eliminate wakefulness drive to the respiratory system *(red cross out)*. *Black arrows* indicate changes in receptor function (*up,* increase; *down*, decrease) that have been published in the literature. Volatile anesthetics reduce the presynaptic release of glutamate and gamma-aminobutyric acid A ($GABA_A$) in respiratory premotor neurons. The cumulative anesthetic effects on the respective neuron groups are depicted *(blue arrows)*. The relative magnitude of the depressant effect is visualized *(number of arrows)*. In humans, peripheral chemodrive is significantly more depressed than central chemodrive. Upper airway motoneurons are significantly more depressed than inspiratory motoneurons. *5-HT_2,* 5-Hydroxytryptamine; *AMPA,* alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionate acid; *NMDA, N*-methyl-D-aspartate

neurons.[181] Interestingly, the state of cortical arousal (asleep or awake) appears to affect whether acidification of these areas is capable of producing an increase in ventilation.[180] The activity of orexin neurons located in the lateral hypothalamus are involved in sleep-wake regulation and feeding and may be partially responsible for this latter effect (see Figure 27-16). These neurons also project to and enhance the function of other chemoreceptor sites including the RTN and medullary raphé. In addition, central chemoreceptor sites seem to function interdependently; that is, the degree of change in ventilation caused by acidification of one site depends on the integrity or simultaneous acidification of other sites.[182] In opposition to this multiple site central chemoreceptor theory, Guyenet suggested that the RTN is singularly equipped to function as the primary if not the sole source of respiratory drive during automatic breathing (i.e., during sleep or volatile anesthesia).[183] The RTN may also serve as the major relay point for wakefulness drive from higher brain centers and regulate CO_2 homeostasis in the conscious state. Interestingly, the actual substrate for central chemosensitivity, namely a pH sensitive channel that is present on all chemoreceptive neurons and increases neuronal discharge under physiologic conditions in vivo, has not been specifically identified.

Chemoreception not only provides the tonic excitatory drive to the respiratory oscillator, premotor neurons, motor neurons, and respiratory muscles that underlie automatic breathing, but it also promotes excitatory drive to neurons regulating upper airway patency and arousal from sleep.[180] The genioglossus muscle, which is typically regarded as representative for the muscles maintaining upper airway patency, receives significant tonic and phasic excitatory drive in the conscious state. Genioglossal muscle activity is reduced during sleep, but high levels of inspiratory CO_2 (>5%) are capable of recruiting

near-normal levels of phasic activity. This phenomenon does not occur during rapid eye movement (REM) sleep because genioglossal muscle activity is absent. Hypercapnia may be another mechanism (aside from hypoxia) by which patients with obstructive sleep apnea (OSA) arouse from sleep and re-establish airway patency. Thus residual subanesthetic concentrations of volatile anesthetics, which may be present for hours in postoperative patients, inhibit both peripheral hypoxic[184] and CO_2 chemosensitivity[185] and may also substantially impair the spontaneous arousal and resolution of upper airway obstruction that would otherwise occur with severe hypoxia or hypercarbia. Interestingly, the level of CO_2 drive and the related orexinergic stimulation of airway vagal preganglionic neurons have also been linked to the patency of the small airways. This observation may be clinically reflected in the incidence of bronchoconstriction, which is highest in the early morning hours when CO_2 sensitivity and orexin levels are lowest.[180]

Central Pattern Generator

Tonic excitatory respiratory drive from the chemoreceptive neurons is conveyed to a central pattern generator that translates all excitatory and inhibitory inputs into a respiratory pattern that consists of distinct inspiratory and expiratory phases. The following description summarizes recent reviews.[186-188] The central pattern generator is currently believed to consist of several nuclei in the pontomedullary network (see Figure 27-15), including the Kölliker-Fuse nucleus and parabrachial nucleus in the pons and the Bötzinger complex, pre-Bötzinger complex, and rostral and caudal ventral respiratory groups in the medulla. In the intact, mature mammal under physiologic conditions, respiratory rhythm is most likely generated by groups of neurons engaged in reciprocal inhibition; that is, by two or more major groups of oscillating neurons that alternate their discharges by inhibiting each other. This alternating inhibition contributes to two distinctly separate respiratory phases. The basic oscillating pattern is reinforced in the pontine respiratory group, which plays a significant role in respiratory phase switching.[189] The connections between the medullary nuclei and the pons are very strong and are paucisynaptic. Notably, the actions of volatile anesthetic on the central respiratory rate are different, depending on the inclusion of the pons in the experimental preparation. This observation indicates that the pons exerts a general inhibitory effect on medullary respiratory rate response. Volatile anesthetics reduce this pontine inhibition and contribute to an increase in respiratory rate.

Integration of Peripheral Inputs

Many afferent inputs from the periphery reach the brainstem respiratory center and influence the respiratory drive and timing. The most important of these peripheral inputs originates from the carotid bodies, which are paired, highly perfused sensory organs located at the bifurcation of the common carotid arteries. Hypoxia or hypercapnia causes an increase in carotid sinus nerve discharge. After a neuronal relay in the NTS, part of this excitatory input directly projects to the central pattern generator and increases respiratory drive. Carotid body afferent signals also project to other chemoreceptive areas of the brainstem, including the RTN, thereby influencing central chemoreception.[190]

Afferent vagal inputs from the lungs and airways are also relayed through the NTS. Pulmonary stretch receptor inputs project to second order *pump* neurons in the NTS, which can provide both excitatory and inhibitory inputs to various parts of the medullary respiratory column. In general, pulmonary stretch receptor inputs promote the phase switch from inspiration to expiration. This vagal expiratory-facilitating reflex (Hering-Breuer reflex) is most prominent in immature mammals but also modulates respiratory phase-timing during resting ventilation in adult human volunteers.[191] Although some of these inputs directly influence the central pattern generator, others are integrated at the level of the bulbospinal or premotor neurons, which project to the motor neurons in the spinal cord.

Respiratory Motor Output and Upper Airway Patency

The excitatory input to phrenic motor neurons (the main inspiratory neurons in the spinal cord) is mediated by inspiratory bulbospinal neurons in the ventral respiratory group.[187] Expiratory motor neurons receive inputs from expiratory bulbospinal neurons and the pons.[187] Phrenic motor neurons are located at the levels C3-C5 of the spinal cord and innervate the diaphragm. Expiratory motor neurons are also located at approximately T7-T12 of the spinal cord and innervate truncal abdominal muscles that powerfully aid with expiration and with expiratory expulsive efforts such as coughing. The spinal motor neurons are the final neurons in the respiratory neuronal hierarchy, which means that their activity tends to be reduced by the cumulative effect of anesthetics on all previous steps of chemoreception and neurotransmission. Phrenic motor neurons are also directly depressed by volatile anesthetics.[192]

Inspiratory muscle activity is closely coordinated with upper airway patency. Genioglossal muscle activity is often chosen as an indicator for upper airway patency and the hypoglossal motor nerve as representative for the neural innervation of upper airway muscles. Hypoglossal motor neurons are located close to the obex in the medulla. The strength of excitatory and inhibitory drive to hypoglossal motor neurons strongly depends on the level of consciousness and differs between the REM and non-REM sleep phases. The primary excitatory drive of hypoglossal motor neurons (both tonic and phasic components) derives from noradrenergic neurons in the locus subcoeruleus and the pontine A5 or A7 region. Additional excitation results from glutamatergic drive from the raphé pallidus and is mediated by both *N*-methyl-D-aspartic acid (NMDA) and non-NMDA glutamate receptors.[193] Excitatory serotonergic inputs from the dorsal raphé nucleus and various histaminergic inputs appear to play only minor roles in conscious and nonvagotomized rodents. Interestingly, glutamate release may be reduced through presynaptic 5-hydroxytryptamine 1A (5-HT1A) and 1B (5-HT1B) receptors. Hypoglossal motor neuronal excitation is modulated by phasic GABAergic inhibition, but GABAergic or glycinergic inhibition does not appear

to produce significant suppression of hypoglossal motor neuronal activity during REM sleep.[194] Hypoglossal motor neurons also receive cholinergic inputs from the pedunculopontine tegmental neurons and the reticular formation. These inputs result in postsynaptic modulation of hypoglossal activity and presynaptic modulation of excitatory (glutamatergic) inputs.[195]

Importance of Sleep and Wake States

Two opposing systems determine the arousal state of an individual and with it the magnitude of respiratory drive and upper airway patency.

The *wakefulness-activating system* is an arousal system ascending from the brainstem that activates the forebrain and maintains consciousness. The orexinergic neurons from the lateral hypothalamus and the cholinergic neurons from the basal forebrain region project to the cortex to maintain cortical arousal. The orexinergic neurons also project to the brainstem to reinforce the activity of the ascending arousal system. The arousal system also increases the hypoglossal nerve activity by stimulating the locus coeruleus, which increases the excitatory noradrenergic input to the hypoglossal motor neurons. The ascending arousal system simultaneously inhibits neurons in the ventrolateral preoptic nucleus (VLPO), an area in which a group of hypothalamic neurons inhibit neurons involved in wakefulness.[195]

Opposing the wakefulness-activating system is the *sleep-activating system*, which consists of the anterior hypothalamus, basal forebrain, and VLPO. The sleep-activating system is responsible for nonREM sleep and directly suppresses the ascending cortical, as well as the brainstem arousal systems via $GABA_A$ergic neurons (also see Chapter 14).

These two antagonistic systems ensure that the brain is either awake or asleep without a partial transition state. GABAergic inhibition profoundly reduces the activity of the brainstem-arousal system mediated by noradrenergic, serotonergic, cholinergic, and histaminergic neurons during sleep. The withdrawal of activity from these neurons also causes a reduction of drive to the hypoglossal motor nucleus and thus a loss in upper airway tone.[195]

Reduced noradrenergic and serotonergic activity in the brainstem neurons leads to diminished presynaptic inhibition ($alpha_2$ and 5-HT1A) of pontine cholinergic neurons. The resultant increase in acetylcholine in the pontine reticular formation triggers REM sleep. During this phase, the locus coeruleus and dorsal raphé are inhibited via GABAergic inhibition. Spinal projections lead to glutamatergic activation of spinal inhibitory interneurons, which inhibit spinal motor neurons and lead to near-complete immobility except for respiration and REMs.

Upper airway patency is compromised by substantially lower concentrations of volatile anesthetics than diaphragmatic muscle activity.[196] This observation may be due, at least in part, to the arousal state—dependence of hypoglossal motor neuron activity. The near-complete loss of genioglossal activity during sleep may contribute to the development of OSA in patients with anatomic predisposition. These patients are at particular risk for upper airway obstruction during anesthesia because volatile anesthetics not only suppress the noradrenergic-mediated wakefulness drive to hypoglossal motor neurons, but they also profoundly depress the glutamatergic drive originating from peripheral and central chemoreception.

EFFECTS OF INHALED ANESTHETICS ON RESTING VENTILATION AND CHEMOREFLEXES IN HUMANS

Volitional control of breathing is reduced during sedation with concentrations of volatile anesthetic of less than 1 MAC and is completely abolished at higher concentrations. This phenomenon is similar to sleep in which breathing is largely controlled by automatic brainstem mechanisms and chemoreflex inputs. During sedation with most volatile anesthetics (in particular, those that undergo significant metabolism such as halothane), not only is there a loss of volitional control, but also a dose-dependent impairment of the peripheral chemoresponses to hypoxia and partial arterial pressure of carbon dioxide ($Paco_2$) occur. Interestingly, depression or enhancement of carotid body activity does not shift the central CO_2 threshold in an additive fashion; rather, it reduces or increases central CO_2 sensitivity, respectively.[197] From a clinical perspective, inhibition of carotid body activity by a volatile anesthetic increases the $Paco_2$ required to stimulate respiratory activity, compared with the conscious state. In the presence of volatile anesthetic concentrations of 1 MAC or higher, breathing in humans is entirely dependent on the automatic control from the pontomedullary respiratory center and afferent excitatory inputs from the *central* chemoreceptors. These anesthetic concentrations lead to a complete depression of the peripheral chemoreflex loop with further respiratory depression rather than stimulation in response to hypoxia.[198] A loss of upper airway muscle tone and function accompanies this process, as does differential depression of neurotransmission at the level of the spinal cord.[199]

EFFECTS OF INHALED ANESTHETICS ON RESTING VENTILATION

All volatile anesthetics cause a dose-dependent decrease in expiratory minute ventilation at concentrations greater than 1 MAC as a result of a decrease in tidal volume. Respiratory rate typically increases (Figure 27-17), but no evidence suggests that this increase in rate is a compensatory mechanism or that it is causally related to the reduction in tidal volume. Of note, the dose-dependent increase in respiratory rate observed with most volatile anesthetics is largely absent during isoflurane anesthesia concentrations greater than 1 MAC. Most volatile anesthetics cause an *increase* in respiratory rate by producing a decrease in both inspiratory and expiratory duration, whereas opioids cause a very prominent *decrease* in respiratory rate that primarily results from a large increase in expiratory duration. In general, the decrease in resting minute ventilation observed during the administration of volatile anesthetics is somewhat less than expected when compared with experiments performed under isocapnic conditions because the central chemoreflex feedback loop

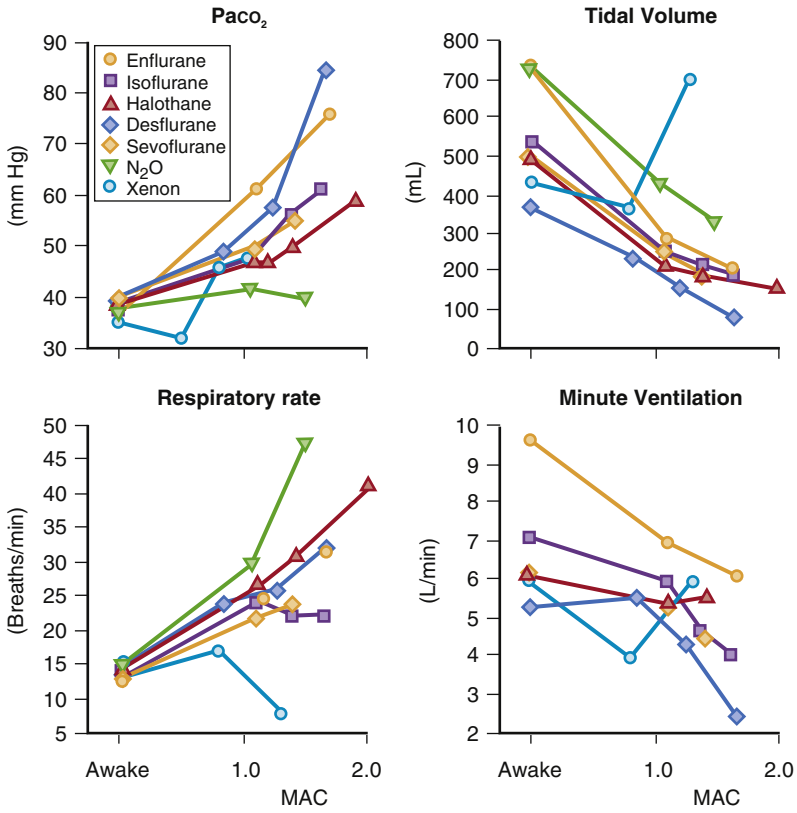

Figure 27-17. Comparison of mean changes in resting partial arterial pressure of carbon dioxide ($Paco_2$), tidal volume, respiratory rate, and minute ventilation in patients anesthetized with various inhaled agents. Most agents cause dose-dependent tachypnea, decreases in minute ventilation and tidal volume, and an increase in $Paco_2$. *MAC,* Minimum alveolar concentration, *N_2O,* nitrous oxide. *(Data are from references 297 and 299-304. Note the data for xenon has been extrapolated from references 291 and 305-307.)*

is *closed*; that is, central chemoreceptor feedback remains largely intact. Thus volatile anesthetic–induced hypoventilation increases $Paco_2$, which stimulates the central chemoreceptors, thereby increasing central chemodrive to the respiratory center.[200-205] As a result, the observed modest decrease in minute ventilation under closed loop conditions incompletely reflects the magnitude of the respiratory depressant effects of a volatile anesthetic and does not accurately predict the magnitude of the depressant effects of the anesthetic on the ventilatory response to either CO_2 or hypoxia. Nonetheless, the resultant elevation in resting $Paco_2$ observed with different volatile anesthetics at similar MAC values follows the order: halothane < sevoflurane < isoflurane < desflurane (see Figure 27-17). Volatile anesthetics also cause a rightward shift of the apneic threshold[206]; that is, the minimum $Paco_2$ required to initiate spontaneous respiration. Thus coordinated spontaneous breathing efforts do not occur if mechanical or assisted ventilation efforts drive the $Paco_2$ levels below the CO_2 threshold during anesthesia.[207]

EFFECTS OF INHALED ANESTHETICS ON THE HYPERCAPNIC VENTILATORY RESPONSE

Peripheral chemoreceptors contribute approximately one third of the CO_2-mediated minute ventilation in awake humans during normoxia. During hypoxia, the peripheral hypercapnic ventilatory response is augmented.[208] The CO_2-mediated component of the peripheral chemodrive remains largely intact, but the hypoxia-mediated component is rapidly abolished during the administration of volatile anesthetic concentrations under 1 MAC.[184,209-215] However, at higher anesthetic concentrations, chemical control of breathing is almost entirely mediated by the CO_2-responsive central chemoreceptors. Thus the central chemoreflex loop and not the hypoxic drive provides the primary excitatory chemodrive to the respiratory pattern generator to sustain respiration during deeper levels of volatile anesthesia.

The relative depressant effects of an equivalent MAC value of volatile anesthetics may be described by measuring the decrease of the sensitivity (slope) of the CO_2 response curve. The ventilatory CO_2 sensitivity is approximately 2 to 3 L/min/mm Hg[216] in conscious patients but significantly depressed by up to 70% during the administration of volatile anesthetics.[217]

EFFECTS OF INHALED ANESTHETICS ON THE HYPOXIC VENTILATORY RESPONSE IN HUMANS

The hypoxic ventilatory response (HVR) in conscious individuals is substantial and rarely observed because hypoxia is rarely encountered under normal circumstances. A mountaineer is exposed to an environmental barometric pressure of only 253 mm Hg at the summit of Mt. Everest (8848 m) without supplemental O_2 with an ambient O_2 tension of only approximately 50 mm Hg (one third of that at sea level). Arterial blood gases in one climber at this altitude showed a pH of 7.72, a partial arterial pressure of oxygen (PaO_2) of 37.6 mm Hg, and a $Paco_2$ of 7.5 mm Hg. These occurred as a result of severe hypoxic hyperventilation with the estimated minute ventilation

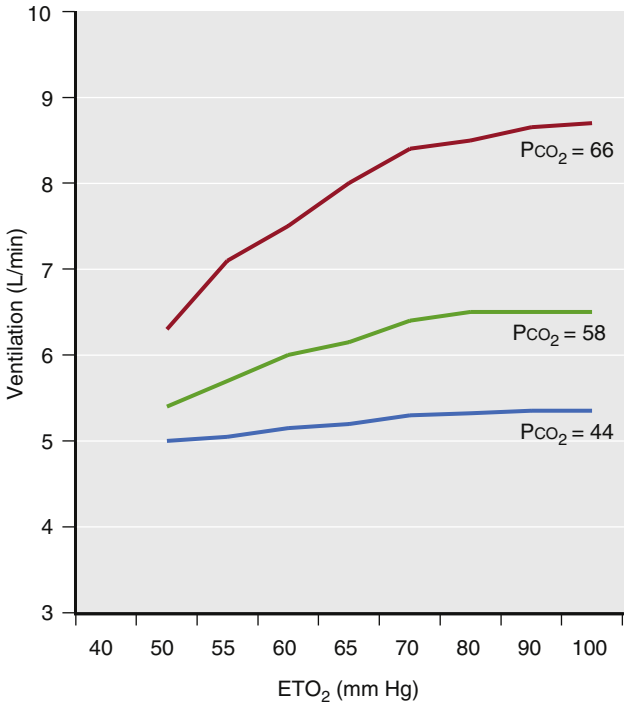

Figure 27-18. Effects of halothane anesthesia on the hypoxic ventilatory response in humans at three steady-state levels of partial pressure of carbon dioxide (P_{CO_2}). Halothane anesthesia (1.1 minimum alveolar concentration [MAC]) completely eliminates the hypoxic ventilatory response and the hypoxic hypercapnic interaction at the peripheral chemoreceptors. *ETO_2*, End-tidal oxygen. *(Modified from Knill RL, Gelb AW: Ventilatory responses to hypoxia and hypercapnia during halothane sedation and anesthesia in man,* Anesthesiology *49:244, 1978. Used with permission.)*

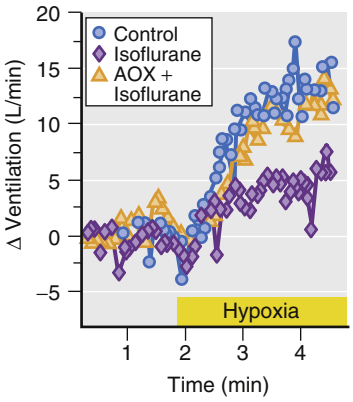

Figure 27-19. Subanesthetic concentrations of isoflurane strongly depress the acute hypoxic ventilatory response in humans. The depression of the hypoxic ventilatory response by subanesthetic isoflurane is prevented by antioxidant (AOX) pretreatment. *(Modified from Teppema LJ, Romberg RR, Dahan A: Antioxidants reverse reduction of the human hypoxic ventilatory response by subanesthetic isoflurane,* Anesthesiology *102:747, 2005. Used with permission.)*

of approximately 166 L/min.[218] Yet, 1.1 MAC halothane anesthesia is able to completely abolish this powerful ventilatory response to hypoxia. In fact, the direct effect of hypoxia on the respiratory centers during the administration of volatile anesthetics causes a reduction in minute ventilation. This central depressant effect of hypoxia in the presence of a volatile anesthetic is especially pronounced during hypercapnia (Figure 27-18). The depression of the HVR occurs at subanesthetic concentrations (0.1 MAC) of volatile anesthetics. In analyzing 37 separate studies investigating the effect of low-dose volatile anesthetics on HPV, Pandit proposed the rank order of potency as halothane > enflurane > sevoflurane = isoflurane > desflurane.[184] The depressant effect on the HVR is due to selective depression of the peripheral chemoreflex loop. The carotid body appears to be the most likely target. The clinical implications of volatile anesthetic–induced depression of HVR are important because subanesthetic concentrations of volatile anesthetics may be present in patients for several hours after a prolonged surgery. As a result, a hypoxia-mediated arousal response may not be present after administering a volatile anesthetic. This is especially the case in patients with OSA and premature infants who are at risk of respiratory depression or apnea during the perioperative period.

The mechanisms by which low concentrations of volatile anesthetics attenuate hypoxic ventilatory drive are not completely understood. The administration of antioxidants to healthy volunteers reversed the attenuation of the HVR to subanesthetic concentrations of halothane and isoflurane (Figure 27-19).[219] These results suggested that volatile anesthetics depress the hypoxic response by influencing the oxidation-reduction state of O_2-sensing elements in the carotid bodies. How antioxidants mediate this response is unclear, but modulation of the mitochondrial electron transport chain, volatile anesthetic binding sites, or K^+ channel function may be plausible explanations.

EFFECTS OF INHALED ANESTHETICS ON RESPIRATORY MUSCLES ACTIVITY

Humans are *bipeds*, unlike the *quadruped* mammals (cat, dog, and rats) in which most invasive in vivo and in vitro respiratory control studies have been performed. This difference in *posture* probably contributes to the divergent contribution of various muscle groups, in particular of the truncal muscles, to the normal respiratory effort and also likely contributes to the different changes in respiratory muscle function under anesthesia between mammalian species. Warner and colleagues performed extensive in vivo studies on the effects of volatile anesthetics, especially halothane, on respiratory muscle activation in dogs both in the presence and absence of CO_2-stimulated breathing.[220] Analogous studies using electromyography, fast CT scanning technology, and impedance plethysmography conducted in supine humans demonstrated that respiratory muscle activation during halothane anesthesia (1.2 MAC) significantly differed from the results observed in dogs.[217,221,222] Scalene and parasternal inspiratory activity are almost universally present during quiet breathing in conscious supine humans, but abdominal expiratory activity is absent. These inspiratory activities are enhanced, and abdominal expiratory activity is universally recruited during CO_2-stimulated rebreathing (which simulates increased chemodrive during exercise).

Halothane *differentially* depresses inspiratory muscle activity. The activity of the diaphragm as the main inspiratory pump muscle is relatively spared (Figure 27-20).

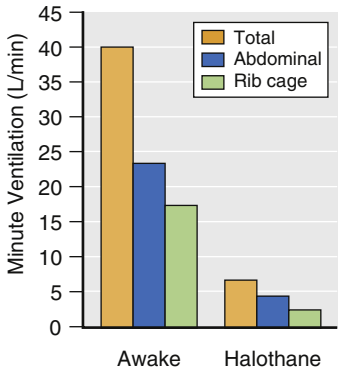

Figure 27-20. Effects of halothane anesthesia on rib cage and abdominal ventilation during hypercapnia (calculated ventilation at partial arterial pressure of carbon dioxide [Pa_{CO_2}] of 55 mm Hg). Compared with being awake, halothane anesthesia strongly depresses minute ventilation. Halothane depresses the rib cage component to ventilation more than the abdominal component (diaphragmatic). Data are means. *(Graph is based on data from Warner DO, Warner MA, Ritman EL: Mechanical significance of respiratory muscle activity in humans during halothane anesthesia,* Anesthesiology *84:309, 1996.)*

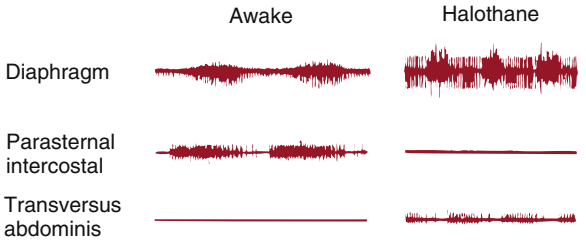

Figure 27-21. Representative record of respiratory electromyograms from one patient while awake and during halothane anesthesia. Halothane anesthesia selectively depresses inspiratory rib cage muscle activity and elicits expiratory abdominal muscle activity. *(From Warner DO, Warner MA, Ritman EL: Human chest wall function while awake and during halothane anesthesia. I. Quiet breathing,* Anesthesiology *82:6, 1995. Used with permission.)*

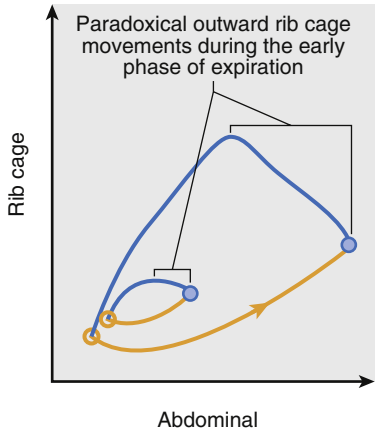

Figure 27-22. Chest wall and abdominal motion during anesthesia in a male patient are plotted as changes in thoracoabdominal movements and measured by respiratory impedance plethysmography at the onset *(small loop)* and conclusion *(large loop)* of rebreathing. Open and closed circles denote the beginning and end of inspiratory gas flow, respectively. After the termination of inspiration (i.e., during early expiration), the patient exhibits paradoxical rib cage motion with rib cage dimensions continuing to increase. *(From Warner DO, Warner MA, Ritman EL: Mechanical significance of respiratory muscle activity in humans during halothane anesthesia,* Anesthesiology *84:309, 1996. Used with permission.)*

Abdominal expiratory activity is routinely recruited during halothane anesthesia in male subjects. During quiet breathing, halothane anesthesia significantly depressed tidal volume (conscious, 707 ± 72 mL versus halothane, 288 ± 15 mL; mean ± standard error of the mean [SEM]) without any significant relative changes in abdominal versus rib cage contribution. An increase in respiratory rate (conscious, 10.6 ± 0.6 breaths/min versus halothane, 26.5 ± 2.8 breaths/min) and a reduction in FRC (335 ± 75 mL) were also reported. Halothane significantly reduced the slope of the expiratory minute ventilation to CO_2 response curve (conscious, 2.21 ± 0.34 L/min/mm Hg versus halothane, 1.49 ± 0.35 L/min/mm Hg). Thus expiratory minute ventilation at partial pressure of carbon dioxide (P_{CO_2}) = 55 mm Hg was dramatically reduced during halothane administration (conscious, 40.5 ± 7.5 L/min versus halothane, 6.7 ± 3.7 L/min). Furthermore, halothane strongly depressed the rib cage response to CO_2 during CO_2 rebreathing, whereas the abdominal (i.e., diaphragmatic) response was unaffected (Figure 27-21).[217]

Significant gender-related differences in respiratory muscle activity were observed during halothane anesthesia in spontaneously breathing humans. Women showed activation of inspiratory parasternal intercostal activity, which was enhanced during CO_2-induced rebreathing, whereas parasternal intercostal activity during halothane anesthesia did not change in men. Phasic inspiratory activity was present in the scalene muscle in the majority of subjects. CO_2-stimulated rebreathing uniformly increased scalene muscle phasic inspiratory activity. In contrast, inspiratory activity in internal intercostal muscles was present in men but not in women. Strong phasic expiratory activity in the transversus abdominis muscle was observed during halothane anesthesia in men but not in women, whereas CO_2 rebreathing elicited expiratory abdominal muscle activity in both genders. These observations demonstrate that, unlike in animals, there are important gender-specific differences on how volatile anesthetics affect respiratory muscles in humans. Indeed, caution should be used when extrapolating results from animal studies.

When expiratory transversus abdominis activity was present, the rib cage became significantly constricted (i.e., inward displacement of the rib cage), which reduced thoracic volume and partially contributed to the observed reduction of FRC during halothane anesthesia. A cephalad motion of the end-expiratory position of the diaphragm was also observed in supine halothane-anesthetized subjects. This alteration in diaphragm position also reduced FRC. Halothane distorted the normal phase relationships between the rib cage and abdominal movements observed in the conscious state with both rib cage and abdomen expanding during inspiration. *Paradoxical* rib cage motion developed in some subjects during halothane anesthesia, such that the rib cage continued to expand during the first portion of expiratory gas flow. Such paradoxical rib cage motion was exaggerated during CO_2-stimulated rebreathing (Figure 27-22).[217,222,223]

Similar to volatile anesthetics, nitrous oxide affects chest wall function and breathing by changing the distribution and timing of neural drive to the respiratory muscles.[224] Nitrous oxide decreases tidal volume as a result of a reduction in rib cage motion and increases phasic expiratory activity in humans.

EFFECTS OF INHALED ANESTHETICS ON THE UPPER AIRWAY

Pediatric anesthesiologists often conduct an inhaled induction of anesthesia (also see Chapter 93) and are very familiar with the upper airway collapse resulting from the administration of volatile anesthetics. As a result, pediatric anesthesia training is focused on mastering the skills of maintaining upper airway patency during mask induction and maintaining anesthesia in spontaneously breathing children. Inspiratory upper airway patency is maintained by the cortical wakefulness drive, fully preserved chemical chemoreceptor sensitivity and chemodrive transmission, and optimal reflex feedback from upper airway receptors in the conscious state. These upper airway receptors are activated by the negative pressure and airflow[225,226] that are generated by the pump muscles (e.g., diaphragm, respiratory chest wall muscles). During sleep, the cortical wakefulness drive is absent, and the sensitivity of the chemoreceptors and upper airway receptors is decreased. Thus both phasic and tonic inspiratory excitatory drives to the upper airway muscles are decreased or entirely absent during volatile anesthesia. The loss of tone in the upper airway muscles (genioglossus and other pharyngeal muscles) predisposes individuals with anatomic limitations (e.g., narrowed upper airway secondary to obesity or craniofacial abnormalities, adenotonsillar hypertrophy, macroglossia, micrognathia) to upper airway obstruction.

The cortical wakefulness drive, peripheral chemodrive from the peripheral chemoreceptors, and excitatory inputs from upper airway mechanoreceptors are already significantly impaired in the presence of subanesthetic concentrations of volatile anesthetics. Such conditions are often present in the immediate postoperative period and may lead to partial or even complete upper airway obstruction, a situation that is further complicated because subanesthetic concentrations of volatile anesthetics also strongly suppress hypoxia-mediated arousal reflexes. Higher anesthetic concentrations of volatile anesthetics cause further loss of upper airway muscle tone, which may lead to airflow limitation or complete airway obstruction, despite the continued function of respiratory pump muscles in patients with or without sleep-disordered breathing or anatomic airway abnormalities.[196,227]

Cortical control of breathing is absent, and respiration depends entirely on automatic brainstem mechanisms and blunted CO_2-mediated central chemoreceptor inputs at clinical levels of volatile anesthesia (≥1.0 to 1.3 MAC). Both tonic and phasic upper airway muscle tone is largely absent, and many anatomically normal patients will demonstrate air flow limitations, as indicated by flow-limited breathing secondary to partial or complete upper airway obstruction during negative inspiratory pressure. The airflow-limiting factor is almost invariably soft-tissue collapse at the level of the nasal velopharynx. The loss of velopharyngeal tone during surgical levels of volatile anesthesia can often be overcome with the simple application of CPAP. Collapse of the upper airway during inspiration, concomitant with inspiratory flow limitation during maximal inspiratory effort, rarely occurs in conscious patients or those with OSA because both phasic and tonic upper airway tone is robust. However, selective suppression of the upper airway reflexes alone (e.g., topical local anesthetics applied to the upper airway) may contribute to upper airway obstruction in some conscious patients with OSA or sleep-disordered breathing.

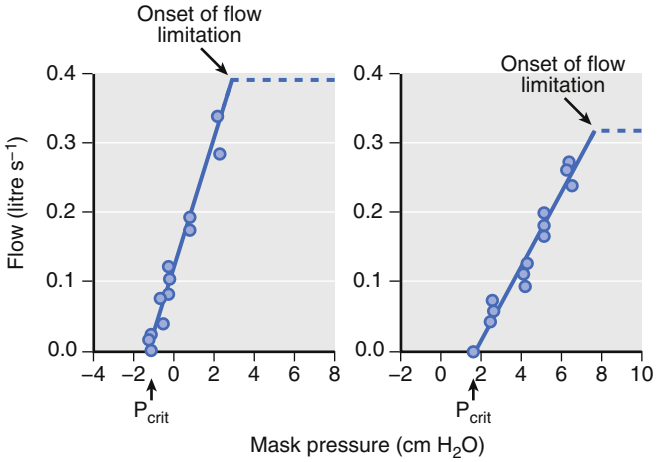

Figure 27-23. Relationship between maximal inspiratory flow and upper airway pressure for two subjects spontaneously breathing at end-tidal isoflurane levels of 1.2%. Both subjects exhibit inspiratory flow limitation as the positive upper airway pressure is lowered. The left panel demonstrates data from a subject with a relatively stable upper airway; note that the critical closing pressure (P_{crit}), indicating complete upper airway collapse is subatmospheric. The right panel demonstrates data from a subject with an unstable airway; note that P_{crit} exceeds atmospheric pressure. *(Modified from Hillman DR, Platt PR, Eastwood PR: The upper airway during anaesthesia,* Br J Anaesth *91:31, 2003. Used with permission.)*

The upper airway pressure proximal to the velopharynx, at which complete upper airway collapse occurs with no inspiratory flow during spontaneous breathing, is defined as the critical closing pressure (Pcrit). Pcrit is negative in normal, conscious individuals. As a result, it is difficult to cause complete airway collapse. Pcrit becomes less negative during sleep but remains typically slightly subatmospheric during the administration of a volatile anesthetic. Indeed, many patients who are anatomically normal show signs of inspiratory flow limitations at higher concentrations (≥1 to 1.3 MAC) of volatile anesthetics because Pcrit approaches zero (i.e., atmospheric pressure). Under these circumstances, CPAP may be required to maintain nasopharyngeal-velopharyngeal patency and to overcome the inspiratory flow limitation (Figure 27-23).[228,229] In patients with significant anatomic airway abnormalities (e.g., OSA, retrognathia), CPAP alone may be insufficient to maintain upper airway patency and additional measures (e.g., sniffing position, jaw thrust) may be required. If these standard maneuvers are insufficient to restore upper airway patency, then insertion of an airway device may be necessary to ensure upper airway patency.

EFFECTS OF INHALED ANESTHETICS ON DEFENSIVE AIRWAY REFLEXES

Vocal cord adduction and coughing in response to foreign material are important defensive reflex mechanisms that protect the airway from aspiration. Volatile anesthetics exert dose-dependent effects on defensive airway reflexes. Volatile anesthetics (≥1 to 1.3 MAC) progressively abolish defensive airway reflexes. The loss of airway protection against gastroesophageal reflux with consequent aspiration of orogastric content into the trachea are major adverse consequences of the loss of protective airway reflexes during the administration of volatile anesthetics. In contrast, lower concentrations of volatile anesthetics, such as those present during transitional states (e.g., mask induction, emergence), may paradoxically enhance and prolong the duration of protective defensive reflexes. Laryngospasm is the sustained and complete reflex glottic closure in response to foreign material (e.g., oral secretions), contacting the vocal cords, or to a poorly timed noxious stimulus (e.g., pain from incision, venipuncture) during the administration of inadequately low concentrations of a volatile anesthetic. Under such circumstances, therapeutic airway maneuvers, such as jaw thrust and sustained positive airway pressure, do not often relieve laryngospasm, and severe hypoxemia may ensue. Sedative-hypnotics or lidocaine may be used to *deepen* the plane of anesthesia rapidly or, alternatively, the administration of a neuromuscular blocker may be used to terminate the laryngospasm. In the absence of intravenous access (as may be the case during mask induction in infants and children), resorting to intramuscular, intraosseous, or intralingual injection of a neuromuscular blocker may be necessary to treat life-threatening laryngospasm. Clinical experience and experimental studies suggest that *severe* hypoxia ultimately silences laryngeal adductor motor neuron activity and terminates laryngospasm, but profound cardiovascular depression may precede relief of laryngospasm under these conditions.

Not all volatile anesthetics are equally prone to elicit unwanted sustained defensive airway reflexes. Desflurane and isoflurane appear to be most irritating to the airways; neither anesthetic is recommended for an inhaled induction of anesthesia. Lerman and associates[228] showed that the maintenance and emergence from desflurane anesthesia caused significantly more severe adverse airway events than did isoflurane anesthesia in spontaneously breathing infants and children with an LMA, especially when the LMA was removed before emergence. Another study in children confirmed the general clinical impression that isoflurane is more irritating to the airway than sevoflurane.[230] Children emerging from isoflurane anesthesia with an LMA in place had significantly more adverse airway reactions when compared with those anesthetized with sevoflurane (also see Chapter 93). Notably, higher concentrations (1.8 MAC) of isoflurane and sevoflurane produced similar attenuation of coughing, tachycardia, and hypertension associated with tracheal stimulation, but desflurane may continue to irritate the respiratory tract at concentrations that exceed 1 MAC. Removal of airway devices (e.g., LMA, endotracheal tube) during higher concentrations (>1.5 MAC) of a volatile anesthetic

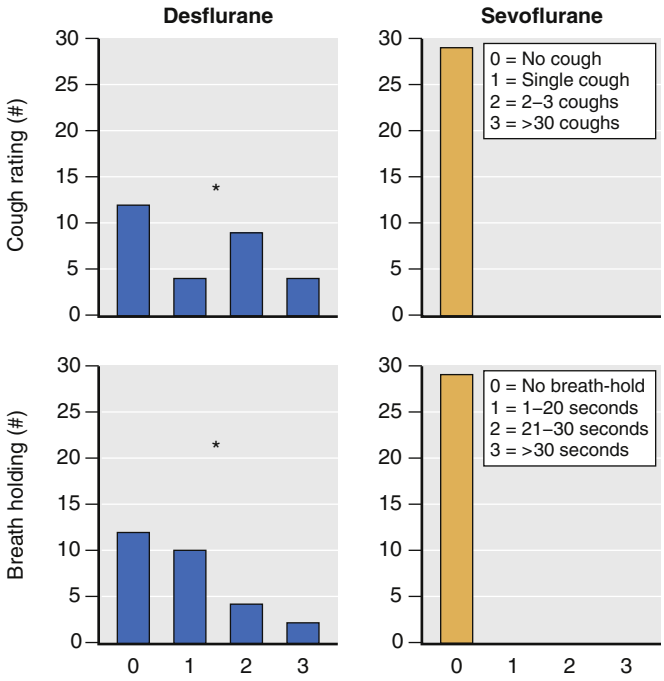

Figure 27-24. Graded responses to coughing and breath holding during transition to 2 minimum alveolar concentration (MAC) desflurane and sevoflurane anesthesia in elective surgical patients. Only desflurane caused adverse respiratory events, as indicated by an *asterisk*. *(Modified from Arain SR, Shankar H, Ebert TJ: Desflurane enhances reactivity during the use of the laryngeal mask airway,* Anesthesiology *103:495, 2005. Used with permission.)*

minimizes the risk of tracheal stimulation and laryngospasm related to the device. Nevertheless, desflurane caused significantly more adverse airway-related events, including coughing and breath holding, compared with sevoflurane,[231] even though patients had received adjuvant medications to blunt adverse airway reflexes (Figure 27-24). These findings contrasted with those of another study[232] that did not observe a difference in the airway-related complications in patients anesthetized with sevoflurane or desflurane. However, an average MAC value of less than 1 was used in this study. Klock and associates[233] confirmed the prevailing clinical opinion that sevoflurane may be better tolerated than desflurane at 1 MAC because cough responses to noxious airway stimulation (cuff inflation and deflation) were reduced. However, little difference was found between the two anesthetics at 1.8 MAC.[234] Anesthesia with desflurane, alone, probably leads to more airway-related adverse events than sevoflurane or halothane. Desflurane-related adverse airway reflexes may be mitigated by the use of adjuvant medications and the appropriate timing of airway device removal. Notably, significant increases in airway irritation were observed in tobacco smokers, independent of the specific volatile anesthetic.[235]

Unlike desflurane and isoflurane, sevoflurane and halothane are not pungent (irritants). This characteristic makes these volatile anesthetics the preferred medication for inhalational induction in infants and children. The mechanisms for the irritant effects of desflurane and isoflurane are not well understood. These volatile anesthetics

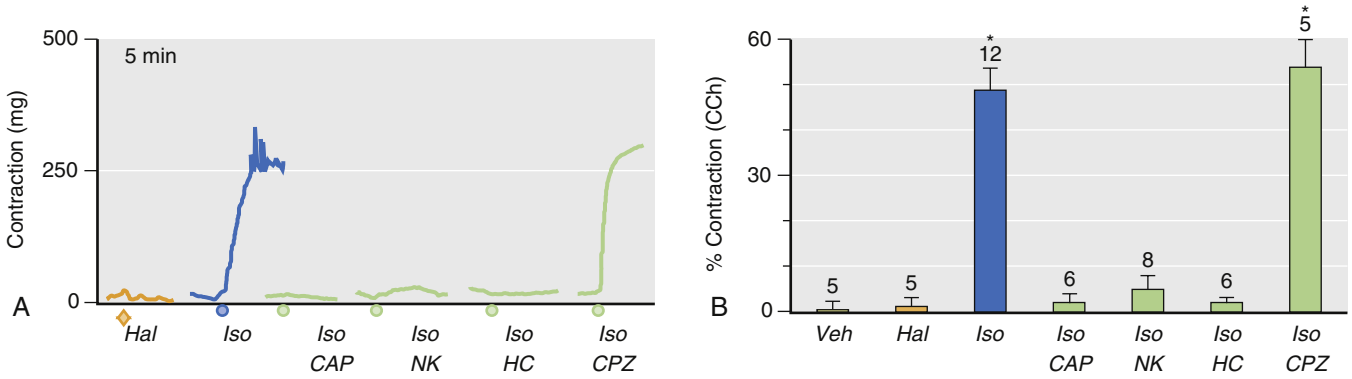

Figure 27-25. Isoflurane induces a contractile response in guinea pig bronchus. Typical traces (**A**) and pooled data (**B**) of the motor responses of guinea pig isolated bronchus to halothane (Hal) (◇) and isoflurane (Iso) *(filled circles)* or their vehicle (Veh) either alone or after pretreatment with capsaicin (CAP), the combination of neurokinin (NK)–receptor antagonists, the transient receptor potential cation channel, member A1, (TRPA1) antagonist (HC), or the transient receptor potential cation channel, subfamily V, member 1, (TRPV1) antagonist capsazepine (CPZ). Each column (in **B**) represents the mean ± standard error of the mean (SEM), and the number of observations for each group is listed in parenthesis. *, $P < 0.05$ versus Veh. *CCh,* Carbachol. *(Modified from Eilers H, Cattaruzza F, Nassini R, et al: Pungent general anesthetics activate transient receptor potential-A1 to produce hyperalgesia and neurogenic bronchoconstriction,* Anesthesiology *112:1452, 2010. Used with permission.)*

activate the excitatory, nonselective cation-channel transient-receptor potential (TRP)–A1, whereas the nonirritant anesthetics, halothane and sevoflurane, do not.[236] TRP-A1 channels detect endogenous and environmental chemical irritants and noxious stimuli. The channels play an important role in mediating protective airway responses. Desflurane and isoflurane also produce bronchoconstriction in experimental animals that is dependent on TRP-A1 activation of sensory neurons that are widely distributed throughout the respiratory tract. Thus it has been postulated that TRP-A1 channels in peripheral nociceptors mediate the irritant effects associated with desflurane and isoflurane (Figure 27-25).[236] Whether this nonadrenergic, noncholinergic (NANC)–mediated mechanism is important in humans remains unclear.

Halothane may be better than sevoflurane at suppressing airway reflexes during airway instrumentation (e.g., direct laryngoscopy, rigid bronchoscopy) because comparable MAC concentrations of halothane may cause stronger depression of noxious stimuli than sevoflurane.[237] However, closed claims outcome data suggest that the cardiovascular safety profile of halothane is inferior to that of sevoflurane[238,239] in infants and children during inhalational induction.[238,239] Endotracheal intubation of infants and children without a neuromuscular blocker after induction of anesthesia via mask is not recommended except under conditions in which maintenance of spontaneous breathing is preferred and when intravenous access cannot be readily achieved (also see Chapter 93). Administering small doses of a neuromuscular blocker significantly improves intubating conditions and decreases adverse airway reactions, compared with a *deep* inhaled sevoflurane anesthesia alone.[240]

Ishikawa and colleagues showed that infants and children who were spontaneously breathing with an LMA in place at a steady-state end-tidal concentration of 1% sevoflurane displayed strong *passive* (laryngospasm, apnea) and *active* (coughing, swallowing) airway reflexes in response to small amounts of water injected onto the vocal cords (Figure 27-26). At an end-tidal sevoflurane

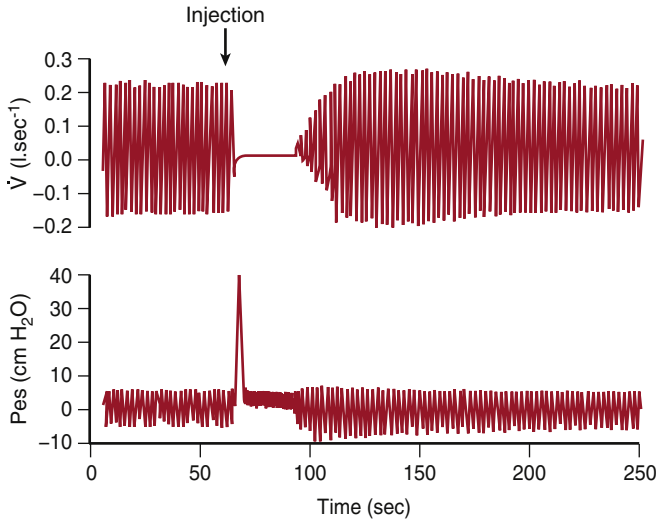

Figure 27-26. Demonstrable responses to laryngeal distilled water instillation. The subject was anesthetized with 1% of sevoflurane in oxygen. After only a few breaths after the instillation, laryngeal closure was observed, followed by laryngospasm and central apnea. Note no respiratory efforts occurred during apnea. A significant increase in esophageal pressure corresponded to the swallowing reflex. $\dot{V}$, Respiratory flow in L/sec.; *Pes,* esophageal pressure. *(From Ishikawa T, Isono S, Tanaka A, et al: Airway protective reflexes evoked by laryngeal instillation of distilled water under sevoflurane general anesthesia in children,* Anesth Analg *101:1615, 2005. Used with permission.)*

concentration of 2%, children continued to display passive responses, but active responses were completely depressed.[241] Thus transient or sustained glottic closures were routinely elicited during sevoflurane (1 MAC) anesthesia.

When volatile or intravenous anesthetics were used as the sole maintenance anesthetic in the absence of neuromuscular blockade, these medications had very different effects on active and passive upper airway reflexes in spontaneously breathing children. Oberer and coworkers[242] concluded that instillation of water onto the vocal

cords during light sevoflurane anesthesia (as determined using BIS monitoring) caused more laryngospasm and apnea than during propofol anesthesia. Conversely, active expiratory airway reflexes were greater when compared with sevoflurane at equivalent BIS values. Interestingly, neither passive nor active airway protective reflexes were completely depressed by 1.2 or 1.8 MAC sevoflurane anesthesia in adult women, results that are in contrast to those obtained in children.[243]

ACUTE LUNG INJURY

MECHANISMS OF ACUTE LUNG INJURY

Acute lung injury resulting from sepsis, pneumonia, ARDS, or asthma is common in patients who are critically ill and involves a vicious cycle of hypoxia and inflammation. Exposure to ambient hypoxia may cause pulmonary edema (e.g., high-altitude pulmonary edema) and an inflammatory response in the absence of pulmonary injury. Irrespective of the cause, acute lung injury is always accompanied by hypoxia and inflammation.[244] Hypoxia-induced inflammation results in enhanced vascular permeability and edema formation, atelectasis, airway plugging, microthrombi, $\dot{V}/\dot{Q}$ mismatch, apoptosis, and release of inflammatory mediators including tumor necrosis factor alpha (TNF-α), macrophage inflammatory protein-2 (MIP-2), monocyte chemoattractant protein-1 (MCP-1), interleukin (IL)–6 or IL-8, and cytokine-induced neutrophil chemoattractant-1 (CINC-1). Infiltration of neutrophils also occurs. Inflammation enhances metabolic and O_2 demand, further worsening the relative tissue hypoxemia, compromising gas exchange, and activating hypoxia-mediated signaling pathways, including those mediated by the A2B adenosine receptor[245,246] (also see Chapters 101 through 103).

The clinical condition of sepsis-induced acute lung injury is modeled in the laboratory by injection or inhalation of lipopolysaccharide (LPS), a component of the outer membrane of gram-negative bacteria. LPSs bind to Toll-like receptor 4 to activate nuclear factor κB, upregulate adhesion molecules, and stimulate cytokine-induced neutrophil migration into the pulmonary parenchyma. The alveolar epithelium may also be injured by endotoxin and may play a critical role in maintaining alveolar homeostasis by producing specific proteins, including surfactant and a variety of cytokines and by clearing excess alveolar liquid. Notably, failure of the alveolar epithelium is associated with increased mortality.[247]

Acute ventilator-induced lung injury (VILI) is manifested as severe distension of and damage to bronchoalveolar structures, lung overinflation, and bronchiectasis.[248] Caveolin-1, an integral membrane protein and component of endothelial caveolae (plasma membrane invaginations) regulates critical cell functions including endothelial uptake, albumin transport, and apoptosis.[249] Caveolin-1 plays an important role in the pathogenesis of acute lung injury. Inflammatory cytokines, including TNF-α, IL-1β and MIP-2, may be released from alveolar epithelial cells, neutrophils, and macrophages. Cytokines are important mediators of leukocyte recruitment and activation. In general, attenuation of the cytokine response is considered beneficial in terms of reducing potential lung injury. Alternatively, blunting the release of inflammatory mediators and attenuation of neutrophil migration into the inflamed lung may be detrimental and predispose immunocompromised patients to a greater risk of pulmonary infections. Unfortunately, the release of cytokines is highly variable, depending on experimental conditions. For example, altering the ventilation strategy may modify lung cytokine responses to LPS,[248] whereas positive pressure ventilation alone in the absence of anesthesia may exacerbate inflammatory responses.[250] NO is derived from inducible nitric oxide synthase (iNOS) in response to inflammation and endotoxin and also appears to play an important role in acute lung injury. Inhibition of iNOS substantially reduced pulmonary lymph filtration and improved oxygenation during endotoxemia in conscious sheep[251] (also see Chapter 104).

The presence of preexisting pulmonary disease, including chronic bronchitis, emphysema, and pneumonia, may exacerbate pulmonary damage that occurs in response to an acute lung injury.[235] As with acute lung injury, tobacco smoking induces an inflammatory state, but inhaled tobacco abuse decreases the response of macrophages and neutrophils. Thus these cells are less capable of releasing cytokines during an infection. In addition, goblet-cell hyperplasia, decreased mucociliary clearance, and increased airway reactivity occur in chronic tobacco smokers and contribute to potential infection, bronchospasm, and acute lung injury.

INHALED ANESTHETICS ENHANCE ACUTE LUNG INJURY

Volatile anesthetics both exacerbate and attenuate acute lung injury. Mechanical ventilation alone, in the absence of acute lung injury or volatile anesthetics, produces inflammatory pulmonary changes and injury known as VILI.[252-254] Cyclic stretching of the lung during mechanical ventilation (1) releases proinflammatory cytokines, such as IL-1 and MIP-2, leading to pulmonary neutrophil accumulation; (2) enhances activity of phospholipase A2, which degrades surfactant; and (3) results in pulmonary edema, hyaline membrane formation, and cellular infiltration. Reduced tidal volume with PEEP was successfully used to mitigate the adverse effects of VILI and ARDS. Nevertheless, inflammatory changes and lung injury still occur, despite this strategy. Thus studies investigating the specific effects of volatile anesthetics on acute lung injury must also account for concomitant damage caused by VILI. Volatile anesthetics enhance gene expression of proinflammatory cytokines and impair immune functions of alveolar macrophages in vitro and in vivo[255-257] (Figure 27-27). Halothane also caused DNA and cell damage, nuclear fragmentation, and apoptotic-like changes in isolated pulmonary epithelial cells.[258] Although desflurane and sevoflurane affect the function and distribution of lymphocytes[259,260] during one-lung ventilation, the clinical significance of this finding remains unclear. Volatile anesthetics exacerbated the extent of lung injury and increased mortality in a rat model of acid aspiration.[261]

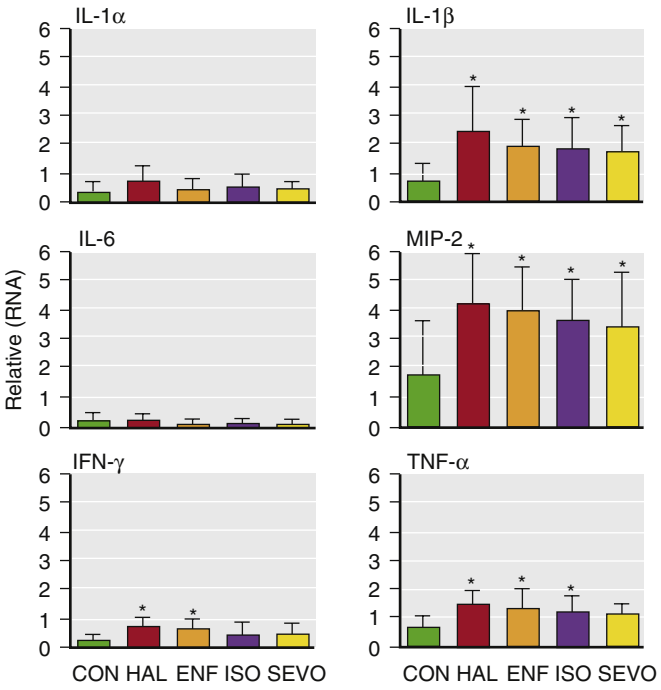

Figure 27-27. Changes in the expression of proinflammatory cytokines from macrophages during mechanical ventilation with and without volatile anesthetics. Values are the ratio of cytokine messenger ribonucleic acid (mRNA) to β-actin mRNA and presented as means ± standard deviation (SD). *, $P < 0.05$ versus the control group (mechanical ventilation without volatile anesthetics). Gene expression for interleukin-1β (IL-1β), macrophage inflammatory protein-2 (MIP-2), interferon-gamma (IFN-γ), and tumor necrosis factor alpha (TNF-α) all significantly increased in comparison with mechanical ventilation alone. *CON,* Control; *ENF,* enflurane; *HAL,* halothane; *IL-1α,*interleukin-1α; *ISO,* isoflurane; *SEVO,* sevoflurane. *(Modified from Kotani N, Takahashi S, Sessler DI, et al: Volatile anesthetics augment expression of proinflammatory cytokines in rat alveolar macrophages during mechanical ventilation,* Anesthesiology *91:187, 1999. Used with permission.)*

The magnitude of the injury and mortality rate was dose dependent. The extent of injury was unaffected by the concomitant infusion of phenylephrine to avoid systemic and pulmonary hypotension. However, compromised pulmonary perfusion may have contributed to the results of this study. Volatile anesthetics may also augment the inflammatory response to mechanical ventilation.[256,262,263] Pigs were anesthetized for 4 hours with propofol or 1 MAC sevoflurane or desflurane.[263] Pigs anesthetized with sevoflurane or desflurane showed the following: (1) fewer alveolar macrophages in the bronchoalveolar lavage fluid (BALF), (2) greater percentage of lymphocytes in the BALF, and (3) greater apoptotic index (as measured by caspase-3 protein), compared with those anesthetized with propofol. Pigs receiving sevoflurane also showed significantly reduced levels of platelet-activating factor (PAF) acetylhydrolase, which limits the deleterious effects of PAF, and more pronounced atelectasis than propofol-anesthetized pigs. Of note, no differences were observed between groups in phospholipase-2 levels, intraalveolar septal thickening, alveolar edema, or wet-to-dry ratios, as indicators of pulmonary edema. In the absence of gross histologic effects, the deleterious effects of the volatile anesthetics appear to be predominantly functional. Similarly, no significant effects on alveolar integrity or ultrastructure were observed after administering high concentrations of sevoflurane in pigs.[264] The confounding factor of mechanical ventilation cannot be completely eliminated from the analysis because this factor alone may be associated with many of the inflammatory responses observed. A lack of PEEP may have also contributed to the observed exacerbation of lung injury in this study.[265] Although the results suggest that volatile anesthesia plays a detrimental, proinflammatory role, one cannot rule out a beneficial role for propofol. However, results from in vivo studies do not support a role for propofol in reducing acute lung injury.

Volatile anesthetics may worsen acute lung injury by increasing alveolar permeability. Using radionuclide scanning, halothane and isoflurane transiently increased pulmonary vascular endothelial damage.[266] Isoflurane also enhanced alveolar epithelial permeability in patients undergoing surgery.[267] Desflurane increased lipid peroxidation as measured in BALF samples from healthy surgical patients,[268] suggesting that the pulmonary alveolar membranes had been injured. Sevoflurane caused less-pronounced effects in this model, suggesting that this anesthetic may exert a protective effect, compared with desflurane. Furthermore, isoflurane, but not sevoflurane, increased albumin permeability and transport in isolated rat lungs.[249] These deleterious actions appeared to be related to an enhancement of caveolin-1–mediated albumin uptake. Similarly, pretreatment with isoflurane but not sevoflurane enhanced neurogenic pulmonary edema in rats.[269] Low concentrations of isoflurane also exacerbated impaired pulmonary gas exchange ($\dot{V}/\dot{Q}$ mismatch and shunting) and worsened O_2 delivery after oleic acid–induced lung injury in mechanically ventilated dogs.[270]

Proinflammatory responses and enhanced cytokine levels in healthy surgical patients undergoing tympanoplasty were more pronounced after desflurane, compared with sevoflurane anesthesia. Patients anesthetized with desflurane had more pronounced systemic and intrapulmonary inflammatory responses (as measured by mediators TNF-α, IL-1β, and IL-6) both before and after initiation of surgery, as compared with those anesthetized with sevoflurane.[255]

INHALED ANESTHETICS REDUCE ACUTE LUNG INJURY

Hypoxia is a common mechanism of acute lung injury. Hypoxia-inducible factor helps ameliorate lung injury via activation of hypoxia-responsive genes (e.g., iNOS, heme oxygenase, vascular endothelial growth factor) under conditions of low O_2 tension in the lung. Exposing isolated pulmonary cells to isoflurane significantly increased hypoxia-inducible factor 1α, and enhanced gene expression for hypoxia-responsive genes.[271] These actions suggest that volatile anesthetics are capable of producing a protective effect during acute lung injury.

Whether volatile anesthetics reduce or exacerbate pulmonary cytokine formation appears to be based on the type of cells studied and the conditions under which the cytokine expression is measured. Volatile anesthetics

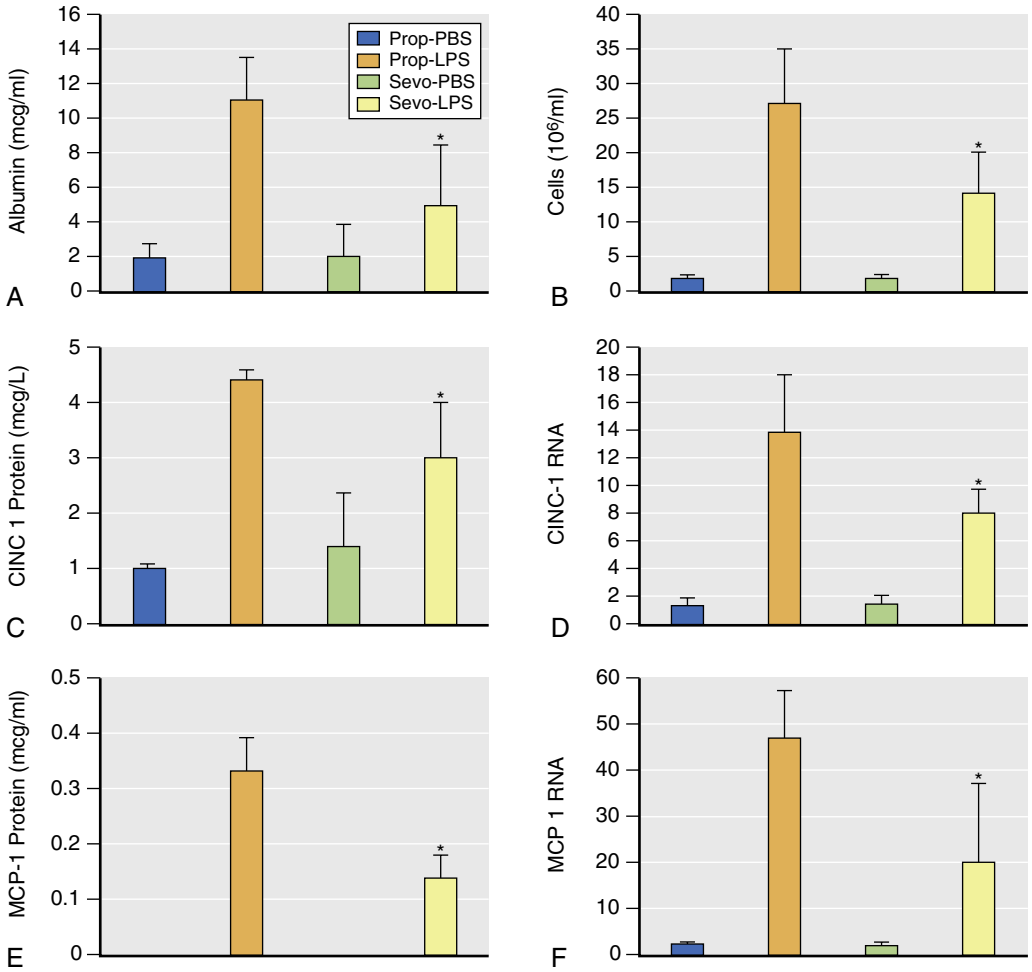

Figure 27-28. Instillation of phosphate-buffered saline (PBS) or lipopolysaccharide (LPS) intratracheally in rats, followed by ventilation and sedation with propofol (Prop) for 2 hours and continued with either propofol or with sevoflurane (SEVO) for an additional 4 hours. Evaluation of **A,** Lung hyperpermeability after 6 hours as measured by the amount of albumin in the bronchoalveolar lavage fluid (BALF). Sevoflurane inhibits the LPS-induced permeability. **B,** Total cell count in BALF. Cell count significantly increased in both LPS groups and were mostly neutrophils. The presence of sevoflurane was associated with a significantly lower total cell count. **C** and **D,** Cytokine-induced neutrophil chemoattractant-1 (CINC-1). CINC-1 protein in BALF and CINC-1 ribonucleic acid (RNA) in lung tissue were significantly increased in both LPS groups, as compared with PBS control groups. The presence of sevoflurane was associated with decreased RNA expression and decreased protein, compared with during propofol. **E** and **F,** Monocyte chemoattractant protein-1 (MCP-1). MCP-1 protein in BALF and MCP-1 RNA in lung tissue were significantly increased in both LPS groups, compared with PBS control groups. The presence of sevoflurane was associated with decreased RNA expression and decreased protein, compared with during propofol. Data are means ± standard deviation (SD). *, $P < 0.05$ versus propofol-LPS. *(Modified from Voigtsberger S, Lachmann RA, Leutert AC, et al: Sevoflurane ameliorates gas exchange and attenuates lung damage in experimental lipopolysaccharide-induced lung injury,* Anesthesiology *111:1238, 2009. Used with permission.)*

increased the secretion and gene expression of some cytokines in alveolar macrophages but reduced the formation of proinflammatory cytokines in alveolar type II cells.[250,272,273] Pretreatment with 1.1% sevoflurane also significantly reduced the inflammatory response and attenuated endotoxin-induced chemotaxis of neutrophils from alveolar type II cells exposed to LPS.[274] Several animal studies also suggest an important antiinflammatory role of volatile anesthetics in reducing acute lung injury. Compared with thiopental anesthesia, pigs anesthetized with sevoflurane exhibited a reduced expression of TNF and IL-1β in lung tissue.[275] Volatile anesthetics appear to exert antiinflammatory effects, including the inhibition of cytokine formation, reduction of neutrophil migration into the lung interstitium and alveolar space, and attenuation of protein leakage and pulmonary edema (Figure 27-28),[250,272,273,276,277] in models of acute lung injury induced with LPS, *Escherichia coli* endotoxin, or IL-1β. LPS-induced acute lung injury was significantly reduced in the presence of sevoflurane, compared with propofol anesthesia.[277] Sevoflurane, but not propofol, improved the oxygenation index and reduced the amount of pulmonary edema. Interestingly, the beneficial effect of sevoflurane on pulmonary edema resulted from a reduction in edema formation rather than water reabsorption or edema resolution. If this is indeed a critical mechanism, then sevoflurane would be expected to have little beneficial effect if the volatile anesthetic was administered after a pulmonary insult. In fact, however, this was not the case.[276] Rats anesthetized with thiopental were mechanically ventilated, anesthesia was continued with propofol infusion, and LPS was administered

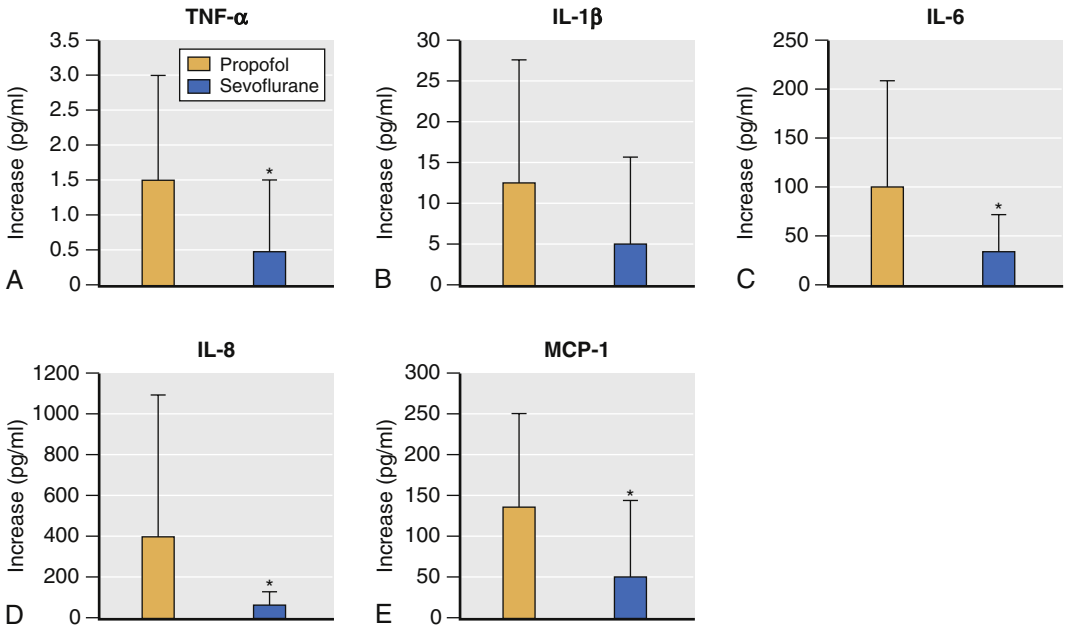

Figure 27-29. Increases in inflammatory mediators from bronchoalveolar lavage fluid in patients during one-lung ventilation receiving either propofol or sevoflurane. *, $P < 0.05$. Values are means ± standard deviation (SD). **A,** Increase in tumor necrosis factor alpha (TNF-α). **B,** Increase in interleukin-1β (IL-1β). **C,** Increase in interleukin-6 (IL-6). **D,** Increase in interleukin-8 (IL-8). **E,** Increase in monocyte chemoattractant protein-1 (MCP-1). Sevoflurane attenuates the release of inflammatory mediators during one-lung ventilation. *(Modified from De Conno E, Steurer MP, Wittlinger M, et al: Anesthetic-induced improvement of the inflammatory response to one-lung ventilation,* Anesthesiology *110:1316, 2009. Used with permission.)*

through an intratracheal approach. Two hours later, anesthesia was continued with either propofol or sevoflurane (0.5 to 1 MAC) for 4 hours, and several markers of lung injury were measured (see Figure 27-28). Rats receiving sevoflurane demonstrated the following: (1) improved gas exchange, (2) reduced amounts of albumin in BALF, (3) smaller total cell count in BALF (fewer neutrophils), and (4) lower cytokine levels in BALF and RNA levels in lung tissue, compared with rats receiving propofol. These data indicate that the administration of sevoflurane after the induction of pulmonary edema significantly attenuates lung injury and preserves lung function.[276] Similarly, isoflurane also protected against warm ischemia-reperfusion injury in an isolated, perfused rat lung model when the volatile anesthetic was administered after the onset of ischemia.[278]

In addition to improving lung function in sepsis, volatile anesthetics decrease lung injury attributable to mechanical ventilation[279] and ischemia-reperfusion.[280] The administration of isoflurane mitigated VILI as indicated by reduced inflammation, transmigration of neutrophils, and cytokine levels in mice.[279] Isoflurane also induced Akt (protein kinase B) phosphorylation; the beneficial effects of the volatile anesthetic were abolished by a selective phosphoinositide 3-kinase (PI3K) inhibitor. These findings strongly suggest that isoflurane-mediated pulmonary protection occurs through PI3K signaling. ATP-regulated K^+ (K_{ATP}) channels play important roles in cardioprotection and neuroprotection by volatile anesthetics, but blockade of these channels did not block the protective effects of isoflurane in this lung injury model.[279] Reductions in oxidative stress and inflammatory responses were also observed during sevoflurane, compared with propofol anesthesia in a porcine model of ischemia-reperfusion injury.[280]

Clinical investigations in patients support a beneficial role for volatile anesthetics in ameliorating lung injury (Figure 27-29).[281-284] For example, short-term positive pressure ventilation with high tidal volumes did not affect systemic proinflammatory or antiinflammatory cytokines in the lungs of healthy, isoflurane-anesthetized patients.[282] Three studies investigated the effects of volatile anesthetics in patients undergoing thoracic surgery using single-lung ventilation.[281,283,284] Single-lung ventilation increased the release of proinflammatory cytokines and mediators in both the dependent and the nondependent lungs. Volatile anesthetics suppressed local alveolar inflammatory responses and cytokine release, compared with propofol (see Figure 27-29). Furthermore, the anti-inflammatory effects of sevoflurane were greater in the dependent compared with the nondependent lung.[283] Patients receiving sevoflurane also had an improved postoperative course as indicated by a shorter ICU stay and fewer adverse events, compared with those treated with propofol.[284]

Whether the immunomodulatory effects of volatile anesthetics are mediated by the ether structure or the halogen, configuration was investigated using isolated pulmonary cells in an in vitro model of acute inflammation.[285] Cells were co-exposed to endotoxin and sevoflurane, diethyl-ether, or various other trifluorinated carbon (CF_3) groups. Expression of inflammatory mediators and chemotactic activity were modified by sevoflurane and molecules containing CF_3 groups but not by the diethyl-ether or structure-similar nonfluorinated molecules. This finding may have potential therapeutic importance; such

molecules may be theoretically provided in a hydrophilic, injectable formulation for the treatment of acute lung injury.[285]

NITROUS OXIDE

Data regarding the actions of nitrous oxide on bronchomotor tone, pulmonary vasculature, mucociliary function, control of ventilation, and acute lung injury have been previously presented. This section addresses specific concerns regarding nitrous oxide and the pulmonary system not included in other sections (also see Chapter 27).

Nitrous oxide, the least potent inhaled anesthetic, is also the oldest anesthetic currently in use, although its longevity is threatened by concerns of adverse effects and postoperative complications.[286] The Evaluation of Nitrous Oxide in a Gas Mixture for Anaesthesia (ENIGMA) trial[287] reported that more postoperative complications associated with use of nitrous oxide occur, compared with high concentrations of O_2 (80% plus 20% nitrogen); these complications include wound infections and adverse pulmonary events such as pneumonia and atelectasis. Notably, this large trial was not blinded and did not show a significant difference for the primary endpoint, that is, for the duration of the hospital stay. A thorough review of the potential toxicity of nitrous oxide suggests that no convincing data exist that document an increase in pulmonary complications.[286] As an inhibitor of methionine synthetase, nitrous oxide causes a long-lasting, dose-dependent increase in plasma homocysteine, reduces DNA and purine synthesis, and suppresses neutrophil chemotaxis. The consequences of an increase in plasma homocysteine are impaired endothelial function, enhanced platelet aggregation, and enhanced oxidative stress; all are potentially deleterious to the pulmonary system. Nevertheless, no randomized, controlled trials have investigated the effects of nitrous oxide in various models of acute lung injury.

In addition to other forms of hypoxia-induced lung injury previously discussed, diffusion hypoxia is a well-known phenomenon that may occur during recovery from nitrous oxide anesthesia. Rapid elimination of nitrous oxide from the blood to the alveoli, combined with slower nitrogen diffusion, reduces alveolar O_2 concentration, resulting in relative hypoxemia.

XENON

The anesthetic properties of the inert gas, xenon, have been known for more than 50 years, and advances in manufacturing technology and scavenging systems have made xenon more cost-effective.[288] Similar to volatile anesthetics, xenon exerts important neuroprotective and cardiovascular effects against ischemia-reperfusion injury.[289] Data on the interactions between xenon and the respiratory system are limited. The estimated MAC of xenon in humans is 63%, and xenon-induced respiratory depression occurs during inhalation of 33% xenon in radiology suites.[290] Xenon does not significantly affect transdiaphragmatic pressure or diaphragmatic electromyography because the gas preserves neuromuscular transmission.[291] The effects of xenon on airway resistance substantially differ from those of volatile anesthetics. Xenon has the lowest blood-gas partition coefficient (0.115) of all known inhaled anesthetics. As a result, induction and emergence from anesthesia is rapid. However, the anesthetic gas has a higher density and viscosity than air[291-293] (also see Chapter 26). Baseline airway resistance was significantly greater during 70% xenon-O_2 than during 70% nitrous oxide–O_2, in pentobarbital-anesthetized pigs, but the peak and mean airway pressures were unaffected. In contrast, airway pressures and resistance were moderately increased during xenon anesthesia in the presence of methacholine-induced bronchoconstriction.[293] In addition, pulmonary resistance during inhalation of 50% xenon was similar to that observed during 50% nitrous oxide or 70% nitrogen in methacholine-treated dogs.[294]

A randomized, double-blind comparison of xenon and nitrous oxide showed that both gases similarly increased expiratory lung resistance to a similar degree. However, patients receiving xenon were less likely to experience decreases in O_2 saturation than those treated with nitrous oxide.[295] Administration of 33% xenon in long-term mechanically ventilated patients may cause transient, elevations in peak airway pressure.[292] This increase in airway pressure was attenuated by reducing the inspiratory flow rate. The higher density and viscosity of xenon increases Reynolds number and probably causes the zone of transition from turbulent to laminar gas flow to move more distally to smaller airways. Arterial O_2 and CO_2 tensions were unaffected during the administration of xenon in anesthetized pigs.[296] However, breathing higher density gas mixtures may reduce the alveolar-arterial O_2 difference, improve the distribution of ventilation, and minimize $\dot{V}/\dot{Q}$ variances.[297] In morbidly obese patients scheduled for gastric bypass surgery, gas exchange (e.g., PaO_2/FiO_2) was enhanced in patients receiving xenon, compared with sevoflurane.[298]

Diffusion hypoxia may be less likely during xenon anesthesia, compared with nitrous oxide, because the blood-gas partition coefficient of the noble gas is similar to that of nitrogen and, as a result, diffusion into the alveoli may be slower. The specific effects of xenon on bronchomotor tone, mucociliary function, pulmonary vasculature, ventilatory control, or acute lung injury have not been described to date.

SUMMARY

Inhaled anesthetics affect every aspect of respiratory physiologic function. Volatile anesthetics are potent bronchodilators that reduce bronchiolar smooth muscle tone. Volatile anesthetics inhibit both ciliary function and bronchial mucous transport. Volatile anesthetics are pulmonary arterial vasodilators and inhibit HPV in vitro, but their net effect on HPV in vivo is minimal. Volatile anesthetics also significantly alter the activity of respiratory afferents, the respiratory control center, and the muscles of respiration. These effects are mediated by actions on pulmonary parenchyma and afferent, central, and efferent neural structures. The depressant effects

of volatile anesthetics are more pronounced in patients with lung disease and sleep-disordered breathing. Volatile anesthetics are also immunomodulatory. In some models, they appear to be proinflammatory, but the majority of studies show that volatile anesthetics ameliorate acute lung injury. The inhaled anesthetics, nitrous oxide and xenon, also affect the respiratory system. Although many actions of xenon have not been as well described, this gas is unusual in that it increases tidal breathing and decreases respiratory rate, an action that is opposite of other inhaled anesthetics. An understanding of the multiple actions of inhaled anesthetics on the respiratory system likely enhances the safe delivery of anesthesia.

Acknowledgment: The editors and publisher would like to thank Drs. Phillip F. Pratt, Jr., and David C. Warltier for contributing a chapter on this topic to the prior edition of this work. It has served as the foundation for the current chapter.

Key Points

- Volatile anesthetics produce dose-related depression of left ventricular (LV), right ventricular, and left atrial myocardial contractility, LV diastolic function, and LV-arterial coupling in the normal heart.
- The negative inotropic effects of volatile anesthetics are related to alterations in intracellular calcium homeostasis within the cardiac myocyte.
- Volatile anesthetics affect the determinants of LV afterload to varying degrees in the presence of normal and dysfunctional myocardium.
- The systemic hemodynamic effects of volatile anesthetics are complex and are determined by the interaction of myocardial effects, direct actions on the arterial and venous vasculature, and alterations in autonomic nervous system activity.
- Volatile anesthetics sensitize myocardium to the arrhythmogenic effects of epinephrine to varying degrees and may prevent or facilitate the development of atrial or ventricular arrhythmias during myocardial ischemia or infarction depending on the concentration of the agent, the extent of the injury, and the location affected within the conduction pathway.
- Volatile anesthetics are relatively weak coronary vasodilators that are not capable of producing coronary steal at typically used clinical concentrations, even in patients with steal-prone coronary artery anatomy.
- Volatile anesthetics exert myocardial protective effects against reversible and irreversible myocardial ischemia in experimental animals and humans when administered before, during, or immediately after the onset of coronary artery occlusion and reperfusion.
- Volatile anesthetics depress baroreceptor reflex control of arterial pressure to varying degrees.
- Nitrous oxide causes direct negative inotropic effects, does not substantially affect LV diastolic function, and produces modest increases in pulmonary and systemic arterial pressure via a sympathomimetic effect. These actions are dependent to some degree on the baseline anesthetic.
- Xenon is essentially devoid of cardiovascular effects but has been shown to protect myocardium against ischemic injury in experimental animals.

INTRODUCTION

This chapter comprehensively describes the cardiovascular pharmacology of modern volatile anesthetics (including isoflurane, desflurane, and sevoflurane), nitrous oxide, and the anesthetic noble gas xenon. Comparison to older volatile anesthetics (halothane and enflurane) will be made only when necessary because these drugs are no longer available in most countries. The actions of inhaled anesthetics on cardiovascular function, cardiac electrophysiology, the coronary circulation, and autonomic nervous system control of the circulation will be examined in detail.

VOLATILE ANESTHETICS

CARDIOVASCULAR FUNCTION

Myocardial Contractility

Isoflurane, desflurane, and sevoflurane depress myocardial contractility in vitro and in vivo. Investigations conducted

in the 1960s demonstrated that halothane and enflurane produce dose-related depression of force-velocity relations and Frank-Starling curves in isolated cardiac muscle preparations and intact hearts, respectively. Circulatory depression occurs during halothane and enflurane anesthesia in humans. Isoflurane produced direct negative inotropic effects as indicated by decreases in maximal velocity of shortening, peak developed force, and maximal rate of force development during isotonic contraction in isolated papillary muscles. These reductions in myocardial contractility by isoflurane also contribute to the cardiovascular depression observed with this anesthetic in humans. Similarly, desflurane and sevoflurane depress intrinsic inotropic state in isolated myocardium, which helps define the hemodynamic effects of these volatile anesthetics in humans with or without heart disease.

The relative degree of myocardial depression produced by volatile anesthetics in vivo is more difficult to establish because simultaneous alterations in systemic and pulmonary hemodynamics and autonomic nervous system activity complicate assessment of left ventricular (LV) systolic function. Early studies using isovolumic- and ejection-phase measures of myocardial contractility demonstrated that halothane and enflurane caused very similar negative inotropic effects in experimental animals and humans. These findings were confirmed using the slope of the LV end-systolic pressure–mid-axis diameter relation as a relatively heart rate– and load-independent index of inotropic state. In contrast, isoflurane produced less myocardial depression than the older anesthetics in vivo. For example, isoflurane caused smaller reductions in maximum rate of LV pressure development (dP/dt) than halothane when identical minimum alveolar concentrations (MACs) were directly compared in the presence and absence of autonomic nervous system function, suggesting that differences in myocardial depression caused by these anesthetics occurred independent of autonomic nervous system activity. Differences in the negative inotropic effects of halothane and isoflurane have been quantified using the slope of the regional preload recruitable stroke work relation derived from differentially loaded LV pressure–segment length diagrams. In these studies, isoflurane maintained contractility an average of 20% higher compared with identical MAC halothane. Differences in the relative degree of myocardial depression produced by isoflurane and the older volatile anesthetics were also inferred in humans using isovolumic- and ejection-phase measures of contractile state. The negative inotropic actions of all volatile anesthetics are exacerbated by hypocalcemia, calcium channel blockers, and β_1-adrenoceptor antagonists and may be reversed by administration of exogenous calcium (Ca^{2+}), cardiac phosphodiesterase fraction III inhibitors, β_1-adrenoceptor agonists, Ca^{2+} channel agonists, and myofilament Ca^{2+} sensitizers. The differential effects of isoflurane and halothane on myocardial contractility are maintained during changes in inotropic state produced by these vasoactive drugs.

Desflurane causes systemic and coronary hemodynamic effects that are similar to those produced by isoflurane. Desflurane and isoflurane depressed myocardial function to equivalent degrees using isovolumic- and ejection-phase measures of contractility in experimental animals and humans. These observations were verified using both end-systolic pressure-volume relations and preload recruitable stroke work (Fig. 28-1) in the presence and absence of autonomic nervous system activity. However, the unique cardiovascular stimulation associated with rapid increases in inspired desflurane concentration in humans may lead to transient increases in myocardial contractility resulting from stimulation of the sympathetic nervous system. The effects of sevoflurane on myocardial contractility are virtually indistinguishable from that produced by isoflurane in dogs. Sevoflurane caused less myocardial depression than equivalent MAC of halothane in pigs and produced less myocardial depression than enflurane in humans evaluated using echocardiography. Sevoflurane decreased contractile function to approximately 40% to 45% of control values at 1.75 MAC in the presence and absence of autonomic nervous system activity using regional preload recruitable stroke work. This magnitude of myocardial depression

Figure 28-1. is similar to isoflurane and desflurane using an identical experimental model. Thus, isoflurane, desflurane, and sevoflurane depress contractile state to similar degrees in normal LV myocardium.

The effects of volatile anesthetics on myocardial contractility in animal models or patients with LV dysfunction have been less extensively studied. An early in vitro study demonstrated that isoflurane causes greater reductions in maximum shortening velocity and the peak rate of force development in papillary muscles from failing compared with normal hearts subjected to chronic pressure overload. Halothane also produced more pronounced myocardial depression in ischemic in contrast to normal myocardium. Isoflurane and halothane caused relatively greater negative inotropic effects in ventricular myocardium obtained from cardiomyopathic hamsters than in normal hamsters (Fig. 28-2). Isoflurane and sevoflurane also produced greater depression of contractility in right ventricular (RV) papillary muscles obtained from ferrets with experimental pressure-overload hypertrophy compared with normal myocardium.[1] These findings suggested that myocardial depression caused by volatile anesthetics in failing or hypertrophied myocardium were accentuated and provided indirect evidence that patients with underlying contractile dysfunction may be more sensitive to the negative inotropic effects of volatile anesthetics. In contrast, isoflurane, sevoflurane, and desflurane caused similar declines in contractility in ventricular myocytes obtained from rats in the presence and absence of chemically induced chronic hyperglycemia.[2]

Volatile anesthetic–induced declines in contractile function were well tolerated and did not precipitate frank systolic dysfunction in experimental models of myocardial ischemia or infarction. In fact, volatile anesthetics exert important beneficial effects on mechanical function during myocardial ischemia and reperfusion injury. Volatile anesthetics reduced experimental myocardial infarct size, preserved metabolic and structural integrity during regional ischemia and reperfusion, enhanced the functional recovery of stunned myocardium, and improved indices of LV diastolic performance during brief coronary artery occlusion. Isoflurane produces beneficial decreases in LV preload and afterload in patients with ischemic heart disease. These improvements in loading conditions in patients with compromised LV function may serve to offset the direct negative inotropic effects of anesthetics and contribute to relative maintenance of cardiac performance by optimizing the Starling relationship or improving LV diastolic function. Isoflurane produced dose-related depression of myocardial contractility in a model of moderate LV dysfunction induced by chronic rapid LV pacing, but isoflurane anesthesia was well tolerated and did not precipitate LV failure. These findings with isoflurane were attributed to simultaneous improvements in LV loading conditions and filling dynamics that contributed to relative maintenance of cardiac output in the setting of moderate LV dysfunction despite concomitant reductions in contractility.

Cellular Mechanisms of Myocardial Depression

Volatile anesthetics depress myocardial contractility by alterations of intracellular Ca^{2+} homeostasis at several subcellular targets in the normal cardiac myocyte. Volatile anesthetics caused dose-related inhibition of the transsarcolemmal Ca^{2+} transient by affecting both L-type and T-type Ca^{2+} channels. Isoflurane produced less-pronounced reductions in intracellular Ca^{2+} transient than the older volatile ansethetics. The structural conformation and functional integrity of the voltage-dependent Ca^{2+} channel were directly altered by volatile anesthetics as indicated by attenuated binding of the Ca^{2+} channel blockers. The partial inhibition of Ca^{2+} influx via sarcolemmal Ca^{2+} channels has several important consequences, including declines in the availability of Ca^{2+} for contractile activation, depression of Ca^{2+}-dependent Ca^{2+} release from the sarcoplasmic reticulum (SR), and reduction of the amount of Ca^{2+} that can be subsequently stored in the SR. Notably, acute preconditioning by isoflurane triggers persistent changes in the inactivation of L-type Ca^{2+} channels that may contribute to attenuation of intracellular Ca^{2+} overload during ischemia-reperfusion injury.[3] In contrast to halothane and enflurane, isoflurane did not stimulate Ca^{2+} release from the SR or directly activate ryanodine-sensitive SR Ca^{2+} release channels, thereby reducing SR Ca^{2+} storage. Unlike halothane, isoflurane also did not cause a nonspecific leak of Ca^{2+} from the SR. When combined with decreases in transsarcolemmal Ca^{2+} flux, these alterations in SR function represent important mechanisms by which halothane and enflurane depressed the intracellular Ca^{2+} transient and reduced myocardial contractility more than isoflurane, desflurane, or sevoflurane. In addition, isoflurane and sevoflurane inhibited Ca^{2+} transport from the cell through the sarcolemmal Ca^{2+}-adenosine triphosphatase (ATPase), an action that partially offset reductions in SR Ca^{2+} stores. The partial preservation of the myocardial

positive frequency staircase effect observed with newer volatile anesthetics at physiologic excitation rates in vitro is due to this relative maintenance of SR function, in contrast to halothane or enflurane.

Volatile anesthetics also depress contractile function by inhibiting Na^+-Ca^{2+} exchange and reducing intracellular Ca^{2+} concentration independent of the voltage-dependent Ca^{2+} channel in vitro. This effect may be particularly important in neonatal myocardium, which may be more sensitive to the negative inotropic actions of volatile anesthetics than adult myocardium. The relative contribution of Na^+-Ca^{2+} exchange inhibition to anesthetic-induced depression of myocardial contractility in the intact heart remains controversial, but a role for Na^+-Ca^{2+} exchange inhibition in preconditioning by volatile anesthetics (see "Preconditioning and Postconditioning") was demonstrated.[4] Volatile anesthetics also may exert direct effects on the contractile apparatus and reduce myofilament Ca^{2+} sensitivity. Volatile anesthetics decreased tension development of skinned cardiac myofibrils and reduced myofibrillar ATPase activity. These actions may contribute to declines in actin-myosin cross-bridge kinetics during contraction, but not through a direct interaction with cardiac cross-bridge mechanics.[5] In addition, volatile anesthetics may modestly reduce myofilament Ca^{2+} sensitivity, but this mechanism probably plays a relatively minor role in the negative inotropic effects of these medications at clinically relevant concentrations in vivo.

The cellular mechanisms responsible for volatile anesthetic–induced depression of myocardial contractility in failing myocardium have not been studied in detail. However, the effects of isoflurane and sevoflurane on intracellular Ca^{2+} homeostasis have been studied in a model of RV pressure-overload hypertrophy.[1] These anesthetics produced more pronounced reductions in peak intracellular Ca^{2+} concentration and exaggerated decreases in myofilament Ca^{2+} sensitivity in ventricular myocytes obtained from hypertrophied compared with normal hearts. Whether similar alterations in intracellular Ca^{2+} regulation are produced by volatile anesthetics in other forms of heart failure remains to be determined. Profound abnormalities in Ca^{2+} homeostasis are characteristic features of failing myocardium, and volatile anesthetics may cause further reductions in contractile function by producing additive or synergistic effects on Ca^{2+} metabolism under these conditions.

Diastolic Function

Definitions of heart failure based solely on contractile dysfunction are inadequate because LV function during diastole significantly influences overall cardiac performance. The heart serves dual roles, propelling blood into the high-pressure arterial vasculature during systole and collecting blood from the low-pressure venous circulation during diastole. Thus, heart failure may occur not only from impaired contractility but also from altered LV diastolic function. The timing, rate, and extent of LV filling are determined by several major factors, including the rate and extent of myocardial relaxation, the intrinsic mechanical properties of the LV itself and those imposed by external constraints, and the structure and function of the left atrium, the pulmonary venous circulation, and the mitral valve.[6] Abnormalities in LV diastolic function may be linked to decreases in myocardial contractility, but heart failure also may result from primary diastolic dysfunction in the absence of or before the appearance of alterations in LV systolic function in a variety of pathologic conditions, including ischemic heart disease, pressure-overload or volume-overload hypertrophy, hypertrophic obstructive cardiomyopathy, and restrictive disease processes.

Volatile anesthetics produce dose-related prolongation of LV isovolumic relaxation in vivo. This delay of isovolumic relaxation is associated with declines in early LV filling but is not of sufficient magnitude to affect LV chamber stiffness. Coronary blood flow is elevated during isovolumic relaxation, and delays in relaxation produced by volatile anesthetics contribute to impairment of coronary flow during early diastole. Prolongation of LV relaxation probably occurs as a result of simultaneous depression of myocardial contractility and not because of a direct negative lusitropic effect. In fact, volatile anesthetics modestly enhanced the rate of relaxation of isolated myocardium in vitro. Volatile anesthetics also cause concentration-related decreases in the rate and extent of early LV filling concomitant with negative inotropic effects. Further, volatile anesthetics reduced LV filling during atrial systole.[7] Isoflurane, desflurane, and sevoflurane did not alter invasively derived indices of regional myocardial or chamber stiffness, indicating that LV distensibility was unaffected by these volatile anesthetics.

The effects of isoflurane and halothane on LV diastolic function in a canine model of dilated cardiomyopathy were described. In contrast to the findings in dogs with normal LV function, isoflurane improved several indices of LV relaxation and filling in cardiomyopathic hearts despite producing simultaneous negative inotropic effects. In addition, halothane did not exacerbate the preexisting diastolic dysfunction inherent in this experimental model. The findings with isoflurane and halothane were most likely related to favorable reductions in LV preload produced by these volatile anesthetics and were not due to direct positive lusitropic effects. Isoflurane-induced improvements of LV isovolumic relaxation and filling dynamics may contribute to relative maintenance of cardiac output in the presence of LV dysfunction despite simultaneous reductions in contractility. The findings in cardiomyopathic hearts supported earlier clinical observations reporting that patients with severe ischemic heart disease or congestive heart failure tolerate isoflurane or halothane anesthesia without acute hemodynamic decompensation.

The afterload dependence of LV relaxation is markedly enhanced in failing myocardium. Thus, afterload reduction may not only increase LV systolic performance by decreasing impedance to LV ejection but also may increase the rate of LV relaxation and contribute to improvements in LV diastolic filling and compliance. The effects of isoflurane and halothane on the afterload dependence of LV relaxation were explored in canine hearts before and after the development of rapid LV pacing–induced cardiomyopathy (Fig. 28-3). The afterload dependence of LV relaxation was unaffected by isoflurane and halothane

anesthesia in this model of dilated cardiomyopathy, further suggesting that these volatile anesthetics do not exert direct actions on LV isovolumic relaxation in failing myocardium independent of negative inotropic effects.

Left Ventricular–Arterial Coupling and Mechanical Efficiency

Optimum transfer of stroke volume from the left ventricle to the arterial circulation requires appropriate matching of these mechanical systems. LV-arterial coupling has most often been described by using a series elastic chamber model of the cardiovascular system. The elastances of the contracting left ventricle (E_{es}) and the arterial vasculature (E_a) are determined from LV end-systolic pressure-volume and end-systolic arterial pressure–stroke volume relationships, respectively. The ratio of E_{es} to E_a defines coupling between the left ventricle and the arterial circulation and provides a useful technique for assessment of the actions of drugs, including volatile anesthetics, on LV-arterial matching in vivo. Analysis of the pressure-volume relationship also creates a framework for the study of LV mechanical efficiency defined by the ratio of stroke work (SW) to pressure-volume area (PVA). LV-arterial coupling is initially maintained during anesthesia because declines in LV afterload may balance simultaneous reductions in myocardial contractility. Low concentrations of isoflurane (1 MAC), but not halothane, maintained E_{es}/E_a, consistent with preservation of mechanical coupling between the LV and arterial circulation. However, isoflurane decreased E_{es}/E_a at 2 MAC, suggesting that the vasodilating effects of this anesthetic were unable to compensate for the relatively greater declines in contractility. Desflurane, sevoflurane, and isoflurane maintained optimum LV-arterial coupling and mechanical efficiency as evaluated by E_{es}/E_a and SW/PVA at low anesthetic concentrations (<0.9 MAC) by producing simultaneous declines in myocardial contractility and LV afterload. However, mechanical matching between the LV and the arterial vasculature and efficiency of total LV energy transfer to external stroke work degenerates at higher anesthetic concentrations, indicating that anesthetic-induced reductions in contractility are not appropriately balanced by declines in afterload. Halothane (<1.0 MAC), but not isoflurane, also reduced the ratio of oscillatory to mean hydraulic power in vivo, indicating that this agent decreases LV mechanical efficiency as well. Detrimental alterations in LV-arterial coupling produced by volatile anesthetics contribute to reductions in overall cardiac performance observed with higher concentrations of the anesthetics in vivo.

Left Ventricular Afterload

A definition of LV afterload that describes the mechanical properties of the arterial vasculature opposing LV ejection is clear, but quantitative evaluation of afterload in vivo remains a difficult problem, the solution of which often confuses this clinically intuitive concept. Systemic vascular resistance, calculated as the ratio of mean arterial pressure to cardiac output, is the most commonly used estimate of LV afterload. However, systemic vascular resistance inadequately describes LV afterload because this index ignores the mechanical characteristics of the blood and arterial walls, fails to account for the frequency-dependent, phasic nature of arterial blood pressure and blood flow, and does not consider the potential effects of arterial wave reflection. As a result, systemic vascular resistance cannot be reliably used to quantify changes in LV afterload produced by drugs, including volatile anesthetics, or cardiovascular disease. Aortic input impedance ($Z_{in}[\omega]$) obtained from power spectral or Fourier series analysis of aortic pressure and blood flow waveforms provides a comprehensive description of LV afterload because $Z_{in}(\omega)$ incorporates arterial viscoelasticity, frequency dependence, and wave reflection. However, analysis of $Z_{in}(\omega)$ is conducted in the frequency domain and not as a function of time, and, as a result, $Z_{in}(\omega)$ is very difficult to apply in a clinical setting. $Z_{in}(\omega)$ is most often interpreted using an electrical three-element Windkessel model of the arterial circulation that describes characteristic aortic impedance (Z_c), total arterial

compliance (C), and total arterial resistance (R). Z_c represents aortic resistance to LV ejection, C is determined primarily by the compliance of the aorta and proximal great vessels and represents the energy storage component of the arterial circulation, and R is the combined resistances of the remaining arterial vasculature. The three-element Windkessel model has been shown to closely approximate $Z_{in}(\omega)$ under a variety of physiologic conditions.

Volatile anesthetics alter $Z_{in}(\omega)$ by affecting the mechanical properties of the arterial vascular tree. Isoflurane produced dose-related decreases in R in a canine model, consistent with isoflurane's effects on systemic vascular resistance, in contrast to the results obtained with halothane. Isoflurane and halothane also increased C and Z_c concomitant with reductions in mean arterial blood pressure. Thus, the major difference between the effects of isoflurane and halothane on LV afterload derived from the Windkessel model of $Z_{in}(\omega)$ was related to R, a property of arteriolar resistance vessels, and not to C or Z_c, the mechanical characteristics of the aorta. In contrast to the findings with sevoflurane, desflurane also reduced R, suggesting that this anesthetic was a more potent peripheral vasodilator, but sevoflurane and desflurane produce similar dose-related decreases in mean arterial pressure in anesthetized patients. Importantly, the inverse relationship between C and mean arterial blood pressure remains unchanged in the presence of a volatile anesthetic, unlike the findings with the arterial vasodilator sodium nitroprusside or the intravenous anesthetic propofol. These data emphasize that volatile anesthetics do not fundamentally affect aortic mechanical characteristics.

Isoflurane and halothane produced alterations in $Z_{in}(\omega)$ in an experimental model of heart failure that are somewhat different from those observed in the normal cardiovascular system. These volatile anesthetics decreased arterial pressure but did not affect C and Z_c in the presence of LV dysfunction. Isoflurane also did not reduce R in the presence of dilated cardiomyopathy, in contrast to the actions of this volatile anesthetic in the presence of normal LV performance. Thus, neither isoflurane nor halothane reduced arterial hydraulic resistance or favorably improved the rectifying properties of the aorta in the presence of a model of cardiomyopathy. The findings suggest that volatile anesthetics do not exert beneficial actions in LV afterload in the presence of heart failure.

Right Ventricular Function

The crescent-shaped right ventricle is composed of embryologically distinct inflow and outflow tracts that differ in their structure and response to autonomic nervous system activity. The sequential contraction of the RV inflow and outflow tracts establishes regional pressure gradients within the right ventricle and accounts for its peristaltic mechanical action during systole. True isovolumic relaxation does not occur in the right ventricle. Instead, ejection of blood from the outflow tract into the pulmonary artery continues after the inflow tract has begun to relax. The effects of volatile anesthetics on the function and contraction sequence of the RV inflow and outflow tracts have been incompletely studied. Halothane produced similar depression of contractile function in RV inflow and outflow tracts when a uniform definition of end-systole and end-diastole was used for both regions of the RV. Halothane also caused dose-related decreases in RV contractility as evaluated by using regional preload recruitable stroke work derived from RV pressure-segment length diagrams in the RV inflow and outflow tracts in the presence and absence of autonomic nervous system reflexes. Importantly, halothane also abolished the normal RV sequential contraction pattern without exerting differential negative inotropic effects in different regions of the RV, suggesting that volatile anesthetics may alter RV contraction dynamics by adversely affecting cardiac autonomic nervous system activity. Isoflurane also exerted qualitatively different effects on RV in contrast to LV afterload and hydraulic power generation that were also partially mediated by the autonomic nervous system. These data suggest that isoflurane produces fundamentally different actions on RV versus LV contraction dynamics in vivo.

Left Atrial Function

The left atrium serves three major roles that exert a profound effect on LV filling and overall cardiovascular performance. The left atrium is a contractile chamber that actively empties immediately before the onset of LV systole and establishes final LV end-diastolic volume. The left atrium is a reservoir that stores pulmonary venous return during LV contraction and isovolumic relaxation after the closure and before the opening of the mitral valve. The left atrium is also a conduit that empties its contents into the left ventricle down a pressure gradient after the mitral valve opens and continues to passively transfer pulmonary venous blood flow during LV diastasis. These contraction, reservoir, and conduit functions of the left atrium mechanically facilitate the transition between the almost continuous flow through the pulmonary venous circulation and the intermittent filling of the left ventricle. Advances in the understanding and clinical significance of left atrial (LA) mechanical function have been reviewed.[7]

The negative inotropic effects of an older volatile anesthetic—halothane—was initially described in atrial myocardium in vitro. Volatile anesthetics also depressed the contractile function of human atrial myocardium.[8] These actions have been attributed to reductions in transsarcolemmal Ca^{2+} influx through voltage-dependent Ca^{2+} channels and decreases in Ca^{2+} availability from the SR, mechanisms that are very similar to those responsible for anesthetic-induced depression of LV myocardium. The negative inotropic effects of volatile anesthetics in the intact left atrium were quantified using pressure-volume analysis.[9] Desflurane, sevoflurane, and isoflurane reduced LA contractility (i.e., E_{es}) by approximately 50% at an end-tidal concentration of 1.2 MAC. The magnitude of this effect in LA myocardium was similar to the degree of LV contractile depression produced by these anesthetics as quantified by LV end-systolic pressure-volume relationships. Desflurane, sevoflurane, and isoflurane also impaired LA and LV relaxation to similar degrees. These data indicate that volatile anesthetics produce equivalent alterations in contractility and relaxation in LA compared with LV myocardium. The magnitude of reductions in the LA inotropic and lusitropic state produced

by volatile anesthetics was also similar in the intact LA, supporting the results obtained in isolated human atrial myocardium.[8]

Desflurane, sevoflurane, and isoflurane altered the passive mechanical behavior of the left atrium.[9] LA reservoir function was maintained during the administration of anesthetic at concentrations less than 1.0 MAC. This preservation of reservoir function contributed to the relative maintenance of LV stroke volume by compensating for decreases in LV filling associated with a reduced contribution of LA contraction. The volatile anesthetics also reduced dynamic LA chamber stiffness, an action that most likely contributed to the preservation of reservoir function because the delays in LA relaxation and declines in LV systolic function that also occurred would be expected to decrease reservoir function. However, LA reservoir function was reduced during the administration of higher concentrations of volatile anesthetics because further impairment of LA relaxation and LV contractility occurred. Decreases in the ratio of LA SW to PVA and the increases in the ratio of LA conduit to total reservoir volume were also produced by desflurane, sevoflurane, and isoflurane. These data indicate that the LA contribution to LV filling becomes less active and more passive during the administration of the volatile anesthetics. Furthermore, desflurane, sevoflurane, and isoflurane decreased the ratio of LA to LV elastance (E_{es}/E_{LV}), consistent with impaired mechanical matching between these chambers. As described earlier, volatile anesthetics have been shown to produce LV diastolic dysfunction by delaying LV isovolumic relaxation and impairing early LV filling in association with direct negative inotropic effects. Thus, the attenuation of transfer of kinetic energy from the left atrium to the left ventricle probably resulted from the combination of LA contractile depression and LV systolic and diastolic dysfunction. Volatile anesthetic–induced abnormalities in LA-LV matching were greater than analogous impairment of LV-arterial coupling evaluated using a similar series elastic chamber model because these anesthetics produced beneficial alterations in the determinants of LV afterload that partially compensate for simultaneous depression of LV myocardial contractility.

The influence of isoflurane on LA function in the presence of preexisting LV dysfunction has also been examined.[10] Isoflurane depressed LA contractility, impaired LA-LV coupling, and reduced the active LA contribution to LV filling in a model of pacing-induced cardiomyopathy, findings that were similar in magnitude to those observed in normal hearts.[9] In contrast to the findings in normal hearts, LA reservoir function was reduced in the presence of LV dysfunction at lower isoflurane concentrations (0.6 and 0.9 MAC).[10] These findings indicated that the ability of the left atrium to act as a reservoir for pulmonary venous return is attenuated during isoflurane anesthesia. Such an isoflurane-induced reduction in LA storage ability suggested that quantity of blood transferred from the left atrium to the left ventricle when the mitral valve opens may be reduced, thereby providing another potential mechanism by which volatile anesthetics reduce early LV filling in the presence of preexisting LV dysfunction.

Systemic Hemodynamics

Volatile anesthetics cause direct negative chronotropic actions in vitro by depressing sinoatrial node activity, but alterations in heart rate in vivo are primarily determined by their interaction with baroreceptor reflexes. Halothane does not appreciably change the heart rate in humans because this anesthetic attenuates baroreceptor reflex responses. In contrast, isoflurane increases heart rate in response to simultaneous decreases in arterial pressure. These findings occur with this volatile anesthetic because baroreceptor reflexes are relatively preserved compared with the older anesthetics. Desflurane also causes dose-related increases in heart rate in humans. Desflurane- and isoflurane-induced tachycardia may be more pronounced in pediatric patients or in the presence of vagolytic drugs and, conversely, may be attenuated in neonates and geriatric patients or by the concomitant administration of opioids. Rapid increases in the inspired desflurane concentration above 1 MAC may be associated with further transient increases in heart rate and arterial pressure resulting from sympathetic nervous system activation. Interestingly, similar increases in heart rate were observed when the inspired isoflurane concentration was rapidly increased. The cardiovascular stimulation induced by rapid increases in desflurane or isoflurane concentration in humans resulted from activation of tracheopulmonary and systemic receptors and was attenuated by pretreatment with β_1-adrenoceptor antagonists, β_2-adrenoceptor agonists, or opioids. In contrast to the findings with isoflurane and desflurane, sevoflurane did not alter heart rate or cause cardiovascular stimulation during rapid increases in anesthetic concentration in humans.

All modern volatile anesthetics cause concentration-related decreases in arterial pressure. The mechanism by which these medications reduce arterial pressure differs among anesthetics. Decreases in arterial blood pressure produced by older volatile anesthetics were attributed to reductions in myocardial contractility and cardiac output, whereas isoflurane, desflurane, and sevoflurane reduce arterial pressure primarily as a result of reductions in LV afterload. Thus, isoflurane, desflurane, and sevoflurane maintain cardiac output because these anesthetics produce less pronounced reductions in myocardial contractility and greater decreases in systemic vascular resistance than halothane or enflurane in humans. Isoflurane and desflurane may preserve autonomic nervous system regulation of the circulation to a greater degree than other volatile anesthetics. The baroreceptor reflex–mediated tachycardia that occurs during isoflurane and desflurane anesthesia maintain cardiac output despite modest decreases in contractility and stroke volume. Declines in arterial pressure produced by volatile anesthetics may be attenuated by surgical stimulation or concomitant administration of nitrous oxide. Volatile anesthetics also cause modest, dose-related increases in right atrial pressure in humans. These effects probably occur as a result of direct negative inotropic actions. The cardiovascular effects of volatile anesthetics are altered by the duration of anesthesia. Increases in myocardial contractility and cardiac output and decreases in LV preload and afterload occur after several hours of constant MAC anesthesia. Recovery

from circulatory depression is greatest during halothane anesthesia but is somewhat less pronounced during prolonged administration of isoflurane and desflurane.

The systemic hemodynamic effects of volatile anesthetics in the presence of LV dysfunction are similar but not identical to those observed in the normal heart. Volatile anesthetics, including isoflurane, modestly increase or do not affect the heart rate in experimental animals with pacing- or doxorubicin-induced dilated cardiomyopathy and patients with coronary artery disease and LV dysfunction. These findings may be attributed to altered baroreceptor reflex activity, β_1-adrenoceptor down-regulation, increases in central sympathetic nervous system activity, and withdrawal of parasympathetic nervous system tone associated with heart failure. Isoflurane and halothane caused pronounced reductions in LV end-diastolic pressure and chamber dimension in cardiomyopathic hearts concomitant with decreases in mean arterial pressure. These findings supported previously observed declines in pulmonary artery pressures during isoflurane anesthesia in patients with coronary artery disease and heart failure and suggested that venodilation represents a major hemodynamic consequence of this volatile anesthetic in experimental and clinical heart failure. In contrast to the findings in normal hearts, isoflurane did not beneficially influence, and the older anesthetic halothane detrimentally affected, the determinants of LV afterload in cardiomyopathic hearts. As a result of these actions and the simultaneous declines in LV preload and myocardial contractility, cardiac output may be more profoundly reduced during isoflurane or halothane anesthesia in the presence of preexisting LV dysfunction.

CARDIAC ELECTROPHYSIOLOGY

Cardiac Conduction

Volatile anesthetics slow the rate of sinoatrial node discharge by direct and indirect effects on sinoatrial node automaticity. These actions may be altered in vivo by vasoactive drugs or autonomic nervous system activity. Older volatile anesthetics and, to a lesser extent, isoflurane shorten cardiac action potential and the effective refractory period duration in normal Purkinje fibers, but these medications prolong His-Purkinje and ventricular conduction times. Halothane, enflurane, and isoflurane also prolong atrioventricular conduction time and refractoriness. When combined with the direct actions of volatile anesthetics on sinoatrial node discharge, these data suggest that volatile anesthetics have the potential to produce bradycardia and atrioventricular conduction abnormalities. However, primary disturbances in atrioventricular conduction leading to second-degree or third-degree atrioventricular block in humans probably do not occur with volatile anesthetics in the absence of conduction disease or the concomitant administration of drugs that directly prolong the atrioventricular conduction time.

Volatile anesthetics may have proarrhythmogenic or antiarrhythmogenic actions against the abnormal cardiac electrophysiologic mechanisms produced by myocardial ischemia or infarction. Halothane, enflurane, and isoflurane have been shown to protect against ventricular fibrillation produced by coronary artery occlusion and reperfusion. Protective effects against ouabain-induced arrhythmias have been demonstrated with halothane. Volatile anesthetics may exert antiarrhythmic effects by opposing subsidiary pacemaker activity in infarcted myocardium. Conversely, halothane and, to a lesser extent, isoflurane may be arrhythmogenic in Purkinje fibers in experimental myocardial infarction by facilitating reentrant activity or increasing temporal dispersion of refractory period recovery. These actions may be related to inhibition of the slow Na^+ current in false tendon fibers and induction of reentry of premature impulses into more refractory Purkinje fibers in the border zone of an ischemic area. Halothane, enflurane, and isoflurane prolong the QT_c interval in humans, suggesting that patients with idiopathic or acquired long QT syndrome may be at greater risk for developing torsade de pointes ventricular tachycardia during anesthesia with these anesthetics.

Epinephrine-Induced Arrhythmias

Halothane and, to a lesser extent, other volatile anesthetics sensitize myocardium to the arrhythmogenic effects of epinephrine. Sensitization is the interaction between volatile anesthetics and catecholamines that leads to reductions in the threshold for both atrial and ventricular arrhythmias. Sequentially escalating doses of epinephrine produce premature ventricular contractions and sustained ventricular tachyarrhythmias during halothane anesthesia. Halothane-epinephrine–induced arrhythmias are attenuated by pretreatment with sodium thiopental, presumably by effects on the atrioventricular node or the upper His bundle. A synergistic interaction between α_1-adrenoreceptors and β-adrenoreceptors has been strongly implicated in the pathogenesis of halothane-epinephrine–induced ventricular arrhythmias. Stimulation of the α_{1A}-adrenoceptor in the His-Purkinje system by epinephrine during halothane anesthesia transiently slows Purkinje fiber conduction. This proarrhythmogenic effect is mediated by phospholipase C and the intracellular second messenger inositol triphosphate. Enhanced conduction in the Purkinje-ventricular muscle junction accompanied by simultaneous α_1-adrenoceptor–mediated depression of Purkinje conduction also plays an important role in halothane-epinephrine–induced arrhythmias. The doses of epinephrine required to produce ventricular arrhythmias during desflurane or sevoflurane anesthesia are similar to, but significantly less than, those observed during administration of isoflurane and halothane. Halothane-catecholamine sensitization also promotes abnormal automaticity of dominant and latent atrial pacemakers. These effects may produce premature ventricular contractions and arrhythmias originating from the His bundle. Intact sinoatrial node function reduces the incidence of epinephrine-induced ventricular escape during halothane anesthesia and is protective against His bundle arrhythmias.

CORONARY CIRCULATION

Coronary Vascular Effects In Vitro

Volatile anesthetics cause direct coronary artery vasodilation in vitro; however, simultaneous reductions in the

determinants of myocardial oxygen consumption (MVo_2), including heart rate, preload, afterload, and inotropic state, produced by these medications cause coronary vasoconstriction in vivo through metabolic autoregulation. Volatile anesthetic–induced alterations in coronary blood flow are also affected by reductions in coronary perfusion pressure. Thus, the combination of direct and indirect actions determines the net effect of volatile anesthetics on coronary vascular tone. Isoflurane and halothane caused vasodilation of isolated coronary arteries. Halothane produced greater coronary artery dilation than did isoflurane at similar MAC concentrations in isolated coronary arteries larger than 2000 μm. In contrast, isoflurane caused vasodilation of predominantly small (<900 μm) canine epicardial coronary arteries. Halothane may produce greater vasodilator effects in large coronary arteries than isoflurane because halothane causes more pronounced suppression of voltage-dependent Ca^{2+} current.

The direct negative inotropic effects of volatile anesthetics caused a reduction in coronary blood flow in isolated, contracting hearts during precise control of loading conditions via flow-metabolism coupling. Thus, a decrease in myocardial O_2 demand was accompanied by an increase in coronary vascular resistance, findings that may be incorrectly interpreted as coronary vasoconstriction. However, examination of the actions of volatile anesthetics on myocardial O_2 extraction and the ratio of myocardial O_2 delivery to MVo_2 revealed that these medications are coronary vasodilators. Halothane and isoflurane decreased myocardial O_2 extraction and increased the ratio of O_2 delivery to consumption in isolated hearts. These findings indicated that volatile anesthetics produce direct coronary vasodilation in isolated hearts because myocardial O_2 delivery exceeds MVo_2 and coronary sinus O_2 tension increases. Halothane, isoflurane, and sevoflurane also caused similar reductions in adenosine-induced coronary flow reserve in tetrodotoxin-arrested, isolated hearts. Because mechanical work was not performed in this preparation, these findings supported the hypothesis that volatile anesthetics cause direct coronary vasodilation of similar magnitude.

Coronary Vascular Effects In Vivo

Halothane has variable effects on coronary blood flow and coronary vascular resistance in vivo that occur concomitant with changes in MVo_2. Decreases in MVo_2 caused declines in coronary blood flow with relative maintenance or modest increases in coronary vascular resistance during halothane anesthesia. Despite the decreases in coronary blood flow, halothane increased coronary sinus O_2 tension and decreased O_2 extraction, indicating that halothane was a relatively weak coronary vasodilator. Like halothane, isoflurane variably altered coronary blood flow in vivo. Isoflurane reduced MVo_2 and simultaneously decreased O_2 extraction, indicating direct coronary vasodilation. Isoflurane also produced mild, transient increases in blood flow independent of changes in MVo_2 and autonomic nervous system activity during inhalation induction. Perfusion of the left anterior descending coronary artery with blood previously equilibrated with isoflurane dramatically increased coronary blood flow, but only mild coronary vasodilation occurred after a period of anesthetic equilibration in a similar experimental model. Isoflurane-induced increases in coronary blood flow were not accompanied by epicardial coronary artery dilation, verifying that isoflurane dilates predominantly small coronary arteries. In contrast, the potent coronary vasodilator adenosine caused considerably greater vasodilation in coronary microvessels than did isoflurane. Isoflurane produced more profound decreases in myocardial O_2 extraction than enflurane, indicating that isoflurane is a more potent coronary vasodilator than its structural isomer.

The influence of desflurane and sevoflurane on coronary blood flow in the intact cardiovascular system has been incompletely examined. Desflurane and isoflurane caused similar increases in the ratio of O_2 delivery to consumption and decreased O_2 extraction, consistent with coronary vasodilation. However, the increases in coronary blood flow produced by desflurane, but not isoflurane, were attenuated by pharmacologic blockade of the autonomic nervous system, suggesting that isoflurane causes relatively greater direct coronary vasodilation in vivo than desflurane. Sevoflurane did not appear to produce any significant degree of coronary vasodilation, in contrast to the findings with isoflurane and desflurane.

Coronary Vasodilator Reserve and Autoregulation

Volatile anesthetics alter coronary vasodilator reserve, defined as the ratio of peak coronary blood flow after brief coronary artery occlusion (reactive hyperemia) to baseline flow. Coronary vasodilator reserve was greater during isoflurane than halothane anesthesia. When considered from this perspective alone, this observation suggested that halothane may be a more potent coronary vasodilator than isoflurane because greater baseline coronary vasodilation should be accompanied by a reduced ability to further increase coronary blood flow in response to a brief ischemic episode. However, halothane also reduced the determinants of MVo_2 to a greater degree than isoflurane in vivo. Peak coronary blood flow during reactive hyperemia and percent flow debt repayment are directly related to the intensity of the ischemic stimulus and the magnitude of O_2 debt accumulated during coronary artery occlusion. Thus, differences in coronary vasodilator reserve produced by isoflurane and halothane may reflect differences in the intensity of ischemia during coronary occlusion and not the relative vasodilator efficacy of these two volatile anesthetics.

Dilation of coronary arteriolar resistance vessels by volatile anesthetics alters pressure autoregulation in the coronary vasculature. Changes in autoregulation produced by vasoactive drugs, including volatile anesthetics, are typically determined by the slope of the pressure-flow curve generated by progressive constriction of a coronary artery. Changes in these pressure-flow curves demonstrated that autoregulation is disrupted during anesthesia in contrast to the conscious state (Fig. 28-4). Isoflurane produced more profound alterations in autoregulation than the older volatile anesthetics, as indicated by greater increases in the slope of the pressure-flow relationship. Coronary perfusion pressure also played a more important role in the determination of coronary blood flow during anesthesia. Volatile anesthetics impaired coronary

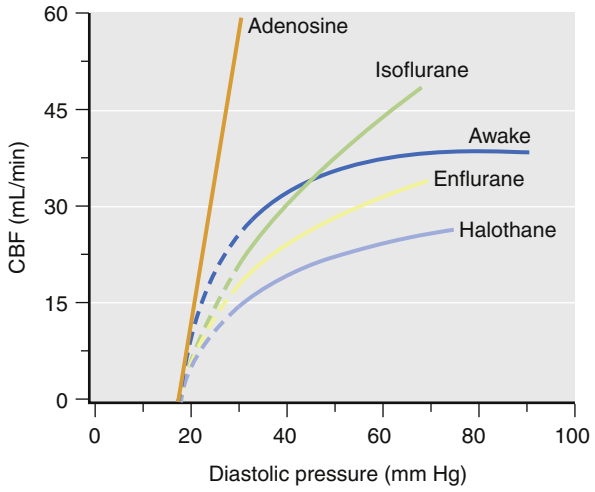

Figure 28-4. A qualitative description of the effects of volatile anesthetics on the coronary blood flow *(CBF)*–diastolic pressure relationship demonstrating the effect of adenosine-induced maximal coronary vasodilation in awake and anesthetized dogs. *Solid lines* are drawn from mean slopes determined by linear regression analysis. *Dashed lines* represent the nonlinear portion of the curve and are estimates. In contrast to the findings obtained in conscious dogs, the anesthetics affect absolute CBF variably but do not increase the slope of the CBF-pressure plots. *(Modified from Hickey RF, Sybert PE, Verrier ED, Cason BA: Effects of halothane, enflurane, and isoflurane on coronary blood flow autoregulation and coronary vascular reserve in the canine heart,* Anesthesiology *68:21-30, 1988.)*

autoregulation to some degree, but these medications did not produce the profound degree of coronary vasodilation and inhibition of autoregulation caused by adenosine or dipyridamole. In contrast to volatile anesthetics, adenosine caused maximal coronary vasodilation and inhibited pressure autoregulation to such a degree that coronary blood flow became directly dependent on coronary perfusion pressure. Thus, volatile anesthetics were shown to be weak coronary vasodilators.

Mechanisms of Coronary Vasodilation

Volatile anesthetics produce direct coronary artery relaxation by affecting intracellular Ca^{2+} regulation at several locations in the vascular smooth muscle cell. Volatile anesthetics inhibit Ca^{2+} influx through voltage-operated and receptor-operated Ca^{2+} channels in coronary vascular smooth muscle. Volatile anesthetics also reduce Ca^{2+} accumulation in, and release by, the coronary vascular smooth muscle SR; inhibit G proteins linked to phospholipase C; and decrease formation of inositol triphosphate. The coronary vasodilating actions of volatile anesthetics are probably not related to the production or release of nitric oxide (NO). Investigations conducted in isolated coronary and aortic vascular preparations and in the intact canine coronary circulation demonstrated that volatile anesthetic–induced coronary vasodilation occurs independent of NO. The weak direct coronary vasodilator effects of isoflurane may be mediated by the vascular endothelium, but, conversely, volatile anesthetics may adversely affect the release or action of NO. The results of one investigation demonstrated that NO-induced formation of cyclic guanylate monophosphate (cGMP) is partially attenuated by halothane, whereas other studies indicated that volatile anesthetics did not affect vasodilation produced by the NO donors sodium nitroprusside and nitroglycerin. Volatile anesthetics may also reduce the stability of NO by generating reactive O_2 species (ROS) while leaving NO release and its action on vascular smooth muscle unaffected. Whether the results of these latter studies conducted in isolated aortic preparations are applicable to the coronary circulation requires further evaluation, but these investigations provided important information about the potential interactions between NO metabolism and volatile anesthetic in the coronary circulation, which may be specifically relevant during myocardial protection (see "Preconditioning and Postconditioning").

Isoflurane and halothane cause coronary vasodilation by activation of adenosine triphosphate (ATP)-sensitive potassium (K_{ATP}) channels. Increases in coronary blood flow in response to halothane and isoflurane were attenuated by the nonselective K_{ATP} channel antagonist glyburide in isolated rat hearts and anesthetized pigs, respectively. Glyburide also partially blocked increases in coronary blood flow during intracoronary administration of volatile anesthetic–equilibrated blood in canine hearts in situ. Isoflurane-induced reductions in coronary vascular resistance were attenuated by a selective adenosine 1 (A_1) receptor antagonist. These data suggest that coronary vasodilation produced by isoflurane may partially occur as a result of stimulation of A_1 receptors coupled to K_{ATP} channels.

Ischemic Myocardium

Isoflurane and halothane decreased subendocardial blood flow and myocardial lactate extraction, produced contractile dysfunction, and caused electrocardiographic changes in the presence of a coronary stenosis concomitant with declines in coronary perfusion pressure. Regional ischemia during isoflurane- or halothane-induced reductions in perfusion pressure was functionally indicated by the appearance of paradoxical systolic lengthening and postsystolic shortening. Contractile dysfunction in the region distal to a critical coronary stenosis was more severe during isoflurane than halothane anesthesia coincident with higher flows in the normal zone and lower flows in the ischemic zone. These findings suggest that coronary vasodilation produced by isoflurane may cause a detrimental redistribution of coronary blood flow away from ischemic myocardium if hypotension is allowed to occur. This phenomenon is known as coronary steal. However, these potentially adverse effects of volatile anesthetics on ischemic myocardium were clearly avoided if coronary perfusion pressure was restored. Subendocardial blood flow in the perfusion bed distal to a critical coronary stenosis was reduced during isoflurane-induced declines in arterial pressure, but treatment of hypotension with phenylephrine restored subendocardial blood flow to values observed before administration of isoflurane. The transmural distribution of coronary blood flow between the subendocardium and subepicardium (endo/epi ratio) decreased during isoflurane anesthesia despite control of arterial pressure. Administration of phenylephrine to maintain arterial pressure increased subepicardial blood

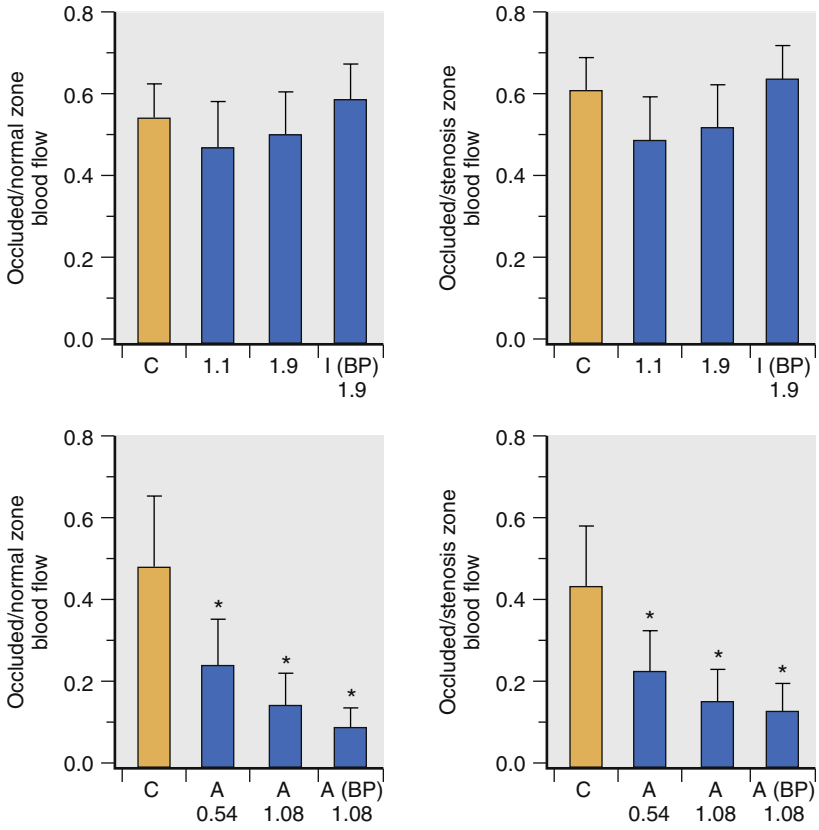

Figure 28-5. Comparison of occluded to normal and occluded to stenotic zone myocardial blood flow in dogs with steal-prone coronary artery anatomy in the conscious state *(C)*, during administration of isofurane at 1.1 and 1.9 minimum alveolar concentration *(I)*, during adenosine *(A)* infusions (0.54 and 1.08 mg/min), and during maintenance of heart rate and arterial pressure at conscious values during the highest doses *(BP)*. Isoflurane does not cause coronary steal, in contrast to significant ($P < .05$) reductions in blood flow to collateral-dependent myocardium produced by adenosine. *(Modified from Hartman JC, Kampine JP, Schmeling WT, Warltier DC: Actions of isoflurane on myocardial perfusion in chronically instrumented dogs with poor, moderate, or well-developed coronary collaterals,* J Cardiothorac Anesth *4:715-725, 1990.)*

flow more than subendocardial flow. This increase in subepicardial perfusion accounted for the decline in the endo/epi ratio in the absence of an absolute reduction in subendocardial flow. Restoration of coronary perfusion pressure to baseline levels during isoflurane anesthesia also increased coronary collateral blood flow and normalized myocardial O_2 tension in the ischemic zone.

Investigations in dogs with steal-prone anatomy (complete occlusion of a coronary artery with collateral flow from an adjacent vessel having a critical stenosis) have repeatedly demonstrated that isoflurane and halothane do not alter collateral-dependent or ischemic zone myocardial blood flow, endocardial-to-epicardial coronary blood flow distribution, or the electrocardiogram ST segment when diastolic arterial pressure is held constant. Coronary collateral perfusion was unchanged during isoflurane or halothane anesthesia in dogs at a mean arterial pressure of 50 mm Hg. Notably, no evidence of coronary steal was found in a chronically instrumented canine model of coronary artery disease with isoflurane, halothane, desflurane, or sevoflurane independent of coronary stenosis severity or coronary collateral development. These findings refuted earlier evidence in dogs with ameroid constrictor–induced augmentation of the coronary collateral circulation suggesting that isoflurane reduces collateral blood flow and causes coronary steal in vivo. The effects of volatile anesthetics are in contrast to those obtained with adenosine, a potent coronary vasodilator that produces coronary steal when arterial pressure is maintained at control levels in models of multivessel coronary artery disease (Fig. 28-5).

Preconditioning and Postconditioning

Acute Preconditioning. In 1986, Murry, Jennings, and Reimer[11] described a phenomenon in which a brief ischemic insult confers protection against a subsequent ischemic episode of similar or greater magnitude. Four brief 5-minute periods of coronary artery occlusion interspersed with 5-minute episodes of reperfusion reduced myocardial infarct size resulting from a subsequent, prolonged 40-minute episode of ischemia and reperfusion. This study demonstrated, for the first time, that the heart not only recognized but also rapidly adapted to stress and, in so doing, became more resistant to additional injury. This process is now known as ischemic preconditioning (IPC) and has been described as a type of "vaccination" that promotes the myocardium's "self-preservation" by altering its phenotype.[12] Since IPC was first reported, the mechanisms, limitations, and potential clinical applicability of this phenomenon have been extensively studied. For example, a recent PubMed search of the phrase "ischemic preconditioning" revealed that nearly 1100 research articles and reviews were published on this subject in 2011 alone.* Many other stimuli, including a wide variety of drugs, NO, ROS, endotoxins, inflammatory cytokines, heat stress, rapid pacing, and intense exercise, also stimulate the development of this prosurvival phenotype and protect the myocardium against ischemic injury without the need for a prior episode of ischemia.[13] Most notably from the perspective of this chapter, volatile anesthetics and the anesthetic gas Xe are among the drugs that

Schematic illustration of canine myocardium subjected to a 60-minute coronary artery occlusion and reperfusion and then stained to identify the region of myocardial infarction *(dark red area)* within the area of myocardium at risk for infarction *(light yellow area)*. Isoflurane decreased the extent of myocardial infarction. The protective effect of isoflurane was equivalent to that produced by ischemic preconditioning and was abolished by pretreatment with glyburide. *Significantly ($P < .05$) different from control. *LV,* Left ventricle; *RV,* right ventricle. *(Modified from Kersten JR, Schmeling TJ, Pagel PS, et al: Isoflurane mimics ischemic preconditioning via activation of KATP channels. Reduction of myocardial infarct size with acute memory phase,* Anesthesiology *87:361-370, 1997.)*

have been shown to mimic the beneficial effects of IPC through very similar intracellular mechanisms.[14,15]

It is important to recognize that the previously described controversy about volatile anesthetic–induced coronary vasodilation and coronary steal proved to be a fundamental distraction from other evidence indicating that volatile anesthetics exert *protective* (rather than detrimental) effects during myocardial ischemia and reperfusion injury. For example, the older anesthetic halothane attenuated ST-segment changes caused by brief coronary artery occlusion and decreased ST-segment elevation to a greater extent than propranolol and sodium nitroprusside despite producing similar hemodynamic effects.[16] These data suggested that volatile anesthetics may indeed produce antiischemic effects independent of simultaneous changes in coronary perfusion. Isoflurane and desflurane modestly improved LV diastolic function during acute regional myocardial ischemia. Isoflurane and sevoflurane decreased myocardial injury and improved functional recovery after global ischemia in isolated hearts. Isoflurane and halothane also hastened the functional recovery of postischemic-reperfused ("stunned") myocardium when these anesthetics were administered before brief periods of myocardial ischemia concomitant with preservation of high-energy phosphates. Volatile anesthetics attenuated the effects of ROS on LV pressure development in isolated hearts. Halothane preserved contractile function and ultrastructural integrity during reperfusion after normothermic cardioplegic arrest. Taken as a whole, the results of these studies raised the intriguing possibility that volatile anesthetics were capable of protecting myocardium against ischemia, suspicions that were subsequently confirmed in 1997 when three research groups independently reported that administration of halothane or isoflurane before prolonged coronary artery occlusion and reperfusion preconditioning reduced myocardial infarct size in vivo (Fig. 28-6). This beneficial effect was termed anesthetic preconditioning (APC) and was found to persist despite discontinuation of the volatile anesthetic before coronary artery occlusion, a short-term "memory" phase that mimicked observations during IPC. Indeed, the mechanisms responsible for APC are strikingly similar to those implicated in IPC, although relatively minor differences between these two phenomena were suggested when the results of microarray gene chip analysis were considered.[17]

APC is dose-related in experimental animals[18,19] and occurs independent of changes in systemic hemodynamics or coronary collateral blood flow. Isoflurane and sevoflurane also caused dose-dependent preservation of isolated ventricular myocyte viability after ischemia in vitro.[20] Isoflurane elicited protection when the volatile anesthetic was discontinued 15 or 30 minutes before prolonged coronary artery occlusion and reperfusion in rabbits and dogs, respectively. Dual as opposed to single exposure to sevoflurane further enhanced APC in guinea pigs, indicating that repetitive administration of a volatile anesthetic appears to cause an additional benefit,[21] but myocardial protection resulting from APC was shown to be restricted to ischemia durations between 25 and 40 minutes.[22] The mechanism of sevoflurane-induced myocardial protection was independent of the type of ischemic stimulus (hypoxia versus metabolic inhibition) in isolated cardiac muscle.[23] These results indirectly suggested that APC may be equally effective at preserving myocardial integrity during supply or demand ischemia in patients with coronary artery disease. Advanced age,[24,25] cardiomegaly,[26] obesity,[27] and hyperglycemia[28] in the presence[29] or absence[30] of diabetes mellitus attenuated the efficacy of APC. These experimental observations have potentially important clinical ramifications in elderly patients with diabetes at risk for the development of myocardial ischemia, such as those undergoing cardiac surgery. In contrast, sevoflurane was capable of exerting antiischemic effects in newborn myocardium.[31]

Volatile anesthetics also may produce beneficial effects on blood flow to, and neutrophil interaction with, ischemic myocardium. As discussed previously, volatile anesthetics cause coronary vasodilation by opening K_{ATP} channels or favorably affecting intracellular Ca^{2+} homeostasis in vascular smooth muscle. However, decreases in collateral blood flow after coronary occlusion were less pronounced than declines in flow to normal myocardium in the presence of the older anesthetic halothane. The ratio of myocardial O_2 delivery to consumption was also increased in collateral-dependent myocardium

during halothane anesthesia. Halothane inhibited platelet thrombi formation by increasing platelet cAMP concentration, thereby decreasing cyclical variations in coronary blood flow associated with a critical coronary stenosis. Sevoflurane increased blood flow to collateral-dependent myocardium when arterial pressure was maintained at conscious levels. Ca^{2+}-activated potassium (BK_{Ca}) channels mediated this process. Sevoflurane also improved recovery of coronary vascular reactivity and enhanced NO release in isolated hearts subjected to global ischemia and reperfusion. Volatile anesthetics attenuated adhesion of neutrophils and platelets in the coronary vasculature after ischemia and reperfusion. Isoflurane pretreatment also inhibited cytokine-induced cell death after ischemia-reperfusion injury in vitro.[32] Furthermore, isoflurane and sevoflurane preconditioned against neutrophil-induced contractile dysfunction through activation of adenosine receptors.[33] Finally, neutrophils pretreated with volatile anesthetics lost their ability to cause cardiac dysfunction through decreased superoxide dismutase production and reduced adherence to coronary vascular endothelium.[34] Collectively, the results of these investigations suggested that beneficial actions of volatile anesthetics on coronary perfusion and neutrophil function may, to some degree, be responsible for protection against ischemia-reperfusion injury.

Other mechanisms for APC have been intensively investigated. The beneficial effects of APC may be attributed to a favorable reduction in myocardial O_2 demand (reductions in ischemic burden) concomitant with preservation of energy-dependent vital cellular processes because volatile anesthetics cause direct negative inotropic, lusitropic, and chronotropic effects and are vasodilators. However, the older anesthetic halothane exerted protective effects during complete functional arrest of the heart induced by cardioplegia. Isoflurane, desflurane, and sevoflurane also protected against ischemic injury when administered solely during reperfusion. These data suggest that preferential alterations in myocardial O_2 supply-demand relationships are not solely responsible for the antiischemic actions of volatile anesthetics. Isoflurane and halothane may significantly lower excessive intracellular Ca^{2+} during reperfusion by directly reducing the net transsarcolemmal Ca^{2+} transient resulting from partially inhibited Ca^{2+} channel activity. Indeed, APC accelerated inactivation of cardiac L-type Ca^{2+} channels, an action that may attenuate intracellular Ca^{2+} overload during ischemia-reperfusion injury.[3] In contrast to this relatively nonspecific intracellular Ca^{2+} reduction hypothesis, other data convincingly demonstrated that APC occurs as a consequence of the activation of several redundant endogenous signaling pathways that lead to myocardial protection. To date, K_{ATP} channels, G protein–coupled receptor ligands, isoforms of protein kinase C (PKC), protein tyrosine kinase (PTK), reactive O_2 and nitrogen species, and key components of the prosurvival reperfusion injury salvage kinase (RISK) cascade including the mitochondrial permeability transition pore (mPTP) have all been shown to mediate APC. We will now discuss each of these elements in greater detail. Events within the myocardial cell itself are not solely responsible for APC, because paracrine crosstalk between factors produced by coronary vascular endothelium (e.g., NO, hypoxia-inducible factor) and the myocardium is essential to this process as well.[35]

The K_{ATP} channel plays a central role in IPC and APC. The K_{ATP} channel is a heteromultimeric complex consisting of an inward-rectifying K^+ channel (K_{ir}) and a sulfonylurea receptor (SUR). Pharmacologically distinct K_{ATP} channels have been identified in cardiac sarcolemmal and mitochondrial membranes. It was originally proposed that opening of sarcolemmal K_{ATP} protects ischemic myocardium by shortening action potential duration and preventing intracellular Ca^{2+} overload. However, subsequent studies performed after the discovery of the mitochondrial K_{ATP} indicated that the beneficial actions of K_{ATP} channel opening occurred independent of action potential duration. Nevertheless, IPC was not observed in the absence of the sarcolemmal K_{ir} channel in transgenic mice, suggesting that protection against ischemic injury requires sarcolemmal K_{ATP}. Despite this controversy about the relative role of sarcolemmal K_{ATP} in IPC, it is very clear that mitochondrial K_{ATP} is a primary mediator of IPC, because preservation of mitochondrial bioenergetic function appears to be vital for cellular protection against myocardial ischemia. Mitochondrial K_{ATP} openers maintained intracellular Ca^{2+} homeostasis and inhibited mitochondrial Ca^{2+} overload. These actions enhanced myocyte survival by preventing tissue necrosis and apoptosis (programmed cell death). Necrosis causes generalized cellular destruction and is associated with a profound inflammatory response, whereas apoptosis is a highly regulated, energy-dependent process in which cell membrane architecture is preserved, inflammation is absent, and DNA is selectively cleaved. Mitochondrial K_{ATP} opening inhibited apoptosis in rat ventricular myocytes by attenuating oxidant stress during reperfusion.[36] Alteration of the mitochondrial oxidation-reduction state by mitochondrial K_{ATP} opening may also promote cellular protection.[37] Experiments conducted in isolated cardiac mitochondria indicated that membrane depolarization, matrix swelling, and uncoupling of ATP synthesis occur as a result of increased O_2 consumption are associated with the opening of mitochondrial K_{ATP}. These actions may preserve cellular viability during IPC.[37] Opening of mitochondrial K_{ATP} depolarized the inner mitochondrial membrane and caused a transient swelling of the mitochondrial matrix, resulting from a shift in the ionic balance. Mitochondrial K_{ATP} opening initially reduced ATP production as a result of membrane depolarization, but subsequently stimulated a compensatory increase in respiration that optimizes the efficiency of oxidative phosphorylation, in part by regulating energy-dependent matrix volume. Potassium influx into the mitochondria occurred as a consequence of the balance between K^+ influx through mitochondrial K_{ATP} and K^+ efflux produced by the mitochondrial K^+-H^+ antiporter. The mitochondrial K_{ATP} opener diazoxide promoted K^+ influx and caused matrix alkalinization in isolated myocardium.[38] ATP and the selective mitochondrial K_{ATP} blocker 5-hydroxydecanoate (5-HD) abolished these effects. Thus, a moderate disturbance of mitochondrial homeostasis caused by mitochondrial K_{ATP} opening may promote myocardial tolerance to ischemic stress by altering bioenergetic systems to reduce Ca^{2+} overload, prevent

the activation of necrotic or apoptotic pathways, or attenuate oxidant stress.

It is hypothesized that a "trigger" (e.g., a brief ischemic episode, exposure to a volatile anesthetic) initiates a cascade of signaling events leading to activation of an "end-effector" that is responsible for resistance to injury. Both sarcolemmal K_{ATP} and mitochondrial K_{ATP} have been strongly implicated as important end-effectors in APC. Administration of isoflurane and sevoflurane preserved myocyte viability using a cellular model of ischemia in contrast to cells that were not exposed to a volatile anesthetic.[20] The selective mitochondrial K_{ATP} (5-HD) but not the selective sarcolemmal K_{ATP} antagonist HMR-1098 abolished this protective effect.[20] The nonselective K_{ATP} channel blocker glyburide attenuated the recovery of contractile function produced by isoflurane in stunned myocardium (Fig. 28-7). Isoflurane-induced reductions in canine myocardial infarct size and its ATP-sparing effects also were abolished by glyburide. 5-HD inhibited APC produced by exposure to isoflurane in rats,[18] rabbits,[39] and isolated human myocardium,[40] whereas both HMR-1098 and 5-HD abolished the protective effects of desflurane in dogs.[41] These latter data supported a role for both sarcolemmal K_{ATP} and mitochondrial K_{ATP} in APC. However, HMR-1098 did not affect APC in human atrial myocardium, suggesting that sarcolemmal K_{ATP} was not involved in this process.[42]

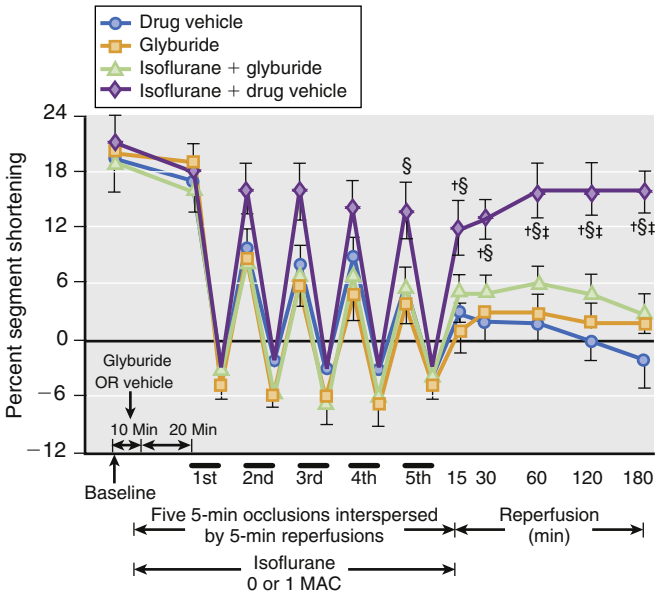

Figure 28-7. Percent segment shortening (%SS) in the intermittently ischemic and reperfused left anterior descending coronary artery (LAD) region. %SS decreases significantly ($P < .05$) from baseline during each 5-minute LAD occlusion and reperfusion in all groups. Significant decreases in %SS during each 5-minute reperfusion and throughout 180 minutes of final reperfusion are observed in dogs pretreated with glyburide, a nonselective K_{ATP} channel antagonist, in the presence or absence of isoflurane. %SS recovers to baseline values after reperfusion in dogs receiving isoflurane alone. †Significantly ($P < .05$) different from dogs pretreated with drug vehicle. ‡Significantly ($P < .05$) different from dogs receiving glyburide and isoflurane. §Significantly ($P < .05$) different from dogs pretreated with glyburide. *MAC,* Minimum alveolar concentration. *(From Kersten JR, Schmeling TJ, Hettrick DA, et al: Mechanism of cardioprotection by isoflurane: role of adenosine triphosphate–regulated potassium [KATP] channels,* Anesthesiology *85:794-807, 1996.)*

Despite some results suggesting that sarcolemmal K_{ATP} opening is not required for APC to occur in vivo, it is clear, based on findings obtained from many carefully conducted in vitro experiments, that volatile anesthetics have profound effects on sarcolemmal K_{ATP}. Isoflurane stimulated outward K^+ current through sarcolemmal K_{ATP} in isolated ventricular myocytes during patch-clamping.[43] Volatile anesthetics also reduced sarcolemmal K_{ATP} sensitivity to inhibition by ATP, thereby increasing the open state probability. Furthermore, volatile anesthetics enhanced sarcolemmal K_{ATP} current by facilitating channel opening after initial activation. The epsilon isoform of PKC (PKC-ε) was shown to prime sarcolemmal K_{ATP} to open in the presence of isoflurane.[44] Facilitation of sarcolemmal K_{ATP} current by isoflurane during reduced intracellular ATP concentrations (such as those observed during ischemia) was also dependent on PKC-dependent signaling.[45] ROS contributed to isoflurane-induced sensitization of sarcolemmal K_{ATP} to the opener pinacidil.[46] Isoflurane also directly opened sarcolemmal K_{ATP} during experimentally induced intracellular acidosis similar to that present during ischemia.[47] Sarcolemmal K_{ATP} acted as an effector during APC against oxidative stress in adult ventricular myocytes.[48] The effects of volatile anesthetics on sarcolemmal K_{ATP} function may persist beyond the duration of administration,[45] suggesting a cellular basis for the early "memory" phase of APC in vivo. Isoflurane APC produced prolonged sensitization of sarcolemmal K_{ATP} to opening through a δ isoform of PKC (PKC-δ–mediated mechanism)[49] or by enhancing PKC induction of sarcolemmal K_{ATP} current.[45] APC caused persistent reductions in the sensitivity of sarcolemmal K_{ATP} to inhibition by ATP and adenosine 5′-diphosphate.[50] The nucleotide-binding domains of the regulatory sulfonylurea receptor SUR2A were also shown to play important roles in isoflurane-induced facilitation of sarcolemmal K_{ATP} activity during moderate intracellular acidosis similar to that encountered during early ischemia.[51] These data provided support for the contention that isoflurane directly interacts with subunits of cardiac sarcolemmal K_{ATP}. Notably, age does not appear to affect the ability of isoflurane to interact with the sarcolemmal K_{ATP} in human atrial myocytes.[52]

It is also clear that volatile anesthetics directly or indirectly open mitochondrial K_{ATP} in vitro. Isoflurane and sevoflurane increased mitochondrial flavoprotein oxidation, an index of mitochondrial K_{ATP} open state, in guinea pig cardiac myocytes; 5-HD inhibited this increase in fluorescence.[53] Isoflurane directly opened mitochondrial K_{ATP} reconstituted in lipid bilayers[54] and protected human embryonic cardiac progenitor cells against oxidative stress through a mitochondrial K_{ATP}-mediated mechanism.[55] Isoflurane-induced increases in mitochondrial flavoprotein fluorescence were not blocked by pretreatment with adenosine, PKC, PTK, or mitogen-activated protein kinase (MAPK) inhibitors, suggesting that isoflurane may directly open mitochondrial K_{ATP}.[56] In contrast, isoflurane and sevoflurane failed to directly enhance flavoprotein fluorescence in rat ventricular myocytes, but these volatile anesthetics did enhance mitochondrial K_{ATP} agonist diazoxide-induced fluorescence.[20] The data suggested that volatile anesthetics indirectly

prime mitochondrial K_{ATP} by acting on other intracellular signaling elements that modulate the open state of the channel. Sarcolemmal K_{ATP} also may be linked to the function of the inner mitochondrial membrane. The ROS generated by mitochondria may act to open sarcolemmal K_{ATP}. An uncoupler of mitochondrial oxidative phosphorylation reversibly activated sarcolemmal current concomitant with nicotinamide adenine dinucleotide oxidation. These and other data led to the contention that crosstalk may occur between sarcolemmal K_{ATP} and mitochondrial K_{ATP} during IPC and pharmacologic preconditioning,[57] but such crosstalk has yet to be specifically demonstrated during APC. To summarize, experimental results collected to date provide somewhat conflicting results about a possible direct action of volatile anesthetics on sarcolemmal K_{ATP} and mitochondrial K_{ATP} open state. Nevertheless, it is clear that volatile anesthetics prime the opening of K_{ATP} channels in both sarcolemmal and mitochondrial membranes. It is also important to recognize that not all myocardial protection during APC is due to K_{ATP} channel opening. For example, APC preserved crucial Ca^{2+} cycling proteins (e.g., Ca^{2+}-release channels, Ca^{2+}-adenosine triphosphatase) independent of sarcolemmal K_{ATP} and mitochondrial K_{ATP} opening, suggesting that protection of major regulators of intracellular Ca^{2+} homeostasis against ischemia-reperfusion injury does not depend entirely on the actions of volatile anesthetics on K_{ATP} channel function.[58]

K_{ATP} channels in vascular smooth muscle cells are also essential regulators of coronary vascular tone when ATP production is reduced. Glyburide attenuated volatile anesthetic–induced coronary vasodilation,[59] indicating an important role for K_{ATP} channels in this process. Thus, it is possible that the beneficial actions of APC may be partially attributed to increases in myocardial O_2 supply mediated by K_{ATP} channel–dependent coronary vasodilation. However, sevoflurane increased coronary collateral blood flow in the presence of glyburide in vivo, indicating that this volatile anesthetic may enhance coronary collateral blood flow independent of K_{ATP} channel opening. Sevoflurane-induced increases in collateral perfusion also occurred as a result of BK_{Ca} and not K_{ATP} channel opening.[60] Thus, it appears highly unlikely that myocardial protection produced by volatile anesthetics is solely related to favorable alterations in coronary vascular tone mediated by K_{ATP} channels.

The sequential activation of several intracellular elements in a transduction pathway may facilitate amplification of the initial signal between other systems. This concept was clearly illustrated by the observation that the direct K_{ATP} channel opener nicorandil enhances the protective effects of isoflurane against ischemia-reperfusion injury. G protein–coupled receptor ligands and their downstream signaling elements converge on the K_{ATP} channel during APC. Pertussis toxin abolished reductions in infarct size produced by isoflurane, indicating that inhibitory guanine (G_i) nucleotide-binding proteins are linked to the signaling pathways that mediate APC.[61] In contrast, pertussis toxin did not prevent the beneficial effects of direct K_{ATP} channel opening produced by nicorandil. These data strongly supported the contention that volatile anesthetics modulate K_{ATP} channel activity through an action similar to that of a second messenger. Halothane-induced protection against infarction was completely abolished by A_1 receptor blockade, and a selective A_1 receptor antagonist also partially attenuated the beneficial effects of isoflurane in stunned myocardium. Isoflurane eliminated increases in interstitial adenosine during repetitive periods of coronary artery occlusion and reperfusion as demonstrated using a myocardial microdialysis technique. These findings suggested that both ATP preservation and a subsequent reduction of adenosine released into the interstitium occur during isoflurane anesthesia. The results were very similar to those obtained during IPC and pharmacologic preconditioning produced by bimakalim. Thus, volatile anesthetics may either directly activate A_1 receptors or indirectly enhance A_1 receptor sensitivity to diminished endogenous adenosine concentrations. The preservation of cardiac myocyte viability during ischemia produced by volatile anesthetics was also sensitive to adenosine receptor and G_i protein–mediated signaling blockade.[20] Moreover, adenosine enhanced APC through both mitochondrial K_{ATP}-dependent and K_{ATP}-independent mechanisms in isolated hearts.[62]

The nonselective opioid antagonist naloxone abolished APC in vivo,[18] indicating the existence of an important link between volatile anesthetics and another family of G_i protein–coupled receptors and their putative ligands. Volatile anesthetics competitively inhibited the ligand-binding site of G_i protein–coupled receptors.[63] Thus, APC appears to be associated with the activation of at least two separate receptor-mediated pathways (A_1 and opioid) that are linked to cell signaling through G_i proteins. Interestingly, the combination of isoflurane and a selective δ_1-opioid receptor agonist further amplified APC.[64] This effect was synergistic and sensitive to inhibition by glyburide. The combined administration of isoflurane and morphine also markedly reduced infarct size in vivo, and this protective effect was abolished by mitochondrial K_{ATP} blocker 5-HD.[18] Thus, combined administration of a volatile anesthetic and an opioid capable of agonist action at the δ_1-opioid receptor subtype may stimulate similar or cooperative signaling cascades that amplify mitochondrial K_{ATP} opening to profoundly augment myocardial protection beyond that produced by either drug alone. A G_s protein–coupled receptor ligand system, the β_1-adrenoceptor and its downstream target protein kinase A, also mediated APC,[65] suggesting that both G_i and G_s may play important roles in APC in vivo.

IPC produces translocation and phosphorylation of several protein kinases, most importantly PKC, involved in the signaling responsible for myocardial protection.[66] The diverse PKC isoform family is a large group of serine-threonine kinases that are distinguished by variable regulatory domains and cofactors. The PKC family displays diverse tissue and species distributions. G protein-coupled receptor ligands, including A_1, δ_1-opioid, and bradykinin, activate PKC during pharmacologic preconditioning. Volatile anesthetics stimulated PKC translocation and activity, possibly by interacting with the regulatory domain of the enzyme. Inhibition of PKC partially attenuated isoflurane-induced augmentation of the functional recovery of stunned myocardium. The beneficial

actions of halothane were entirely blocked by selective inhibition of PKC. Colchicine, a drug that depolymerizes microtubule assemblies, prevented isoflurane-induced reductions in myocardial infarct size. This result suggests that an intact cytoskeleton is essential for translocation of the PKC to occur. Indeed, volatile anesthetic–induced PKC translocation and activation appears to be required to open K_{ATP} channels. For example, a nonselective PKC antagonist abolished sevoflurane-induced increases in mitochondrial K_{ATP} open state and prevented protection against ischemic damage in rat ventricular myocytes.[20] Patch-clamp experiments demonstrated that isoflurane did not facilitate K_{ATP} channel opening in excised membranes but enhanced K_{ATP} channel current in a whole-cell configuration concomitant with PKC stimulation.[67] These observations were supported by findings that both adenosine and PKC enhance K_{ATP} channel open state during IPC. Specific PKC consensus sites were demonstrated on K_{ATP} channels, thereby suggesting a molecular basis for phosphorylation and opening of the channel by this enzyme.[68] Translocation of PKC-δ, but not PKC-ε, was initially shown to play an important role in APC in isolated hearts.[69] Phosphorylation of the serine 643 residue of PKC-δ appeared to mediate transfer of the preconditioning stimulus (exposure to 1.5 MAC isoflurane) to mitochondrial K_{ATP}. Both PKC-δ and PKC-ε translocation were implicated in APC produced by isoflurane in vivo, and opening of mitochondrial K_{ATP} and generation of ROS accompanied this PKC activation.[70] Another study implicated PKC-ε alone during APC produced by sevoflurane,[71] whereas PKC-α and PKC-ε, but not δ, specifically mediated the acute memory phase of sevoflurane APC in isolated guinea pig hearts.[72] PKC-α was shown to be important in sevoflurane-induced myocardial protection via production of ROS in rat myocardium.[73] A role for PKC-ε was also demonstrated in isoflurane APC in rats,[74] but only at lower concentrations (<0.5 MAC) of the volatile anesthetic. Desflurane APC produced time-dependent translocation of PKC-ε through activation of extracellular signal-regulated kinases 1 and 2 (ERK1/2).[75] In contrast, PKC-δ mediated APC by sevoflurane through ROS production independent of mitochondrial K_{ATP}.[76] This process depended on modulation of the reverse mode of the Na^+-Ca^{2+} exchanger.[73] When considered together, the data indicate that at least three different isoforms of PKC (α,ε, and δ) appear to be important mediators of APC, but PKC-ε has been most frequently implicated across various species, including humans.

PKC stimulates PTK and several MAPKs during IPC, and these latter proteins are also involved in APC independent of receptor activation. A nonselective PTK inhibitor and a *Src*-selective inhibitor abolished APC by isoflurane in rats,[70] but nonselective PTK inhibitors did not alter desflurane APC in rabbits.[77] These findings suggest that the role of PTK in APC may be species-dependent. The MAPK proteins are also serine-threonine kinases that are crucial for signal transduction from the cell surface to the nucleus and are key regulators of apoptosis. ERK1/2 is a MAPK (p42/p44) that mediates cell division, proliferation, and survival.[78] ERK1/2 is phosphorylated and activated by the upstream enzyme mitogen-activated protein kinase–extracellular signal-regulated kinase-1 (MEK-1) through occupation of PTK or G protein–coupled receptors. ERK1/2 was previously implicated in IPC and opioid-induced preconditioning. Reductions in infarct size and ERK1/2 phosphorylation produced by administration of desflurane before ischemia and reperfusion were abolished by a selective ERK1/2 inhibitor,[75] providing the first evidence suggesting that ERK1/2 mediates APC. ERK1/2 was also shown to trigger isoflurane APC in rabbits.[79]

ERK1/2-related signaling proteins control the expression of several genes essential for cell survival against ischemic stress, most notably, hypoxia-inducible factor-1α (HIF-1α), an important DNA-binding complex whose activity is influenced by intracellular O_2 tension. Myocardial hypoxia is a potent inducer of HIF-1α expression, and the combination of reduced O_2 tension and activation of ERK1/2 signaling are known to potentiate HIF-1α expression and activity.[80] HIF-1α also up-regulates transcription of vascular endothelial growth factor (VEGF), an important angiogenic protein that plays a central role in coronary collateral development in response to chronic myocardial ischemia.[81] Enhanced expression of both HIF-1α and VEGF occurs during myocardial ischemia.[82] ERK1/2-dependent up-regulation of HIF-1α and VEGF was shown during IPC and hypoxic preconditioning.[83] Isoflurane APC also produced temporal up-regulation of HIF-1α and VEGF protein expression by activating ERK1/2 in rabbit myocardium.[79,84] Another MAPK (p38) that was strongly implicated in IPC also mediated APC in isolated rat hearts.[85] p38 MAPK interacts with the actin cytoskeleton through MAPK-activated protein kinase-2 (MAPKAPK-2) and heat shock protein 27 (Hsp27). APC by isoflurane preconditioning was activated by both MAPKAPK-2 and Hsp27 downstream of PKC and p38 MAPK,[86] providing yet another link between APC and the cytoskeletal-specific translocation of signaling elements involved in myocardial protection. Two other protein kinases that deserve comment have been implicated in APC. 5′AMP-activated protein kinase (5′AMPK) is a regulator of cellular energy status known to mediate IPC. Sevoflurane APC phosphorylated 5′AMPK and its downstream target endothelial NO synthase (eNOS) concomitant with a reduction in myocardial infarct size in isolated rat hearts.[87] A selective 5′AMPK inhibitor abolished these effects. Finally, Pim-1 kinase is a regulator of cardiac myocyte survival during physiologic stress that was also shown to mediate desflurane APC in mice.[88]

Phosphatidylinositiol-3′-kinase (PI3K) has been shown to be responsible for the phosphorylation of a variety of subcellular targets implicated in cell survival, protein synthesis, and metabolism. Activation of this kinase pathway not only reduces cell necrosis but also contributes to the preservation of viable myocardium by inhibiting apoptosis and maintaining mitochondrial integrity.[78] PI3K converts phosphatidylinositol-4,5-bisphosphate (PIP2) to phosphatidylinositol-3,4,5-trisphosphate (PIP3),[89] and PIP3-stimulated phosphorylation of the serine-threonine kinase Akt (protein kinase B) by phosphoinositide-dependent kinase 1 (PDK1) subsequently inhibits the formation of several proapoptotic proteins (e.g., Bad, Bax, caspases). PDK1 is a also a potent activator of other protein kinases,[89] including PKC and PTK, implicated in APC.[90] A role for PI3K signaling in APC by isoflurane was previously

demonstrated.[91] A selective inhibitor of PI3K abolished reductions in infarct size and also blocked phosphorylation of the downstream enzyme target Akt produced by administration of isoflurane before prolonged coronary occlusion and reperfusion in rabbits. Isoflurane preconditioning increased Akt phosphorylation and expression of the antiapoptotic B-cell lymphoma-2 (Bcl-2) protein and reduced expression of the apoptotic protein Bax in rabbits concomitant with decreases in infarct size and the number of apoptotic myocytes.[92] Selective PI3K antagonists abolished these actions, indicating that PI3K-induced modulation of proapoptotic and antiapoptotic protein balance plays a role in APC produced by isoflurane. Activation of Akt by isoflurane protected rat atrial and ventricular myocytes against apoptosis produced by exposure to hypoxia, hydrogen peroxide, or activated neutrophils concomitant with increased expression of Bcl-2.[93] The antiapoptotic effect of APC was also mediated by phosphorylation of the apoptosis repressor with caspase recruitment domain through a PI3K-dependent mechanism.[94] These results emphasize that APC-induced myocardial protection is at least partially caused by attenuation of apoptosis, similar to the findings during IPC.[95,96]

Opening of the nonspecific channel mPTP within the inner mitochondrial membrane abolishes the mitochondrial membrane potential ($\Delta\Psi_m$). This effect has several consequences that rapidly produce cell death, including inhibition of oxidative phosphorylation, unimpeded swelling of the mitochondria, and stimulation of the release or activation of several apoptotic proteins, including cytochrome c. The mPTP contains three major components: a voltage-dependent anion channel, the enzyme adenine nucleotide translocase, and cyclophilin D, a *cis/trans* peptidyl-propyl isomerase located within the mitochondrial matrix.[97] Cyclophilin D was proposed to bind to adenine nucleotide translocase in the presence of pathologic elevations in intramitochondrial Ca^{2+} concentration. The combination of these moieties prevented nucleotide transport and caused the channel of the mPTP to form. However, knockout mouse models suggest that neither the voltage-dependent anion channel nor adenine nucleotide translocase is truly essential for mPTP formation,[98,99] whereas cyclophilin D appears to be a critical component of mPTP.[100,101] Interestingly, the commonly used immunosuppressant medication cyclosporin A (CsA) binds cyclophilin D and prevents mPTP formation.[102,103] The combined effects of intramitochondrial Ca^{2+} overload, ROS, and inorganic phosphates accumulated during ischemia because of exhausted adenine nucleotide metabolism cause mPTP to open; these abnormalities are especially apparent during early reperfusion. In contrast, adenine nucleotides, magnesium and other matrix cations, and acidosis inhibit mPTP formation.

mPTP opening has been strongly implicated as an end-effector in myocardial necrosis and apoptosis resulting from ischemia-reperfusion injury.[104] Activation of the PI3K-Akt and ERK1/2 pathways exert regulatory control over the transition state of mPTP.[97] Administration of CsA reduced myocardial infarct size to a similar magnitude as IPC.[105] A radiolabeled 2-deoxyglucose entrapment technique was used to show that IPC directly inhibits mPTP opening during reperfusion.[106] Similarly, delayed mPTP opening in response to Ca^{2+} overload was observed in isolated cardiac mitochondria that had been previously exposed to IPC, CsA, or a cyclophilin D–selective CsA derivative. Delayed IPC regulated mPTP formation through enhanced expression of Bcl-2.[107] Pharmacologic preconditioning by mitochondrial K_{ATP} opener diazoxide[105] or volatile anesthetics[108] also involves mPTP inhibition. For example, APC improved the resistance of mPTP to Ca^{2+}-induced opening in rabbit mitochondria[108] through a PKC-ε–dependent mechanism.[109] CsA restored sevoflurane APC in the presence of hyperglycemia through inhibition of mPTP formation.[110] Isoflurane selectively phosphorylated the Tyr194 residue of the adenine nucleotide translocase component of mPTP, thereby favorably regulating mitochondrial bioenergetics.[111] APC was shown to modestly reduce $\Delta\Psi_m$ in stressed cardiac myocytes, thereby attenuating excess ROS production, delaying mPTP opening, and increasing cell survival through a decrease in mitochondrial Ca^{2+} uptake.[112,113] Notably, reductions in $\Delta\Psi_m$ were sustained after discontinuation of the volatile anesthetic, and this mitochondrial uncoupling may represent another contributing factor to the memory phase of APC.[112] Isoflurane also modified the response of the voltage-dependent anion channel to O-linked-β-N-acetylglucosamine; this modification inhibited mPTP opening and conferred protection against ischemia-reperfusion injury in cardiac myocytes.[114]

Reperfusion of ischemic myocardium is associated with the release of large quantities of ROS that disrupt intracellular Ca^{2+} homeostasis, cause lipid peroxidation, damage cell membranes, depress contractility, and produce reversible and irreversible tissue injury.[115] Volatile anesthetics, including isoflurane, have been shown to attenuate the toxic effects of O_2-derived free radicals on LV pressure development in isolated hearts. Isoflurane decreased hydroxyl radical generation in the ischemic rat heart, and halothane had a similar effect in dogs. The protective effects of sevoflurane were associated with reduced dityrosine formation, an indirect marker of reactive O_2 and N_2 species.[116] These results supported the contention that volatile anesthetics may reduce the release of deleterious quantities of ROS immediately after coronary artery occlusion and reperfusion. In contrast to these data implicating a pathologic role of large amounts of ROS, a variety of preconditioning stimuli, including brief ischemia, mitochondrial K_{ATP} openers, opioids, and volatile anesthetics, stimulate a small burst of ROS that initiates downstream signaling events and produces protection from subsequent ischemic injury. Pretreatment with low concentrations of ROS mimicked the beneficial effects of IPC, and free radical scavengers administered before or during ischemia attenuated this myocardial protection. These findings suggest that IPC is mediated by small quantities of ROS released during the preconditioning stimulus. Scavengers of superoxide anion and inhibition of nitric oxide synthase (NOS) abolished the beneficial actions of sevoflurane against ischemic damage.[116] Thus, small amounts of superoxide anion may act to trigger APC, whereas NO may scavenge larger quantities of superoxide anion on reperfusion to reduce injury. NO also mediated desflurane APC.[117] Scavengers of ROS attenuated isoflurane-induced

reductions in myocardial infarct size[118] and inhibited the salutary actions of mitochondrial K_{ATP} opening.[119] Isoflurane also directly increased superoxide anion formation in vivo independent of ischemia and reperfusion.[120] Thus, volatile anesthetics may be capable of producing small amounts of superoxide anion that exert protective effects during subsequent ischemia. These data provide compelling evidence that small quantities of ROS play a critical role in APC.

ROS are important regulatory mediators in many signaling processes that protect the cardiac myocyte from oxidative stress. ROS-induced PKC or MAPK activation[121] was implicated in IPC and pharmacologic preconditioning. ROS also activated G proteins that play a role in IPC.[122] Similarly, evidence connects ROS production by volatile agents to activation of protein kinases implicated in the signaling pathways responsible for APC. For example, administration of ROS scavengers inhibited isoflurane-induced PKC translocation and blocked APC.[70] Scavenging of ROS blocked desflurane and sevoflurane APC and attenuated mitochondrial uncoupling associated with these volatile anesthetics in vitro.[123] A cause-and-effect relationship between mitochondrial K_{ATP} opening and ROS production during IPC and APC also has been suggested. Mitochondrial K_{ATP} opening triggered IPC by generating ROS.[119] Similarly, agonist-induced mitochondrial K_{ATP} opening produced ROS that appeared to be essential for activation of MAPK and the subsequent beneficial effects against ischemic injury. For example, diazoxide enhanced cell viability after hypoxia and reoxygenation in vitro concomitant with ROS generation.[124] These beneficial actions were attenuated in cells pretreated with 5-HD or ROS scavengers, suggesting that myocardial protection produced by mitochondrial K_{ATP} agonists occurred as a result of triggering by ROS. The G protein–coupled receptor ligand morphine increased the fluorescence intensity of a hydrogen peroxide–sensitive probe. These effects were blocked by 5-HD,[125] thereby establishing a link between opioid-induced mitochondrial K_{ATP} opening and ROS production. Diazoxide and cromakalim (another mitochondrial K_{ATP} opener) directly caused release of superoxide anion from complex I of the electron transport chain in isolated rat heart mitochondria concomitant with matrix alkalinization.[126] In contrast to these studies indicating that mitochondrial K_{ATP} opening stimulates ROS production, other investigations suggest that ROS modulate mitochondrial K_{ATP} conformational state. For example, xanthine oxidase–derived superoxide anion opened mitochondrial K_{ATP} obtained from bovine ventricular myocardium and reconstituted in lipid bilayers.[127] ROS also triggered mitochondrial K_{ATP} opening, and this event subsequently generated additional quantities of both ROS and NO.[128] Thus, whether mitochondrial K_{ATP} opening acts as a trigger or effector of IPC or pharmacologic preconditioning may be unresolved to some degree, but it is clear that a complementary interaction between ROS and mitochondrial K_{ATP} exists during these preconditioning phenomena.

Whether mitochondrial K_{ATP} opening by volatile anesthetics precedes or follows ROS production during APC also remains in question. Pretreatment with 5-HD or a ROS scavenger before exposure to isoflurane abolished ROS production in rabbits,[39] whereas administration of 5-HD after discontinuation of isoflurane, but before prolonged coronary artery occlusion, only partially attenuated this effect. These results suggest that mitochondrial K_{ATP} opening acted as a trigger for APC by producing ROS. In direct contrast, sevoflurane-induced ROS production was not inhibited by 5-HD pretreatment in isolated guinea pig hearts.[129] Despite these equivocal findings, it is quite evident that ROS play a major role in APC in conjunction with mitochondrial K_{ATP}. Interestingly, a quantity of ROS that exceeds a critical threshold produced opening of the mPTP and a subsequent burst of ROS[130] that stimulated further release of additional ROS from other mitochondria.[131] This ROS-induced ROS release contributed to mPTP-dependent cell death in rat myocytes after ischemia-reperfusion.[132] Thus, volatile agents and other mitochondrial K_{ATP} openers may prevent opening of the mPTP in an oxidant-sensitive fashion to produce myocardial protection.

ROS derived from the mitochondrial electron transport chain have been shown to mediate IPC and pharmacologic preconditioning.[125] Whereas a complex III antagonist inhibited hypoxia-induced and acetylcholine-induced ROS production and abolished preconditioning in vitro, volatile anesthetics blocked complexes I and III in isolated cardiac mitochondria.[133,134] Sevoflurane-induced complex I inhibition was attenuated by a superoxide dismutase mimetic[134] and an NOS inhibitor,[135] suggesting that ROS, NO, or their reaction products may inhibit mitochondrial respiration through a positive feedback mechanism to amplify free radical signals for triggering APC. Conversely, a complex III inhibitor abolished isoflurane-mediated myocardial protection and ROS generation,[136] suggesting that complex III may be the source of ROS during APC. These data suggested the possibility that volatile anesthetics may modulate multiple sites of the electron transport chain either directly or indirectly through a ROS-mediated feedback mechanism. Indeed, the results of a recent study demonstrated that isoflurane produces ROS at complexes I and III of the electron transport chain by attenuating complex I activity in isolated mitochondria.[137] The actions of volatile anesthetics on complex I appear to reduce unfavorable reverse electron flow within the electron transport chain, thereby attenuating excessive ROS release in the mitochondria during reperfusion. Interestingly, it is this volatile anesthetic–induced inhibition of complex I activity that may be responsible for the production of small quantities of mitochondrial ROS known to trigger myocardial protection during APC.[138,139] A selective inhibitor of cyclooxygenase-2 (COX-2), but not COX-1 or COX-3, blocked isoflurane-induced myocardial protection in rabbits,[140] indicating that modulation of arachidonic acid metabolism by volatile anesthetics may represent another potential source of ROS during APC. Thus, at least three sources of O_2- or N_2-derived free radicals (mitochondrial electron transport, NOS, and COX-2) have been identified to date, but whether other enzymes (e.g., nicotinamide adenine dinucleotide oxidase, lipoxygenase, xanthine oxidase, cytochrome P450 [CYP450]) known to generate reactive intermediates are involved in APC remains to be determined.

The precise identity of the ROS involved in APC has not been defined. Superoxide anion directly opened mitochondrial K_{ATP} in vitro,[127] implicating this reactive intermediate in IPC. Isoflurane directly enhanced ethidium fluorescence in rabbit myocardium independent of subsequent ischemia and reperfusion.[39,120] Dihydroethidium is oxidized by intracellular superoxide anion to produce ethidium that subsequently binds to DNA, further amplifying its fluorescence. These data strongly suggested that superoxide anion mediates APC. Sevoflurane also generated superoxide anion before ischemia and reperfusion in isolated hearts.[129] In contrast to these findings implicating superoxide anion as a putative mediator of preconditioning, other results suggested that hydrogen peroxide may play a role in this phenomenon. Hydrogen peroxide stimulated PTK-dependent activation of phospholipase C in mouse embryonic fibroblasts, rendering these cells resistant to stress. Hydrogen peroxide has been shown to activate G_i and G_o proteins[122] and other protein kinases involved in reducing cellular injury. Hydrogen peroxide may be converted to more reactive species that subsequently modify cysteine residues specific to G proteins and selectively activate these proteins.[141] Thus, hydrogen peroxide or its immediate free radical metabolites represent another group of ROS known to affect many of the signaling molecules implicated in APC. Dismutation of superoxide anion leads to production of hydrogen peroxide, hydroxyl radical, and peroxynitrite, and these radicals may differentially alter channel or protein kinase activity. For example, superoxide anion and hydrogen peroxide enhanced, but peroxynitrite reduced, BK_{Ca} channel function.[1,42] Whether APC also produces other ROS that activate mitochondrial K_{ATP} or inhibit formation or intermediates such as peroxynitrite that adversely affect these channels has yet to be defined.

Heat shock proteins (Hsps) are constitutively expressed proteins that play essential roles in cell survival.[143] Hsps usually act as molecular chaperones by easing proper folding of other proteins, assisting in protein complex assembly, maintaining the structural integrity of steroid receptors, and helping move proteins throughout the cell. Hsps are also synthesized in response to tissue injury (most notably, hyperthermia, but also ischemia, inflammation, infection, and toxin exposure); this response stimulates restoration of denatured proteins and facilitates metabolism of proteins that are damaged beyond repair.[144,145] Importantly, induction of Hsps transiently protects the cell from damage by subsequent, potentially lethal insults of similar or differing origin or intensity, in part by inhibiting apoptosis.[144] Hsps are classified on the basis of molecular weight. The 70-kDa species (Hsp70) is one of the most thoroughly studied[146] because it has been strongly implicated in myocardial protection against reversible and irreversible ischemic injury.[147] For example, brief global or regional myocardial ischemia caused induction of Hsp70, and this increase in Hsp70 protected myocardium against subsequent ischemic damage. Repetitive, brief episodes of coronary artery occlusion conducted 24 hours before prolonged ischemia and reperfusion increased intracellular Hsp70 concentration concomitant with reductions in myocardial infarct size. Gene transfection of Hsp70 limited infarct size and preserved LV function after prolonged ischemia.[148] Furthermore, the viability of mitochondria isolated from transgenic mice overexpressing Hsp70 was enhanced after hypoxia-reoxygenation in contrast to those obtained from wild-type mice.[149] Hsp70 induction may also protect myocardium in patients undergoing coronary artery surgery.[150]

The role of Hsps in APC has been recently explored. Pharmacologic induction of Hsp70 24 hours before ischemia and reperfusion was shown to lower the threshold of sevoflurane APC in vivo.[151] Whereas 0.5 MAC sevoflurane failed to provide myocardial protection alone, administration of this concentration of the volatile anesthetic to rabbits pretreated with an Hsp70 inducer reduced myocardial infarct size to a significantly greater extent than observed with the Hsp70 inducer alone. Similar to the results of other studies in which exposure to volatile anesthetics did not affect Hsp70 expression,[152,153] sevoflurane APC failed to alter Hsp70 expression in the presence or absence of the Hsp70 inducer. Thus, it is unlikely that administration of a volatile anesthetic shortly before a prolonged ischemic episode produces myocardial protection by acutely enhancing Hsp70 transcription and translation. Like volatile anesthetics, Hsp70 exerts protective effects against ischemic injury through PKC activation and mitochondrial K_{ATP} opening. Thus, Hsp70 may enhance the beneficial actions of APC by simultaneously affecting these and other signaling components. In contrast to the findings with Hsp70, isoflurane APC was associated with up-regulation of lower molecular weight Hsps,[152] and an important role for Hsp27 (a key mediator of cytoskeletal integrity) has been reported during APC.[86] These results suggest that smaller Hsps also may be directly involved in APC. Finally, Hsp90-induced activation of eNOS colocalization has been shown to mediate APC through a tetrahydrobiopterin-dependent mechanism.[30,154]

Delayed Preconditioning. Seven years after the publication of Murry's original paper,[11] two groups[155,156] independently reported that two discrete chronologic phases of IPC exist: an acute or "early" phase of intense protection against infarction that occurs shortly after the inciting ischemic event and persists for a brief duration (1 to 2 hours) and a delayed, "late," or "second window" phase distinguished by a more protracted period (3 to 4 days) of myocardial protection against both reversible and irreversible injury that develops 6 to 12 hours after the initial ischemic event (Fig. 28-8). The mechanisms responsible for acute and delayed IPC are quite different. Whereas posttranslational modification of existing proteins mediates the early phase (thereby explaining its rapid onset and relatively short duration of protection), synthesis of new proteins is required for the late phase (explaining its delayed onset and more prolonged duration of protection).[12] An initial episode of ischemia is postulated to cause the release of small quantities of several molecules, including NO, ROS, and adenosine, that then stimulate a cascade of events culminating in delayed IPC. These molecules interact with endogenous signaling proteins, including PKC-ε, ERK1/2, the Src and Lck PTK isoforms, and the Janus-activated kinases 1 and 2, which then converge on and activate transcription factors, including nuclear factor κB(NF-κB), HIF-1α, and STAT1 and STAT3.

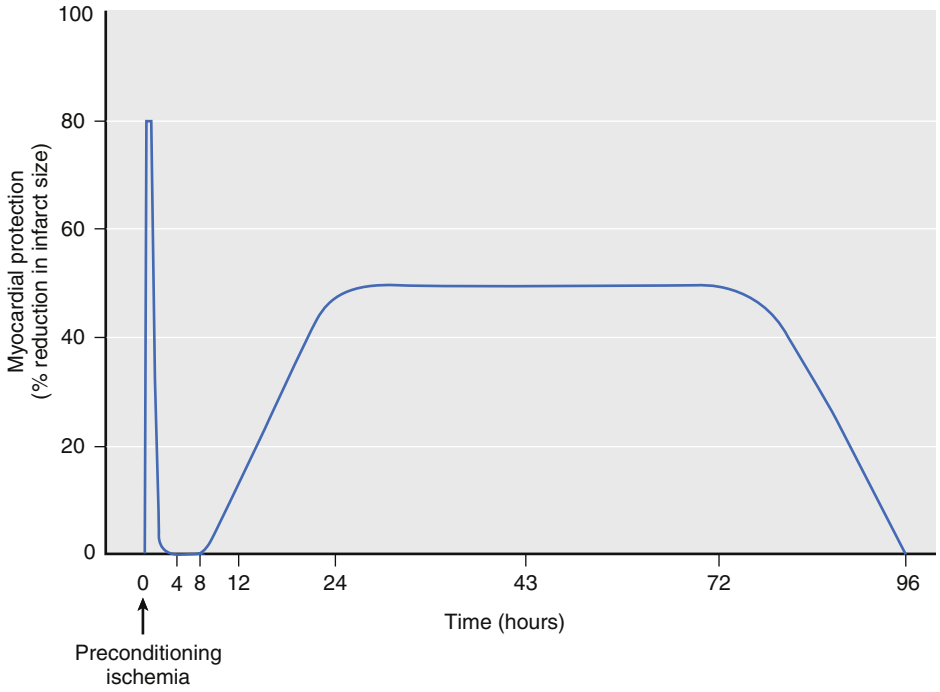

Figure 28-8. Schematic illustration depicting the two phases of ischemic preconditioning. Myocardial protection (expressed as a percentage reduction in infarct size) is plotted against time. After the application of a preconditioning (PC) stimulus (e.g., brief ischemia), rapid development of a preconditioned state occurs that confers powerful protection (80% to 90% reduction in infarct size in some models). However, the protection is transient, lasting only 1 to 2 hours. This is followed by the slower development of a late phase of protection, which becomes fully manifested at 24 hours after the PC stimulus and persists for approximately 72 hours. Thus, the duration of the late phase is 30- to 50-fold longer than that of the early phase of PC. *(From Bolli R: Preconditioning: a paradigm shift in the biology of myocardial ischemia,* Am J Physiol Heart Circ Physiol *292:H19-H27, 2007.)*

These transcription factors are usually quiescent, but cause genetic up-regulation and synthesis of iNOS, COX-2, heme oxygenase-1 (HO-1), and several antioxidants (e.g., extracellular superoxide dismutase, aldose reductase) in response to physiologic stress, including ischemia. These newly synthesized enzymes and their products, including NO, prostacyclin (prostaglandin I_2; PGI_2), and prostaglandin E_2, are considered to be the "mediators" of myocardial protection by inhibiting intracellular Ca^{2+} overload, producing antioxidant effects, opening mitochondrial or sarcolemmal K_{ATP} channels, blocking β-adrenoreceptor signaling, and preserving the closed conformation of mPTP.[157] Thus, a brief ischemic episode initiates several parallel and redundant events, including nuclear translocation of key transcription factors, stimulation of new protein synthesis, and release of new molecules, that produce late IPC through their actions on mitochondria and ion channels.

Remote administration of a volatile anesthetic before prolonged ischemia and reperfusion produces protective effects that are very similar to those of delayed IPC.[158] This "delayed" APC was first demonstrated in rabbit hearts subjected to a 2-hour exposure to 1% isoflurane 24 hours before prolonged ischemia and reperfusion.[159] Reduced myocardial infarct size and enhanced LV-developed pressure recovery were observed after this remote administration of isoflurane. The magnitude of the delayed protective effect was similar to that observed during acute APC. Pretreatment with 5-HD abolished the beneficial effects of remote isoflurane exposure in this model, whereas HMR-1098 attenuated them. As discussed earlier, both mitochondrial K_{ATP} and sarcolemmal K_{ATP} appear to be essential for acute APC,[90] and their involvement in delayed APC is certainly not surprising. Nevertheless, the relative roles of these channels in delayed APC have yet to be definitively established. Crosstalk between mitochondrial and sarcolemmal K_{ATP} may explain the apparent dual roles of these channels in acute and delayed IPC,[160] and a similar interaction between these channels may occur during delayed APC. Despite this minor controversy, it is abundantly clear that mitochondrial K_{ATP} plays a central role in late APC. For example, brief (5 minutes) administration of 1.0 MAC sevoflurane caused a further reduction in myocardial infarct size after delayed IPC in open-chest rabbits.[161] Pretreatment with 5-HD inhibited this beneficial effect of sevoflurane, indicating that the volatile anesthetic conferred additional protection in the presence of late IPC through mitochondrial K_{ATP} opening. Roles for BK_{Ca} channels and mPTP in desflurane-induced delayed APC have been recently suggested.[162]

In contrast to the aforementioned findings,[159] another group simultaneously reported that a 6-hour exposure to 1.0 MAC isoflurane did not cause late APC in a canine model, whereas acute APC was associated with substantial myocardial protection independent of alterations in systemic hemodynamics or coronary collateral blood flow.[163] The findings of this investigation appeared to contradict those of the previously discussed study[159] and suggested that isoflurane may not cause delayed APC in dogs or, alternatively, that late APC may be a species-specific phenomenon. Late IPC and other forms of delayed pharmacologic preconditioning were observed in several canine models,[164] but dogs may be less susceptible to preconditioning phenomena depending on the intensity of the initial stimulus, the temporal delay before the prolonged ischemic event, and the total duration of ischemia and reperfusion.[165] Thus, the duration and dose of isoflurane pretreatment may be crucial factors in determining whether delayed APC occurs. Interestingly, a 2-hour exposure to 1% isoflurane (≈0.5 MAC) caused robust myocardial protection in isolated rabbit hearts, but a 2-hour exposure to 2% isoflurane did not.

These results suggest that prolonged exposure to a greater isoflurane concentration did not cause a delayed APC effect, as suggested by the findings in dogs. Exposure to 1.0 MAC sevoflurane for 60 minutes followed by global ischemia and reperfusion 24 or 48 hours later decreased myocardial necrosis, enhanced recovery of LV function, maintained intracellular ATP concentrations, preserved intracellular pH, and maintained Na^+ and Ca^{2+} homeostasis in isolated rat hearts in contrast to those not receiving sevoflurane pretreatment.[166] Notably, the salutary actions of sevoflurane were greater 48 hours in contrast to 24 hours after exposure and may be functionally relevant for as long as 2 weeks after ischemia-reperfusion injury.[167] Similar findings were also described with isoflurane[168] and desflurane.[169] When considered collectively, these results suggest that a latency period greater than 24 hours after volatile anesthetic exposure may be needed to establish maximal protective effects in some experimental models of late APC. Considering these data, it is certainly plausible that myocardial protection may have been observed in dogs as well, if prolonged ischemia and reperfusion had occurred more than 24 hours after isoflurane pretreatment.

All investigations conducted after the single negative study in dogs demonstrated that remote administration of a volatile anesthetic before prolonged ischemia and reperfusion does, indeed, produce delayed protection against ischemic injury. For example, a 2-hour pretreatment with 1.0 MAC isoflurane conducted 24 hours before a 30-minute coronary artery occlusion and 3 hours of reperfusion reduced myocardial infarct size by 43% in rabbits.[170] The magnitude of the decreases in myocardial necrosis during late compared with early APC was nearly identical.[39] Additional studies from the same laboratory subsequently confirmed these findings.[171,172] Isoflurane (0.75 and 1.5 MAC) also caused dose-related and time-related delayed myocardial protection in rats.[168] Interestingly, pretreatment of rats with 1.5 MAC isoflurane 48 hours before ischemia and reperfusion caused the largest reductions in myocardial infarct size and the greatest recovery of LV-developed pressure during reperfusion.[168] Similar findings with desflurane- or sevoflurane-delayed APC were also reported.[169,173] Administration of a unique intravenous emulsified sevoflurane preparation did not produce sedation or respiratory depression in conscious rabbits, but the drug significantly reduced infarct size in contrast to lipid vehicle alone.[174] Notably, the plasma concentration of sevoflurane required for this beneficial effect was equivalent to a MAC value of approximately 0.17, suggesting that only a small amount of the volatile anesthetic may be required to produce delayed myocardial protection.

The mechanisms responsible for late APC in experimental animals have been incompletely studied to date. Bolli[175] proposed that iNOS plays a central role in delayed IPC because ischemia stimulates iNOS synthesis. The NO that is subsequently produced from newly synthesized iNOS may then exert protective effects. Bolli and associates[176] demonstrated that NO derived from eNOS triggers delayed IPC, whereas NO produced by iNOS mediates it. In contrast, targeted deletion of the *iNOS* gene also abolished late IPC. NO derived from neuronal NOS (nNOS; a regulator of catecholamine release expressed in sympathetic nerve terminals) may also mediate the late phase of IPC concomitant with activation of COX-2.[177] Similar to the findings with late IPC, NO has been shown to play an essential role in delayed APC, but the precise source of NO (iNOS, eNOS, or nNOS) is controversial. iNOS was shown to be important during late APC in rats exposed to 0.75 or 1.5 MAC isoflurane for 2 hours before global ischemia and reperfusion was conducted 24 to 96 hours later.[168] Remote exposure to isoflurane reduced infarct size, improved LV functional recovery, and enhanced iNOS expression and activity in a dose-dependent and time-dependent manner (Fig. 28-9). The maximal effects were observed 48 hours after exposure to 1.5 MAC isoflurane, and a selective iNOS inhibitor abolished myocardial protection in this model. These data strongly implicated iNOS as the primary enzymatic source for NO that mediates delayed APC.

Another group confirmed these findings in rats exposed to 1.0 MAC isoflurane for 1 hour followed by coronary artery occlusion and reperfusion 24 hours later.[178] Reduced infarct size, enhanced iNOS protein expression, increased myocardial NO content, translocation of the p65 subunit of NF-κB from the cytosol to the nucleus, and augmented NF-κB DNA-binding activity were observed. Pretreatment with a nonselective NOS antagonist or a NF-κB inhibitor before administration of isoflurane or a selective iNOS inhibitor immediately before ischemia abolished the protective effects of isoflurane. NF-κB is an important transcription factor involved in inflammatory response to oxidative stress that is activated during ischemia-reperfusion injury. The inhibitory protein IκB sequesters the major subunits of NF-κB (p50 and p65) within the myoplasm, thereby maintaining the transcription factor in its quiescent state under resting conditions. However, ischemia causes phosphorylation and degradation of IκB, allowing the p50 and p65 NF-κB subunits to associate and translocate to the nucleus, bind to promoter gene regions, and initiate transcription. IPC has been shown to reduce NF-kB activation and blunt production of inflammatory cytokines, chemokines, and adhesion molecules, thereby contributing to a reduction in myocardial necrosis. Sevoflurane preconditioning also attenuated NF-κB activation and reduced NF-κB–dependent inflammatory gene expression in isolated and intact hearts.[179,180] A reduction in apoptosis appears to play an important role in this NF-κB–mediated effect during APC.[181] Activation of NF-κB also was previously shown to play a central role in delayed IPC. The *iNOS* gene is a common target of NF-κB; binding of the transcription factor to the promoter-enhancer region of the gene initiates the protein's transcription. Thus, remote administration of isoflurane before prolonged ischemia and reperfusion generates NO and sequentially triggers activation of NF-κB, expression of iNOS, and synthesis of additional NO that the mediates delayed APC in rats. Administration of a NF-κB inhibitor before isoflurane exposure blocked the increases in NF-κB protein and its DNA-binding activity and inhibited myocardial protection. Thus, early activation of NF-κB may be an obligate step during delayed APC.

Values are mean ± standard error of the mean of five experiments. $^{*}P < .05$ compared with control. **C** to **E,** Immunohistochemical analysis of iNOS protein expression in control heart (**C**), 48 hours after oxygen inhalation (**D**), and 48 hours after inhalation of 1.5 minimum alveolar concentration isoflurane (**E**). Scale bars, 20 μm. *(From Wakeno-Takahashi M, Otani H, Nakao S, et al: Isoflurane induces second window of preconditioning through upregulation of inducible nitric oxide synthase in rat heart,* Am J Physiol Heart Circ Physiol *289:H2585-H2591, 2005.)*

eNOS has been implicated in late APC. Administration of a nonselective NOS inhibitor, but not selective iNOS or nNOS inhibitors, either before remote isoflurane exposure or before coronary occlusion and reperfusion abolished reductions in infarct size produced by the volatile anesthetic concomitant with increases in eNOS but not iNOS transcription and translation in rabbits.[171] Delayed APC also was observed in only adult male, but not female, rabbits.[172] Estrogen enhances eNOS expression, favorably modulates endothelial NO release, and stimulates eNOS binding to Hsp90. The latter effect substantially increases eNOS activity. The interaction between eNOS and Hsp90 was demonstrated during acute APC.[154] Thus, the gender specificity of delayed APC is most likely related to the actions of estrogen on eNOS expression and activity in female rabbits that confers protection against infarction independent of any subsequent remote administration of a volatile anesthetic.[172] These findings also indirectly suggest that the protective effect of NO may be derived from eNOS and not iNOS.

The experimental disagreement about the specific source of NO (iNOS versus eNOS) that mediates delayed APC merits further discussion. NO derived from eNOS followed by iNOS acts as a trigger and mediator, respectively, of delayed IPC, but whether late pharmacologic preconditioning occurs through such a clearly defined sequence of events is not so clearly defined. For example, eNOS may "masquerade" as iNOS during delayed preconditioning produced by adenosine.[182] Selective iNOS inhibition before prolonged ischemia and reperfusion also did not alter the protective effects of remote administration of adenosine,[183] in contrast to the findings during the late IPC. Activation of eNOS by Akt also mediated late preconditioning produced by the mitochondrial K_{ATP} channel opener diazoxide.[184] A central role for the PI3K cascade was previously demonstrated in volatile anesthetic preconditioning and postconditioning.[185] Thus, the apparent predominance of eNOS-derived compared with iNOS-derived NO during delayed APC described in rabbits may be related, at least in part, to the relative importance of PI3K signaling in this species. Marked differences are seen in the type and distribution of NOS in rabbits, compared with rats and mice, which may profoundly influence cellular response to ischemia.[186] Thus, the animal species in which the studies were performed may partially account for observed variations in the source of NO. Nevertheless, experimental evidence accumulated to date indicates that NO is a critical trigger and mediator of delayed APC regardless of whether the source of the molecule is iNOS or eNOS.

ROS have been shown to trigger late APC.[187] A 2-hour exposure to 0.8% isoflurane conferred protection against

infarction and improved recovery of LV-developed pressure after global ischemia and reperfusion were imposed 24 hours later.[187] Administration of a superoxide anion scavenger 15 minutes before isoflurane abolished this myocardial protection. Isoflurane increased dihydroethidium fluorescence consistent with ROS production; pretreatment with a mitochondrial electron transport chain inhibitor attenuated this effect. These results suggested that the oxidative phosphorylation cascade was the source of ROS involved in delayed APC, similar to findings during acute APC and IPC.[96] For example, ROS triggered IPC through mitochondrial K_{ATP} opening in rabbits.[119] Isoflurane directly generated ROS independent of subsequent ischemia and reperfusion, and these reactive intermediates mediated myocardial protection[118] by opening mitochondrial K_{ATP}[39] and activating the electron transport chain.[136] However, it remains unclear whether ROS produced during remote volatile anesthetic exposure stimulates transcription and translation of new protein mediators of delayed APC similar to the triggering actions of NO. This mechanism appears likely because ROS activated PKC-ε and caused nuclear translocation of NF-κB during late IPC.[188]

COX-2 and its metabolites are also important mediators of delayed IPC.[12,189] COX-2 transcription and translation occurred 24 hours after an ischemic stimulus concomitant with elevated myocardial PGE_2 and 6-keto-$PGF_{1\alpha}$ (a PGI_2 metabolite) concentrations. Prostacyclin also was shown to produce salutary effects by stimulating mitochondrial K_{ATP} to open and abrogating oxidative damage as a result.[190] In contrast, pretreatment with a COX-2 inhibitor (e.g., celecoxib) abolished prostaglandin production and blocked reductions in myocardial necrosis during late IPC.[191] Coinduction of iNOS and COX-2 occurred after brief ischemia. This observation suggested that interaction of these two proteins is crucial for cellular defense in response to ischemia.[192] In fact, iNOS was shown to be an upstream regulator that modulates COX-2 expression and activity during delayed IPC.[192,193] COX-2 and its metabolites also mediated late pharmacologic preconditioning through the δ-opioid receptor.[194] COX-2 was shown to mediate acute and delayed APC in vivo.[140,170] Administration of celecoxib 2.5 hours before prolonged ischemia and reperfusion, but not immediately before isoflurane, abolished the myocardial protection associated with remote exposure to the volatile anesthetic. These data suggested that COX-2 functions as a mediator of delayed APC. Isoflurane exposure also produced time-dependent increases of COX-2 protein expression and activity that were associated with a decline in myocardial necrosis.[195] Thus, it is clear that COX-2 and metabolites are key mediators of late APC.

Arachidonic acid released during ischemia may be metabolized by lipoxygenases and CYP450 isoforms to generate other products that elicit myocardial protection.[196] For example, enhanced activity of 12-lipoxygenase and formation of 12-hydroxyeicosatetraenoic acid (12-HETE) mediated the cardioprotective effects of acute IPC through a PKC-dependent mechanism. Remote exposure to a selective δ-opioid receptor agonist reduced infarct size and enhanced 12-lipoxygenase transcription and translation, and these effects were attenuated by administration of a 12-lipoxygenase inhibitor.[197] A selective 12-lipoxygenase inhibitor also abolished the protective effect of exposure to 1.0 MAC isoflurane 24 hours before ischemia and reperfusion, suggesting that 12-lipoxygenase may be a mediator of delayed APC.[196] 12-Lipoxygenase expression was significantly increased 12 and 24 hours after isoflurane exposure; new protein was localized to the intercalated disk regions adjoining cardiac myocytes (Fig. 28-10). Conversely, another 12-lipoxygenase inhibitor did not appear to affect late APC.[195] Differences in experimental design and animal species may be responsible for these apparently contradictory results. However, it is clear that delayed APC up-regulates expression and enhances activity of a key enzyme (12-lipoxygenase) that metabolizes arachidonic acid to hydroxyeicosatetraenoic acid products that have been implicated in other forms of acute and delayed preconditioning.[197] Another arachidonic acid metabolite [15-deoxy-(12,14)-prostaglandin J_2] known to activate peroxisome-proliferator–activated receptor γ also was shown to mediate desflurane-induced delayed APC in rabbits.[198]

Lipid rafts are small regions (0.01 to 0.2 μm) suspended in membrane phospholipid bilayers that contain high concentrations of glycosphingolipids, sterols, and scaffolding proteins (termed caveolins).[199-201] Lipid rafts exist in myocardial sarcolemmal and mitochondrial membranes and are dynamic regulators of signal transduction molecules.[202] Caveolae are a type of lipid raft consisting of small membrane invaginations (0.06 to 0.08 μm) that bind and regulate the activity of G protein–coupled receptors, ERK1/2, and eNOS. Caveolins are required for caveolae to form. Thus, expression of caveolins directly influences the number of caveolae available for signal modulation.[203] Of the three known caveolin isoforms, caveolin-3 is the predominant type in myocardium.[202] Overexpression of caveolin-3 was shown to mimic IPC through a PI3K-mediated mechanism.[204] Similarly, caveolin-3 also played an obligate role in acute APC.[202,205] Remote exposure to isoflurane reduced infarct size in wild-type and caveolin-1, but not caveolin-3, knockout mice concomitant with up-regulation of caveolin-3 protein and microscopic evidence of caveolae.[206] These data implicated caveolin-3 in delayed APC. Late APC also increased expression of glucose transporter-4 (GLUT-4; the major transporter for cellular uptake of glucose), and this protein was colocalized with caveolin-3.[206] GLUT-4 translocation from the intracellular compartment to caveolae may facilitate substrate delivery for anaerobic glycolysis during ischemia. GLUT-4 was also previously shown to mediate acute and delayed IPC through its interaction with caveolin-3 and signaling proteins, including PKC, Akt, and eNOS.[207,208] Furthermore, NO and arachidonic acid metabolites caused transcription, translation, and translocation of GLUT-4.[209,210] Taken together, these results suggest the GLUT-4 is another important component of the delayed APC cascade that acts with caveolin-3 downstream from NOS and COX-2.[206]

The previously discussed studies of the efficacy of, and mechanisms responsible for, delayed APC were conducted in healthy adult experimental animals. Whether late APC occurs in models of cardiac disease has not been extensively studied. The effects of postinfarction remodeling

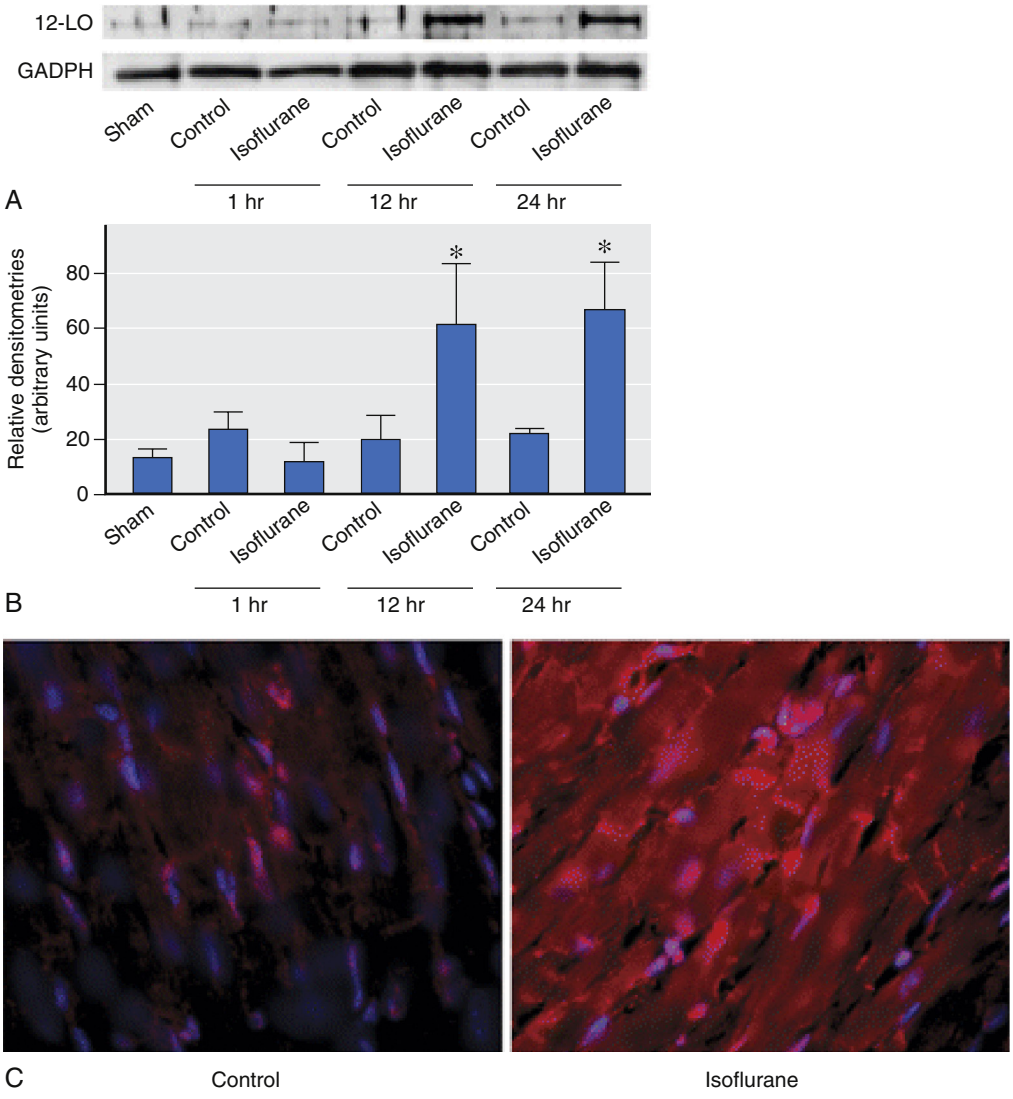

Figure 28-10. A, Immunoblots illustrating total 12-lipoxygenase (12-LO) after different recovery periods. Glyceraldehyde-3-phosphate dehydrogenase (GADPH) immunoblot was performed to determine equal protein loading. **B,** Densitometry of immunoblots in **A** was normalized to GADPH values. Isoflurane significantly increased 12-lipoxygenase protein at 12 and 24 hours of recovery (n = 3 in each group). Data are shown as mean ± standard error of the mean. $^{*}P < .05$ versus control. **C,** Immunofluorescence analysis of the expression and localization of 12-lipoxygenase (*red pixels*) in mouse ventricular tissue after 24-hour recovery period after isoflurane. *(From Tsutsumi YM, Patel HH, Huang D, Roth DM: Role of 12-lipoxygenase in volatile anesthetic-induced delayed preconditioning in mice,* Am J Physiol Heart Circ Physiol *291:H979-H983, 2006.)*

on delayed APC were examined in isolated Langendorff-perfused hearts 6 weeks after coronary artery ligation.[195] This model is characterized by compensatory LV hypertrophy and chamber dilatation. Late APC was observed in postinfarction remodeled hearts, and the magnitude of this protection was similar to that observed in normal hearts, but several differences were noted. The duration of late APC was limited to only 24 hours after brief isoflurane exposure in postinfarction remodeled hearts in contrast to at least 48 hours in normal hearts. Differences in COX-2 protein expression and activity between remodeled and normal hearts paralleled these findings. COX-2 inhibitors abolished delayed APC in both normal and postinfarction remodeled hearts. Thus, COX-2 plays an obligate role in late APC in both models. However, postinfarction remodeled hearts showed more pronounced sensitivity to COX-2 inhibitors compared with normal hearts (Fig. 28-11). Remote exposure to isoflurane also caused nuclear translocation of the COX-2–related transcription factor HIF-1α in normal and infarct remodeled hearts. However, nuclear translocation of another important transcription factor, cyclic adenosine monophosphate (cAMP) response element–binding protein (CREB), did not occur in remodeled hearts. In addition, increased expression of the CREB antagonist inducible cAMP early repressor (ICER) was observed.[195,211] It appears likely that the lack of isoflurane-induced CREB translocation after infarction may have contributed to the narrower window of delayed APC observed in this model.[195]

Two studies of isolated leukocytes provided evidence that remote exposure to a volatile anesthetic may abrogate the proinflammatory responses of white blood cells to ischemia-reperfusion injury.[212,213] Leukocytes were collected from healthy volunteers during and after a 60-minute inhalation of sevoflurane (0.5% to 1.0%) and analyzed using gene microarray analysis and flow cytometry. Sevoflurane produced dramatic alterations in gene expression, including several key transcripts implicated in late IPC. The temporal changes in gene expression resulting from sevoflurane exposure bore many similarities to those observed during late IPC.[214] Sevoflurane also reduced neutrophil surface receptor L-selectin (CD62L) expression and partially inhibited neutrophil responsiveness to inflammatory stimuli 24 and 48 hours after exposure to the anesthetic.

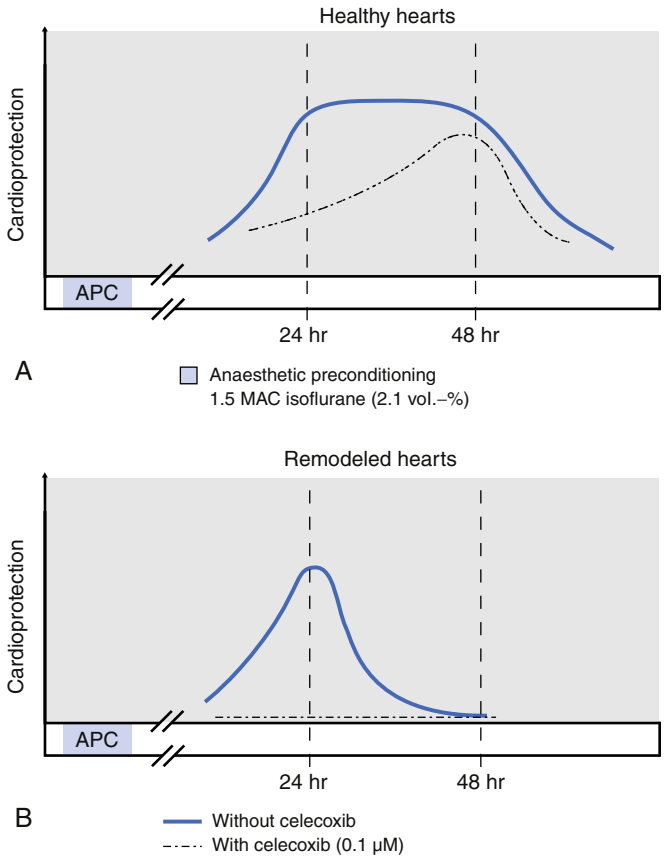

Figure 28-11. The second window of preconditioning is different in healthy and remodeled hearts. The panels show the second window of preconditioning at 24 and 48 hours after isoflurane exposure (anesthetic preconditioning *[APC]*) in healthy (**A**) and infarct remodeled (**B**) hearts in the absence *(solid line)* and presence *(dashed line)* of celecoxib (0.1 μM). *(From Feng J, Lucchinetti E, Fischer G, et al: Cardiac remodelling hinders activation of cyclooxygenase-2, diminishing protection by delayed pharmacological preconditioning: role of HIF1 alpha and CREB,* Cardiovasc Res *78:98-107, 2008.)*

Adhesion molecules, including L-selectin and β_2-integrin, are responsible for neutrophil binding to injured vascular endothelium. These molecules stimulate leukocyte extravasation into the extravascular space during early reperfusion.[115] Specifically, L-selectin facilitates tethering and rolling of neutrophils on the endothelial surface that initiates the extravasation process.[215] Thus, inhibition of L-selectin expression by remote exposure to sevoflurane may contribute to a persistent reduction in neutrophil binding and activity during late APC, thereby abrogating the adverse effects of these leukocytes during reperfusion injury. Another research group examined superoxide anion production in response to receptor-dependent and receptor-independent stimuli in canine neutrophils after remote administration of 1.0 MAC isoflurane.[213] Exposure to isoflurane caused an immediate and sustained 50% reduction in superoxide anion formation in neutrophils activated by platelet activating factor or formyl-methionyl-leucyl-phenylalanine. Late APC was also recently shown to be associated with improved antioxidant defenses as indicated by enhanced activity of superoxide dismutase, catalase, and glutathione peroxidase and reductase.[216] When considered collectively, the results of these studies suggest that inhibition of neutrophil activity and enhanced antioxidant capability may be important contributors to delayed APC.

In summary, evidence accumulated over the past 10 years indicates remote exposure to a volatile anesthetic before prolonged ischemia and reperfusion protects against myocardial infarction. The mechanisms responsible for this late APC are very similar to those reported for delayed IPC. NO and ROS trigger synthesis of several proteins, including iNOS, COX-2, 12-lipoxygenase, caveolin-3, and GLUT-4, through the concerted actions of NF-κB, HIF-1α, and CREB. These newly synthesized proteins produce several crucial mediators of late APC, including NO, PGE_2 and I_2, and 12-HETE; contribute to caveolae formation; and enhance anaerobic metabolism (Box 28-1). In addition, late APC also inhibits the activity of neutrophils during early reperfusion through modulation of adhesion molecule expression. Sustained myocardial and mitochondrial proteome remodeling involving proteins related to ATP generation and transport has been demonstrated during late APC, suggesting that favorable alterations in bioenergetic balance may represent yet another mechanism by which delayed APC produces antiischemic effects.[217,218] Notably, the beneficial actions of delayed APC are attenuated in a model of chronic myocardial infarction, but whether other cardiac diseases adversely affect this process is currently unknown. Volatile anesthetics may have the potential to produce

delayed myocardial protection in patients at risk for ischemic injury, but the potential clinical applicability of late APC remains to be determined.

Postconditioning. Reperfusion after coronary artery occlusion is a double-edged sword—it is obviously required to salvage ischemic myocardium, but it also contributes to further injury.[115,219] Buckberg and colleagues first suggested that modification of reperfusion conditions favorably reduces the injury that occurs when coronary blood flow is restored. For example, selective low-pressure (40 to 50 mm Hg) reperfusion before full restoration of coronary blood flow reduced infarct size, enhanced LV systolic function, and mitigated myocardial tissue edema compared with abrupt reperfusion. Similarly, elimination of compensatory increases in blood flow resulting from coronary vasodilation after ischemia (reactive hyperemia) during early reperfusion maintained myocardial metabolism, reduced intracellular Ca^{2+} accumulation, and improved regional wall motion compared with conventional reperfusion. Gradual reperfusion of the ischemic territory during the first 30 minutes after prolonged coronary occlusion also preserved endothelial function in vitro. Thus, "gentle" or "staged" control of coronary blood flow during early reperfusion was shown to be important in preserving myocardial integrity and function after an ischemic episode. Nevertheless, these interesting observations were largely ignored because preconditioning, and not events occurring at the onset of reperfusion, was the primary focus of experimental and clinical research in myocardial protection during the late 1980s and 1990s. However, it is quite clear that coronary artery occlusion cannot be temporally predicted in the vast majority of patients with acute myocardial ischemia or infarction to any degree of certainty. As a result, application of preconditioning is limited primarily to conditions in which the onset of ischemia can be precisely determined. Inflation of an angioplasty balloon during cardiac catheterization, aortic cross clamp application during cardiopulmonary bypass, and temporary coronary artery occlusion for anastomosis during off-pump coronary artery bypass grafting (OP-CAB) are notable examples of clinical situations in which myocardial ischemia occurs in a predictable fashion. Under such circumstances, preconditioning strategies may be both clinically relevant and genuinely applicable.

The conditions during which reperfusion conditions may be altered to favorably reduce myocardial injury were reexamined in 2003.[220] In this seminal work, a series of brief (30-second) episodes of coronary artery occlusion interspersed with 30-second periods of complete reperfusion were used before coronary blood flow was fully reestablished in a canine model. This brief, repetitive occlusion-reperfusion technique (often termed "stuttering" reperfusion) reduced infarct size, decreased neutrophil accumulation, blunted ROS production, partially preserved endothelial function, and inhibited apoptosis.[220,221] The reductions in myocardial injury caused by this ischemic postconditioning (IPostC) phenomenon were very similar to those produced by IPC.[220] ERK1/2 activation and NO formation were initially shown to mediate IPostC.[220,222] Subsequently, PI3K-Akt signaling also was implicated, including the downstream enzymes eNOS and mammalian target of rapamycin 70-kDa ribosomal protein s6 kinase (mTOR/p70s6K).[223,224] The PI3K cascade modulates cellular necrosis and apoptosis by influencing the balance of proapoptotic and antiapoptotic proteins, the activity of the regulatory enzyme glycogen synthase kinase-3β (GSK-3β), and the transition state of mPTP[97,157] (Fig. 28-12). A large number of other studies demonstrated that administration of G protein–coupled receptor ligands (e.g., adenosine, bradykinin, opioid), insulin, statins, and growth factors immediately before or during early reperfusion mimicked the beneficial actions of IPostC. Many components of prosurvival signaling implicated in IPostC were shown to mediate this pharmacologic postconditioning.[78,225] Activation of the RISK pathway[78] by IPostC also occurred in a model of postinfarction ventricular hypertrophy,[226] suggesting that this phenomenon may be preserved in the presence of cardiac disease. Clinical evidence of IPostC was further demonstrated, because brief repetitive balloon inflation and deflation performed during coronary angioplasty preserved myocardial integrity and function in patients with acute myocardial infarction.[227] Furthermore, peak creatine kinase release was lower in patients with acute coronary syndrome who received four or more balloon inflations during angioplasty compared with those treated with one to three inflations.[228] These findings suggested that relief of sustained ischemia by stuttering reperfusion protected against permanent myocardial damage. Similarly, IPostC improved coronary artery blood flow velocity after final reperfusion, mitigated cellular necrosis, enhanced regional LV systolic function 8 weeks after intervention, and stimulated recovery of endothelial-dependent vasoreactivity compared with conventional reperfusion.[229,230] Since its initial description 10 years ago, IPostC has attracted intense interest because reperfusion is a controllable event in many patients with acute coronary syndrome.

Volatile anesthetics are capable of exerting protective effects when administered immediately before or during reperfusion. Halothane prevented hypercontracture of cardiac myocytes during reoxygenation after hypoxia and also reduced reperfusion injury after regional myocardial ischemia in rabbit hearts. Isoflurane enhanced the functional recovery of stunned myocardium, and desflurane and sevoflurane reduced infarct size, associated with brief and prolonged ischemia, respectively, when the volatile anesthetics were administered solely during reperfusion. Administration of sevoflurane after ischemia also improved contractile function, metabolism, and Ca^{2+} loading in guinea pig hearts.[231] Halothane abolished reoxygenation-induced attenuation of sarcoplasmic reticulum–dependent oscillations of Ca^{2+} concentration in cardiac myocytes, suggesting that volatile anesthetics may prevent intracellular Ca^{2+} overload during early reperfusion. Additionally, isoflurane and sevoflurane reduced postischemic adhesion of neutrophils to reduce Ca^{2+} overload or attenuate the deleterious effects of neutrophils during early reperfusion.

Isoflurane (1.0 MAC) administered during the final 3 minutes of coronary artery occlusion and the first 2 minutes of reperfusion was shown to reduce myocardial

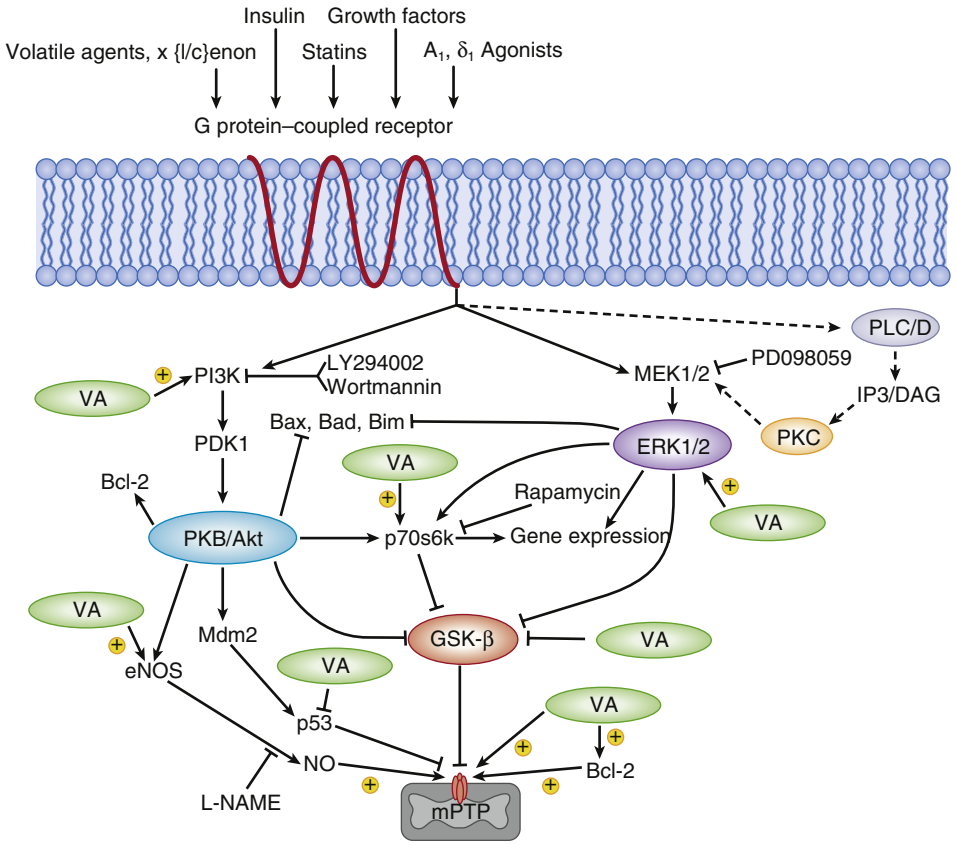

Figure 28-12. Schematic illustration depicting the potential sites of action of volatile anesthetics *(VA)* on myocardial protective signaling during early reperfusion. G protein–coupled receptor ligands (e.g., adenosine A_1, opioid δ_1), VA, insulin, statins, and growth factors activate parallel phosphoinositol-3-kinase *(PI3K)* or extracellular signal–regulated kinase *(ERK1/2)* cascades to produce protection. G protein–coupled activation of protein kinase C *(PKC)* by phospholipases *(PLC/D)* through the second messengers diacylglycerol *(DAG)* and inositol triphosphate *(IP3)* also contributes to activation of PI3K and ERK1/2. PI3K phosphorylates phosphoinositide-dependent kinase *(PDK1)*, which activates Akt (also known as protein kinase B *[PKB]*). This moiety stimulates the activity of antiapoptotic proteins (e.g., B-cell lymphoma-2 *[Bcl-2]*) and simultaneously inhibits activity of proapoptotic proteins (e.g., *Bax, Bad, Bim,* caspases). Akt/PKB also inhibits the β-isoform of glycogen synthase kinase *(GSK-β)* and activates endothelial nitric oxide synthase *(eNOS)*, 70-kDa ribosomal protein s6 kinase *(p70s6K)*, and murine double minute 2 *(Mdm2)* protein. p70s6K also inhibits GSK-β activity. Nitric oxide *(NO)* produced by eNOS inhibits whereas Mdm2-induced phosphorylation of the proapoptotic protein p53 opens the mitochondrial permeability transition pore *(mPTP)*. Inhibition of GSK-β and activation of mitochondrial K_{ATP} channels also act to close mPTP. The transition state of the mitochondrial pore is critical for the preservation of mitochondrial integrity and cell viability during ischemia and reperfusion. Activation of ERK1/2 also inhibits GSK-β and blocks the formation of proapoptotic proteins. LY294002 and wortmannin, rapamycin, PD 098059, and L-arginine methyl ester *(L-NAME)* block the activity of PI3K, p70s6K, ERK1/2, and eNOS, respectively. Volatile anesthetics have been proposed to enhance the activity of PI3K-Akt, p70s6k, ERK1/2, and eNOS. Volatile anesthetics have also been suggested to directly inhibit GSK-β and mPTP concomitant with enhanced expression of Bcl-2 and inhibition of p53. Volatile anesthetic–induced activation of mitochondrial K_{ATP} channels also inhibits mPTP. These actions of volatile anesthetics may contribute to the cardioprotective effects during early reperfusion.

infarct size in rabbits.[232] This experimental design was used to establish a plasma concentration of isoflurane and thereby create a pharmacologic effect immediately on reperfusion. The reductions in myocardial necrosis observed with this anesthetic postconditioning (APostC) were similar in magnitude to those obtained with IPostC and APC.[39,232] Postconditioning with 0.5 MAC isoflurane (an anesthetic concentration that did not decrease infarct size alone) also reduced the time threshold required for IPostC.[232] A selective PI3K antagonist (wortmannin) abolished the salutary actions of APostC and also blocked isoflurane-induced phosphorylation of the PI3K downstream enzyme Akt (protein kinase B). The data demonstrated that activation of the PI3K signaling pathway was responsible for the protective effects of APostC in vivo. Exposure to equivalent MAC concentrations of isoflurane, sevoflurane, and desflurane before and during early reperfusion were subsequently shown to produce almost identical reductions in myocardial infarct size in mice, indicating that the magnitude of APostC was very similar among modern volatile anesthetics.[233] APostC most likely reduces reperfusion injury by recruiting other endogenous signaling kinases and preventing apoptosis through PI3K.[232] APostC was also shown to be mediated by PI3K-Akt signaling in human atrial myocardium.[234] A central role for PI3K-Akt signaling in APostC was subsequently demonstrated in infarct-remodeled myocardium, suggesting that APostC may be preserved after myocardial infarction[235] (Fig. 28-13).

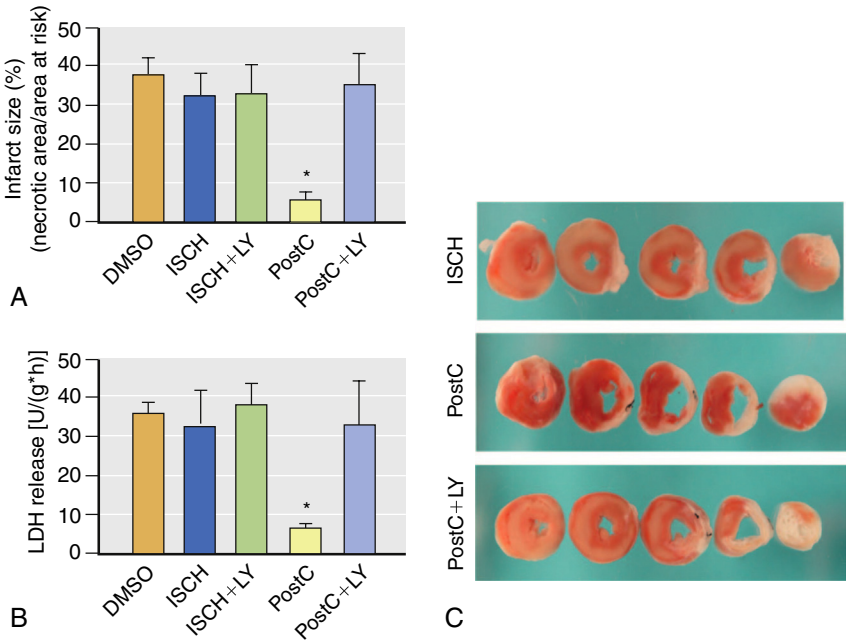

Figure 28-13. Infarct size was determined by using 1% triphenyltetrazolium chloride staining. Areas infarcted in vivo by coronary artery ligation were excluded from infarct size determination (**A**). The scarred chronic infarct *(white)* resulting from coronary ligation was clearly distinguished from fresh infarcts *(salmon pink)*. Release of lactate dehydrogenase (LDH) during reperfusion (**B**) served as an independent method to estimate infarct size. Transverse sections demonstrate representative experiments (**C**). *DMSO,* Dimethyl sulfoxide (< 0.1%; used to dissolve PI3K antagonist LY294002); *IPostC,* ischemic postconditioning; *ISCH,* unprotected remodeled hearts exposed to ischemia-reperfusion alone; *LY,* LY294002 (15 μM); *PostC,* anesthetic postconditioning. Data are mean ± standard deviation (n = 5 in each group). $^{*}P < .05$ versus ISCH. *(From Feng J, Fischer G, Lucchinetti E, et al: Infarct-remodeled myocardium is receptive to protection by isoflurane postconditioning: role of protein kinase B/Akt signaling,* Anesthesiology *104:1004-1014, 2006.)*

Reperfusion may initiate or accelerate apoptosis,[236] an observation that makes attenuation of apoptosis an especially important feature of postconditioning. Selective inhibition of apoptotic signaling by volatile anesthetics was crucial to minimize myocardial damage during early reperfusion. Brief administration of isoflurane immediately before and during early reperfusion reduced cytochrome c translocation from mitochondria (an important early marker of apoptosis) and decreased the number of terminal deoxynucleotidyl transferase–mediated dUTP nick end labeling (TUNEL [another index of apoptosis])-positive ventricular myocytes in situ.[237] Isoflurane-induced PI3K activation also protected atrial and ventricular myocytes against apoptosis in models of oxidative stress.[93] Enhanced expression of Bcl-2 also was observed. Furthermore, volatile anesthetics abolished norepinephrine-induced apoptosis in ventricular myocytes (e.g., reductions in TUNEL-positive cell staining, attenuation of annexin V staining [an index of DNA laddering], and inhibition of caspase-9 activity).[238] More recently, APostC was shown to prevent activation of caspase-3 and caspace-9 by phosphorylation of antiapoptotic signaling proteins, including Akt, after ischemia-reperfusion injury.[239] Thus, volatile anesthetics have been shown to attenuate apoptosis associated with many forms of severe myocardial stress.

G protein–coupled receptor-mediated activation of PI3K and ERK1/2 signaling during several forms of postconditioning, including APostC, was recently emphasized.[237] For example, opioid-induced postconditioning was mediated by activation of δ_1-opioid receptors, PI3K-mediated signaling, and mitochondrial K_{ATP}.[240,241] Similar to the findings observed during opioid-induced preconditioning, morphine (when administered in a dose that does not affect infarct size alone) lowered the threshold of APostC by isoflurane in rabbits.[237] The protective effects were abolished by pretreatment with a selective PI3K antagonist and naloxone, indication that PI3K and G protein–coupled opioid receptors were required for APostC and its augmentation by morphine. Like PI3K, ERK1/2 also stimulates prosurvival signaling to favorably affect reperfusion injury.[78] ERK1/2 mediated ischemic[222] and pharmacologic postconditioning in vivo.[242] For example, activation of ERK1/2 during IPostC reduced infarct size in rabbit hearts.[243] Administration of G protein–coupled receptor ligands, including an adenosine A_1/A_2 agonist and bradykinin, on reperfusion decreased necrosis concomitant with phosphorylation of Erk1/2. These actions were blocked by pretreatment with a selective MEK-1 inhibitor.[242] Another A_1/A_2 receptor agonist also exerted protective effects during reperfusion through an ERK1/2-mediated mechanism.[244,245] Reductions in infarct size produced by APostC were abolished by pretreatment with a selective MEK-1 inhibitor in rabbit[246] and human myocardium.[247]

Both PI3K-Akt and ERK1/2 phosphorylate and activate mTOR and its target p70s6K. The latter enzyme is an important regulator of protein translation and a key inhibitor of GSK-3β. [248] A selective mTOR inhibitor abolished myocardial protection during IPostC.[223] mTOR/p70s6K was also implicated in pharmacologic postconditioning, because reductions in infarct size produced by administration of morphine or a δ_1-selective opioid agonist during early reperfusion were blocked by an mTOR inhibitor.[240] mTOR/p70s6K mediated the beneficial effects of an A_1/A_2 agonist[249] and insulin[250] during reperfusion. Similarly, isoflurane-induced APostC was mediated by mTOR/p70s6K in rabbits.[246] In addition, a selective PI3K inhibitor abolished isoflurane-induced phosphorylation of mTOR/p70s6K in infarct-remodeled rat myocardium when the volatile anesthetic was administered during the first 15 minutes of reperfusion.[235] These data suggested that APostC may retain its salutary actions in diseased myocardium through activation of the PI3K-Akt-mTOR/p70s6K axis. A role for mTOR was subsequently also implicated in APC.[84]

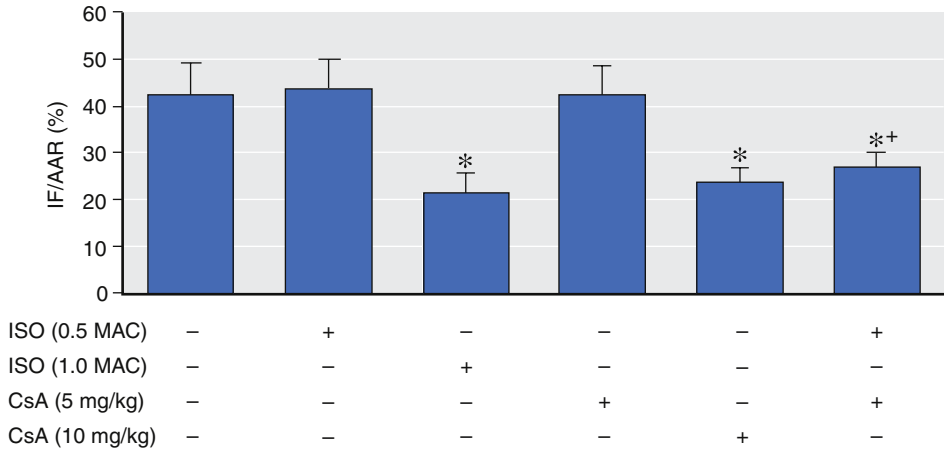

Figure 28-14. Histograms illustrating infarct size *(IF)* presented as a percentage of left ventricular area at risk *(AAR)* in rabbits in the presence (+) or absence (–) of postconditioning with isoflurane (*ISO;* 0.5 or 1.0 minimum alveolar concentration [MAC]) or the mPTP inhibitor cyclosporin A (*CsA;* 5 or 10 mg/kg). Isoflurane (1.0 but not 0.5 MAC) and cyclosporin A (10 but not 5 mg/kg) reduced infarct size compared with control. The combination of subthreshold doses of isoflurane (0.5 MAC) and cyclosporin A (5 mg/kg) also reduced infarct size to an equivalent degree as 1.0 MAC isoflurane and 10 mg/kg cyclosporin A. Data are mean ± standard deviation. *(From Pagel PS: Postconditioning by volatile anesthetics: salvaging ischemic myocardium at reperfusion by activation of prosurvival signaling,* J Cardiothorac Vase Anesth *22:753-765, 2008.)*

Other signaling molecules have been implicated in APostC. PI3K-Akt activates eNOS and thereby increases NO formation. A central role for eNOS-derived NO has been demonstrated in IPostC.[220,223] A nonselective NOS inhibitor *N*-nitro-L-arginine methyl ester, but not selective inducible or neuronal NOS antagonists, abolished reductions in infarct size produced by the administration of isoflurane before and during early reperfusion, suggesting that eNOS mediates APostC.[246] Thus, administration of isoflurane during early reperfusion enhanced the protective effect of IPostC through an NO-dependent mechanism. The eNOS-dependence of APostC was subsequently confirmed in knockout mice.[251] APostC also increased eNOS expression through PI3K in infarct-remodeled myocardium.[235] Thus, NO generated by eNOS mediated APostC through PI3K activation. NO is an important regulator of apoptosis, preserves ERK1/2 activity, nitrosates and inactivates several caspases, and blocks metabolism of Bcl-2. These actions combine to prevent mitochondrial disruption and cytochrome c release through inhibition of mPTP formation. These proposed intracellular actions of eNOS-derived NO were also implicated in APostC.[251]

mPTP opening is reperfusion-dependent, and inhibition of this process mediates IPostC.[103,252] IPostC and a cyclosporin A analogue reduced infarct size and decreased the quantity of Ca^{2+} loading necessary to open the mPTP to equivalent degrees in intact hearts and isolated mitochondria, respectively. Not surprisingly, a role for mPTP inhibition has been demonstrated during APostC. The mPTP opener atractyloside abolished, whereas cyclosporin A enhanced, decreases in myocardial necrosis produced by brief administration of isoflurane immediately before and during early reperfusion in rabbits[253] (Fig. 28-14). Atractyloside and a selective PI3K antagonist also abolished APostC in rats.[254] A PI3K inhibitor blocked phosphorylation of Akt and GSK-3β and opened mPTP, thereby demonstrating a critical link between prosurvival signaling and mPTP conformation during APostC.[254] APostC inhibited mitochondrial permeability transition, preserved $\Delta\Psi_m$, and maintained ATP synthesis during reperfusion by attenuating respiration, reducing pH, and causing depolarization of mitochondria.[255]

Mitochondrial K_{ATP} opening is also a postulated end-effector of APostC.[253,256] As described previously, volatile anesthetics either directly open mitochondrial K_{ATP} or prime their opening in response to other signaling molecules. Mitochondrial K_{ATP} opening during IPC alters intramitochondrial homeostasis and protects against subsequent ischemic damage by regulating matrix volume through an mPTP-dependent mechanism.[257] Mitochondrial K^+ influx through mitochondrial K_{ATP} also favorably regulated matrix volume and enhanced mitochondrial function during simulated ischemia and reperfusion.[258] A selective mitochondrial K_{ATP} antagonist inhibited APostC produced by isoflurane or sevoflurane.[253,256] A similar effect was observed in human atrial myocardium exposed to desflurane APostC in vitro.[247] A close interaction between mitochondrial K_{ATP} and mPTP was previously identified during APC.[108] The finding that reductions in cyclosporin A–induced decreases in myocardial infarct size were abolished by 5-HD pretreatment emphasized this interaction.[253] Adenine nucleotide translocase (a component of mPTP) was also shown to mediate H^+ and K^+ ion flux to the mitochondrial matrix produced by mitochondrial K_{ATP} openers. Thus, the effects of volatile agents on mitochondrial K_{ATP} may not be solely responsible for APostC, but may be dependent on an interaction between mitochondrial K_{ATP} opening and mPTP inhibition.

GSK-3β is a crucial regulator of cellular function. Activation of GSK-3β was implicated in the pathogenesis of diabetes mellitus and Alzheimer disease, whereas inhibition of the enzyme plays a key role in myocardial protection.[259,260] Reductions in infarct size during IPC were associated with inactivation of GSK-3β through a PI3K-dependent mechanism.[259] Inactivation of GSK-3β by PI3K also stimulated angiogenic and antiapoptotic signaling through the induction of VEGF, Bcl-2, and surviving during IPC.[261] GSK-3β inhibition also mediated the protective effects of opioids[240,262] and adenosine[260] administered either before ischemia or during early reperfusion.

Chronic hyperglycemia[263] and estrogen deficiency associated with age attenuated myocardial protection produced by PI3K-mediated GSK-3β inactivation associated with aging,[264] suggesting a mechanism by which diabetes mellitus and postmenopausal reductions in estrogen concentration may be associated with a reduced myocardial tolerance to ischemic events. GSK-3β was shown to be not only an important target of several prosurvival signaling enzymes but also a central regulator of mPTP formation.[248] Thus, it appears that several redundant signaling pathways converge on and reduce the activity of GSK-3β, thereby preventing mPTP opening and producing protection against reperfusion injury.[265] Administration of isoflurane during the first 15 minutes of reperfusion inactivated GSK-3β concomitant with reductions in myocardial infarct size in isolated hearts.[254] These actions were abolished by pretreatment with a selective PI3K antagonist. In contrast, the mPTP opener atractyloside failed to block isoflurane-induced phosphorylation of PI3K and GSK-3β, but the drug did abolish reductions in infarct size through its direct actions on the mPTP. Isoflurane preserved mitochondrial function as indicated by accumulation of a mitochondrial-specific probe, and this action was also blocked by atractyloside pretreatment. Thus, APostC protects against reperfusion injury in normal myocardium by preventing mPTP opening through GSK-3β inhibition.[254] Similar results were also reported in infarct-remodeled myocardium.[235] A selective inhibitor of GSK-3β lowered the threshold of APostC.[266] The beneficial effects of GSK-3β inhibition and its augmentation by isoflurane were inhibited by atractyloside but not the PI3K or mTOR/p70s6K antagonists. Thus, volatile anesthetics may also produce a direct inhibitory effect on GSK-3β independent of their actions on PI3K and mTOR/p70s6K activity to cause APostC. Interestingly, the serine protease inhibitor and antifibrinolytic drug aprotinin was shown to abolish APostC through a GSK-3β–mediated mechanism in isolated hearts.[267]

The mechanisms by which APostC inhibits GSK-3β to prevent mPTP opening and to cause protection during early reperfusion are unknown. Activated GSK-3β binds to and promotes the actions of p53, and this tumor suppressor protein subsequently causes mitochondrial disruption during apoptosis. Activated p53 translocates to mitochondria and opens the mPTP through an interaction with the apoptotic protein Bax, thereby abolishing $\Delta\Psi_m$ and causing the release of cytochrome c. Inhibition of p53 appears to play an important role in myocardial and neuronal protection against cellular injury. Hypoxia and ROS activated p53, which then stimulated apoptotic signaling,[268] enhanced transcription of other apoptotic proteins,[269] and caused cell death. IPC attenuated the increase in p53 expression that is typically observed after ischemia and reperfusion in isolated ventricular myocytes.[270] IPC also blunted p53 transcription and translation in hippocampal pyramidal neurons in a model of global forebrain ischemia and reperfusion. Inhibition of p53 using a selective antagonist or augmented degradation of the protein by the regulatory murine double minute 2 protein (Mdm2; an oncogenic factor[271]) protected against ischemic injury in isolated hearts.[272] Phosphorylated Mdm2 binds to and inactivates p53 by blocking its active site and promoting its degradation through formation of a ubiquitin complex.[273] These data suggested that IPC blocks the detrimental effects of p53 through PI3K-Mdm2 signaling.[272] A selective antagonist of p53 protected against ischemia-induced neuronal cell death.[274] Targeted deletion of p53 also prevented cardiac rupture after infarction in transgenic mice. This salutary effect most likely occurred because the protective effects of IPC were simulated by inhibition of p53-mediated apoptosis.[275]

Inhibition of p53 enhanced the beneficial actions of APostC in rabbits. Administration of a dose of a selective p53 inhibitor that did not affect the magnitude of irreversible ischemic injury alone lowered the threshold concentration of isoflurane required to cause APostC.[276] Atractyloside blocked this beneficial effect, suggesting that the myocardial protection was mediated by the combined actions of the selective p53 inhibitor and the volatile anesthetic on mPTP. Thus, APostC may favorably modulate the interaction between GSK-3β and p53 to prevent mPTP opening and thereby preserve myocardial integrity. A PI3K inhibitor also blocked decreases in infarct size produced by a combination of subthreshold doses of the p53 inhibitor and isoflurane, demonstrating that this phenomenon was PI3K-dependent. This process may depend on activation of Akt by isoflurane,[232] which leads to Mdm2 phosphorylation and subsequent inactivation and degradation of p53. Such an action may effectively prevent the latter protein's deleterious interaction with GSK-3β. IPC activated Mdm2 and enhanced phospho-Mdm2-p53 binding in a PI3K-dependent manner,[272] but whether APostC specifically causes a similar phospho-Mdm2-p53 interaction is unknown.

The effects of APostC on another important regulator of apoptosis during reperfusion were described.[93,277] The Bcl-2 protein is located in the outer mitochondrial membrane, regulates the transition state of mPTP, and has been implicated in myocardial protection against ischemia-reperfusion injury.[278] Bcl-2 reduced damage associated with ischemia by preventing mitochondrial cytochrome c release, attenuating intracellular Ca^{2+} overload, and preserving endoplasmic reticulum integrity. IPC also reduced apoptosis by up-regulating Bcl-2 expression in isolated hearts. Intermittent hypoxia mitigated reperfusion-induced apoptosis by favorably influencing the balance of Bcl-2 to Bax in ventricular myocytes.[279] Overexpression of Bcl-2 in transgenic mice attenuated apoptosis and protected against myocardial ischemia-reperfusion injury.[280] An interaction between Bcl-2 and mPTP closure was also postulated during delayed IPC.[107] A selective Bcl-2 inhibitor blocked increases in Bcl-2 expression and attenuated reductions in apoptosis produced by isoflurane in isolated myocytes subjected to cellular stress.[93] Furthermore, a Bcl-2 inhibitor blocked APostC and IPostC, but not cyclosporin A–induced myocardial protection in rabbits.[277] These results suggested that the salutary actions of APostC also may occur because the mPTP is maintained in its closed conformation by Bcl-2.[277] PI3K is known to phosphorylate and activate Bcl-2 in concert with inactivation of Bad, Bax, and p53. Thus, activation of PI3K signaling by APostC most likely produces favorable changes in apoptotic protein homeostasis to promote myocardial protection.

In summary, volatile anesthetics cause myocardial protection when exclusively administered immediately before or during early reperfusion after ischemia. The mechanisms responsible for APostC share many similarities with those recognized for APC. Research data collected to date emphasize that APostC activates many prosurvival proteins downstream from PI3K and ERK1/2 that favorably modulate mPTP. APostC also protects against apoptosis by shifting the balance between proapoptotic and antiapoptotic proteins. APostC will most likely protect the human heart from reperfusion injury in vivo because this process has been shown to occur in isolated human myocardium in the laboratory[234,247] and because IPostC has already been shown to do so in patients with acute myocardial infarction.[227] Notably, APostC most certainly has the potential to provide myocardial protection in clinical situations in which reperfusion is a predictable event.

Coronary Vascular Effects in Humans

Evaluation of the actions of volatile anesthetics on the human coronary circulation is difficult not only because the methods used to determine coronary blood flow in humans are limited but also because the interpretation of clinical findings during anesthesia are complicated by changes in hemodynamics, the impact of surgery, and the use of adjuvant anesthetics or vasoactive drugs. Halothane decreased MVo_2 and variably altered coronary blood flow in patients with coronary artery disease, but metabolic or electrocardiographic evidence of ischemia has not been observed during halothane anesthesia. A report published in 1983[281] described the occurrence of myocardial ischemia as indicated by new electrocardiographic changes and abnormal myocardial lactate extraction in 10 of 21 patients anesthetized with isoflurane undergoing major vascular surgery. Five patients were treated with phenylephrine and pacing to return arterial pressure and heart rate to control values, and after these interventions, electrocardiographic and metabolic derangements resolved in 2 of the 5 patients. Despite the apparent dependence of these new episodes of myocardial ischemia on alterations in systemic hemodynamics, the authors proposed that isoflurane had caused coronary steal in these patients, even though no specific evidence of blood flow redistribution between normal and collateral-dependent zones was presented. The data have not been uniformly supported by subsequent studies. Coronary blood flow remained unchanged during isoflurane anesthesia in patients undergoing coronary artery bypass graft surgery, but coronary sinus O_2 content increased consistent with modest coronary vasodilation. Isoflurane alone did not produce electrocardiographic or metabolic evidence of ischemia. Instead, myocardial ischemia occurring during isoflurane anesthesia was most often associated with tachycardia or hypotension. In addition, isoflurane actually increases the tolerance to pacing-induced ischemia in patients with coronary artery disease. Comparisons of studies examining the effects of isoflurane on the incidence of intraoperative myocardial ischemia were also complicated by differences in patient age, surgical procedure, operative time, and preoperative LV ejection fraction. Importantly, compelling evidence demonstrating redistribution of coronary blood flow away from ischemic to normal myocardium in humans anesthetized with isoflurane has yet to be reported.

The incidence of intraoperative myocardial ischemia in susceptible patients has been difficult to define. Less than 50% of intraoperative ischemic episodes have been linked to alterations in systemic hemodynamics.[282] The strongest predictor of intraoperative ischemia remains preexisting ischemia on arrival to the operating room and not anesthetic technique.[283] The only hemodynamic event definitively related to intraoperative ischemia in patients undergoing CABG surgery is tachycardia.[283] Perioperative use of β_1-adrenoceptor antagonists to prevent myocardial ischemia strongly supports this contention. Sternotomy caused greater increases in calculated indices of MVo_2, myocardial lactate production, and the incidence of hypertension requiring treatment with vasoactive drugs during morphine compared with halothane anesthesia. In contrast, induction of anesthesia with desflurane in patients undergoing CABG surgery may be associated with tachycardia, hypertension, and a greater incidence of ischemia than occurring during induction with sufentanil. Steal-prone anatomy was identified in 23% of patients with coronary artery disease, but patients with steal-prone coronary anatomy did not have a greater incidence of ischemia during desflurane anesthesia than with other forms of coronary artery disease. The incidence of myocardial ischemia and adverse cardiac outcomes has been shown to be similar in patients with cardiac disease undergoing noncardiac surgery during sevoflurane versus isoflurane anesthesia. New electrocardiographic changes, incidence of postoperative myocardial infarction, and mortality were similar in patients undergoing CABG surgery independent of anesthetic technique or the presence of steal-prone anatomy. Thus, despite the findings that volatile anesthetics are mild coronary vasodilators, these medications did not cause abnormal redistribution of myocardial perfusion resulting in ischemia when tachycardia and hypotension were avoided in patients with coronary artery disease.

Myocardial Protection in Humans

Volatile anesthetics protect human myocardium against ischemia-reperfusion or hypoxia-reoxygenation in vitro[40,42] through mechanisms that bear striking similarity to those described in experimental animals. However, whether laboratory data in isolated human myocardium may be translated into meaningful improvements in clinical outcome in patients at risk for myocardial ischemia remains open to question. In 1999, two groups independently suggested that volatile anesthetics had the potential to produce myocardial protection in cardiac surgical patients. Penta de Peppo and associates[284] reported that administration of enflurane (0.5% to 2.0%) before cardioplegic arrest enhanced postischemic functional recovery of contractility measured using LV pressure-area relations in 22 patients undergoing elective CABG.[284] Belhomme and colleagues[285] demonstrated that brief, 5-minute exposure to 2.5 MAC isoflurane during cardiopulmonary bypass (before aortic cross clamping; analogous to APC) reduced postoperative release of troponin I and the myocardial form of creatine kinase (CK-MB) in 20 patients undergoing CABG. The results of these two small clinical trials suggested that APC with

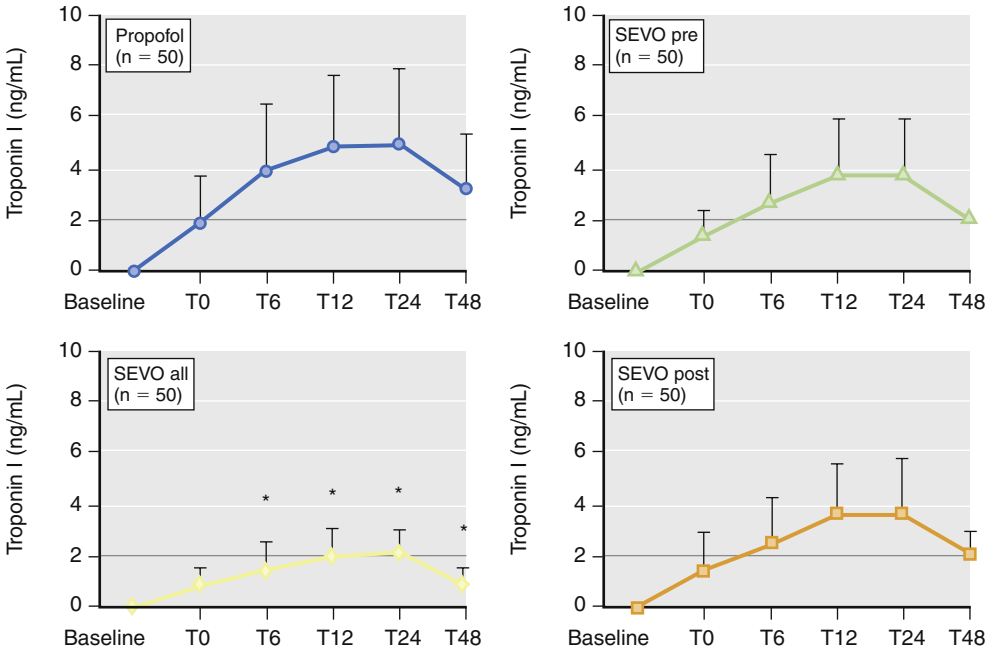

Figure 28-15. Cardiac troponin I concentrations observed in the four groups before surgery (baseline), at arrival in the intensive care unit *(T0)*, and after 6 *(T6)*, 12 *(T12)*, 24 *(T24)*, and 48 *(T48)* hours. Data are presented as mean ± standard deviation (SD). *Statistically significant difference with the propofol group ($P < .05$). In all groups, a transient increase in troponin I concentrations was observed. Only in the SEVO all group was this increase significantly less than in the propofol group. For the sake of clarity, the SD bars are represented in only one direction. *(From De Hert SG, ten Broecke PW, Mertens E, et al: Sevoflurane but not propofol preserves myocardial function in coronary surgery patients,* Anesthesiology *97:42-49, 2002.)*

enflurane or isoflurane may enhance contractile function after and decrease myocardial necrosis associated with cardiopulmonary bypass in patients with coronary artery disease.[284,285] These initial observations were extended by the findings of two subsequent studies in which sevoflurane or desflurane compared with propofol preserved myocardial function in patients undergoing CABG with or without preexisting LV dysfunction concomitant with a reduction in troponin I release.[286,287] Another study indicated that sevoflurane maintains postoperative LV myocardial contractility (as assessed using the maximum rate of increase of LV pressure; +dP/dt) and decreases plasma troponin I concentrations during the first 36 hours after surgery in contrast to a propofol-based anesthetic in patients with severe aortic valve stenosis (aortic valve area of 0.6 to 0.7 cm^2) undergoing aortic valve replacement.[288] The incidence of atrial fibrillation early after CABG also may be reduced by sevoflurane compared with propofol or midazolam.[289] Release of inflammatory mediators (interleukin-6 [IL-6], neutrophil integrins, and tumor necrosis factor-α [TNF-α]) was decreased and myocardial function (LV stroke work index) was preserved in patients undergoing CABG receiving sevoflurane compared with total intravenous anesthesia consisting of propofol, midazolam, and fentanyl.[290] Troponin I release was also less pronounced when sevoflurane or isoflurane was used as the primary anesthetic compared with propofol in patients undergoing CABG.[291] Notably, volatile or intravenous anesthetics were administered continuously throughout the operation in each of these studies, and a preconditioning technique per se was not examined. Thus, the salutary effects of sevoflurane or desflurane observed in these investigations may have been due, at least in part, to favorable alterations in the determinants of myocardial O_2 supply-demand relationships produced by the volatile anesthetic.

Myocardial protection associated with differing approaches to sevoflurane administration were examined and compared in 200 patients undergoing CABG.[292] As in the previously described investigations, two groups of patients received either propofol or sevoflurane throughout surgery, but in this trial, two additional groups also received sevoflurane either before cardiopulmonary bypass alone or solely after construction of coronary anastomoses to mimic the effects of APC and APostC, respectively (Fig. 28-15). Sevoflurane significantly reduced troponin I release and decreased intensive care unit and hospital length of stay only when the volatile anesthetic was administered throughout the operation and not when preconditioning or postconditioning methods of administration were used.[292] Nevertheless, other investigators have suggested that APC may occur in patients undergoing CABG. For example, Meco and associates[293] used a preconditioning protocol in which 28 patients undergoing CABG were exposed to 2.5 MAC desflurane or placebo for 5 minutes followed by a 10-minute washout period before aortic cross clamping and cardioplegic arrest. This desflurane APC reduced postoperative troponin I and N-terminal pro-brain natriuretic peptide (NT-proBNP; a biochemical marker of global LV contractility) release and also enhanced LV function assessed using mitral valve annulus tissue Doppler imaging. Inhalation of 4% sevoflurane for the first 10 minutes of cardiopulmonary bypass in 18 patients undergoing CABG during baseline propofol-opioid anesthesia reduced postoperative release of NT-proBNP compared with a control cohort (Fig. 28-16). These findings occurred concomitant with activation and translocation of PKC-δ and PKC-ε in atrial myocardial biopsies that had been obtained during cannulation[294] (Fig. 28-17). Similar translocation of PKC isoforms was previously demonstrated in experimental models of APC.[20,70] However, no differences in ST-segment changes, troponin T or CK-MB release, or arrhythmias were observed between groups in this study.[294] In contrast to the previous findings,[292] administration of sevoflurane before cardiopulmonary

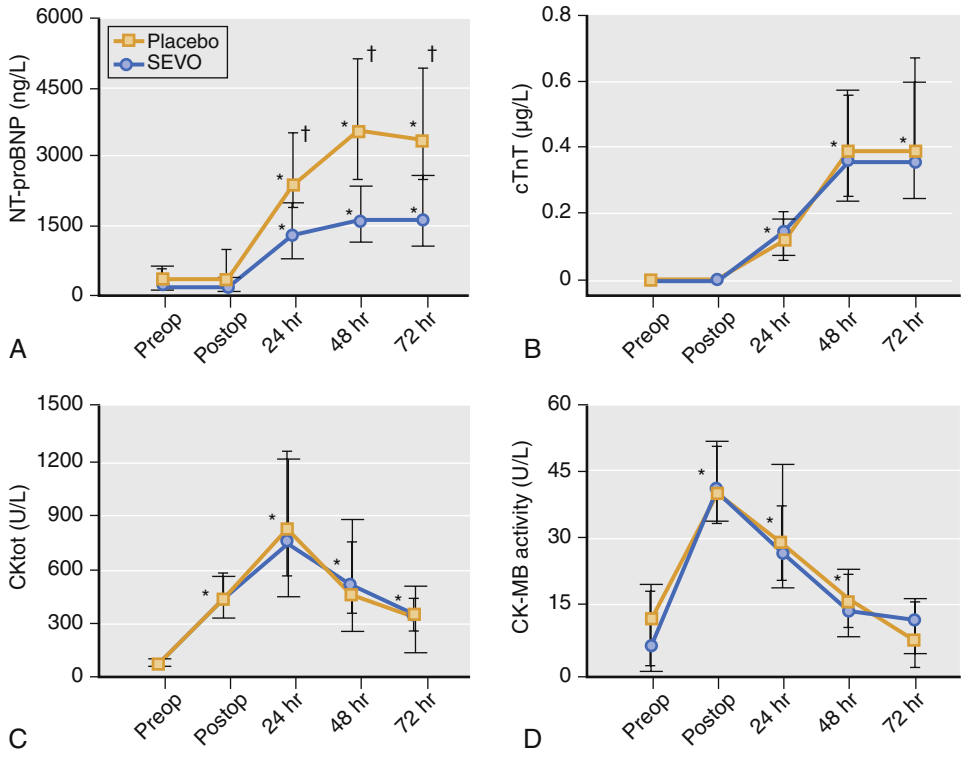

Figure 28-16. Biomarkers of myocardial injury at various time points for the placebo *(PLACEBO)*-treated and sevoflurane *(SEVO)*-treated groups: N-terminal pro-brain natriuretic peptide *(NT-proBP)* (**A**), cardiac troponin T *(cTnT)* (**B**), total creatine kinase *(CKtot)* (**C**), and creatine kinase–myocardial bound *(CK-MB)* isoenzyme activity (**D**). Two-factor repeated-measures analysis of variance indicated that the groups significantly differed in plasma NT-proBNP concentrations (time effect, $P < .001$; group effect, $P < .001$; group-time interaction, $P = .003$). No difference was found for cTnT, CKtot, and CK-MB activity concentrations. Multiple t tests with the Bonferroni correction for multiple comparisons were used to compare the plasma concentrations of the different biomarkers at each time point with the respective preoperative baseline value within groups and to compare plasma concentrations at each time point between groups. *(From Julier K, da Silva R, Garcia C, et al: Preconditioning by sevoflurane decreases biochemical markers for myocardial and renal dysfunction in coronary artery bypass graft surgery: a double-blinded, placebo-controlled multicenter study,* Anesthesiology *98:1315-1327, 2003.)*

bypass alone reduced postoperative myocardial necrosis (troponin T and CK-MB release) and enhanced global LV function (myocardial performance index) compared with continuous administration of sevoflurane or propofol throughout surgery.[295] However, cytokine release and lengths of stay in the intensive care unit and the hospital were similar between groups.[295] Indeed, the specific preconditioning protocol was shown to have an important impact on sevoflurane-induced myocardial protection in patients undergoing CABG. A single 5-minute exposure to 1.0 MAC sevoflurane followed by discontinuation of the volatile anesthetic for 10 minutes before beginning cardiopulmonary bypass did not reduce peak postoperative troponin I concentrations compared with continuous administration of propofol, whereas two cycles of sevoflurane preconditioning significantly attenuated postoperative release of this biochemical marker of myocardial necrosis.[296] Garcia and associates[297] reported their results in 36 CABG patients receiving brief (10-minute) administrations of 4% sevoflurane or placebo during cardiopulmonary bypass.[297] Patients exposed to 4% sevoflurane had reduced platelet-endothelial cell adhesion molecule-1 concentrations (PECAM-1; an important determinant of leukocyte migration through vascular endothelium during ischemia-reperfusion injury) and increased catalase expression in atrial biopsies.[297] Interestingly, late cardiac events during the first year after surgery occurred

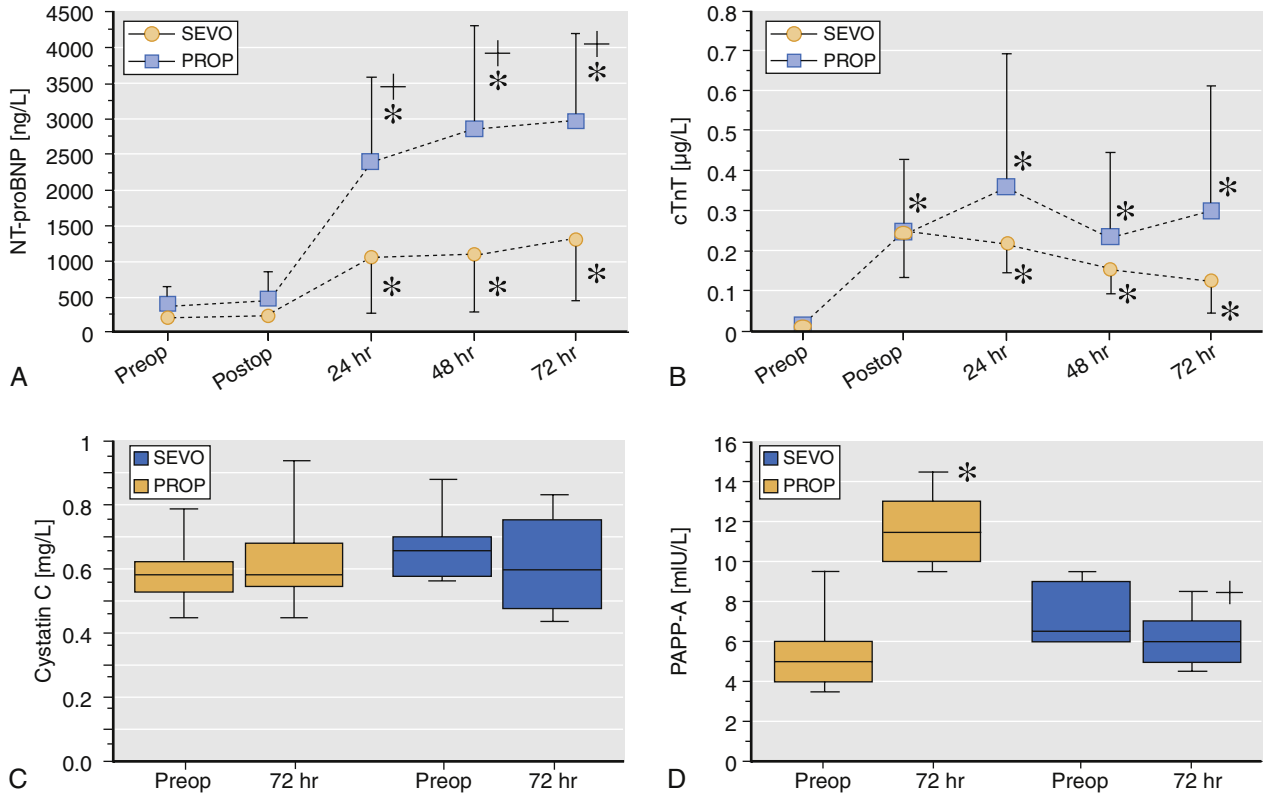

Figure 28-18. Cardiovascular biomarkers. Perioperative levels of N-terminal pro-brain natriuretic peptide (NT-proBNP) were significantly more elevated in the propofol *(PROP)* group compared with the sevoflurane *(SEVO)* group (**A**). No difference between groups was found in cardiac troponin T (**B**) or cystatin (**C**), whereas pregnancy-associated plasma protein A *(PAPP-A)* was exclusively increased postoperatively in the PROP group (**D**). *(From Lucchinetti E, Hofer C, Bestmann L, et al: Gene regulatory control of myocardial energy metabolism predicts postoperative cardiac function in patients undergoing off-pump coronary artery bypass graft surgery: inhalational versus intravenous anesthetics.* Anesthesiology *106:444-457, 2007.)*

significantly less often in sevoflurane-treated patients than in controls (3% versus 17%, respectively; $P = .038$). Patients who suffered late cardiac events also had greater peak troponin T and NT-proBNP concentrations in contrast to those who did not sustain subsequent injury. The data supported the hypothesis that use of a volatile anesthetic in patients at risk for perioperative myocardial ischemia may exert a favorable long-term benefit by reducing the incidence of major adverse cardiac events. Nevertheless, it is essential to recognize that this small study[297] is the only prospective clinical trial conducted to date to specifically demonstrate a long-term cardiovascular benefit associated with administration of a volatile anesthetic to patients undergoing CABG. Finally, Amr and Yassin[298] randomized 45 patients scheduled for elective CABG to receive APC (a 10-minute exposure to 2.5% isoflurane followed by a 5-minute washout) or IPC (three episodes of brief aortic cross clamping interspersed with reperfusion).[298] The authors demonstrated that these protective strategies caused similar improvements in hemodynamics, reductions in postoperative CK-MB and troponin I release, and decreases in inotrope requirements, but patients who did not receive either intervention were not studied in a control group.

The potential for volatile anesthetics to produce myocardial protection in patients undergoing off-pump or minimally invasive direct CABG (OP-CAB or MID-CAB, respectively) has been examined. Transient coronary artery occlusion is often required to construct new vascular anastomoses during these procedures, thereby providing a predictable setting in which ischemia-reperfusion injury may occur in patients who are already at risk for myocardial ischemia because of preexisting flow-limiting coronary stenoses. Postoperative troponin I release was reduced in sevoflurane-treated compared with propofol-treated patients undergoing OP-CAB.[299] Desflurane also reduced troponin I release, use of positive inotropic medications, and the number of patients requiring prolonged hospitalization compared with a propofol-opioid–based anesthetic technique in patients undergoing OP-CAB.[300] Patients anesthetized with sevoflurane undergoing MID-CAB had preserved LV systolic (myocardial performance index) and diastolic (ratio of early-to-late transmitral blood flow velocity; E/A) function in contrast to those receiving propofol anesthesia, but no differences in troponin T and CK-MB release were observed between groups.[301] Postoperative NT-proBNP concentrations were lower and echocardiographically derived indices of LV function were preserved in patients undergoing OP-CAB who were anesthetized with sevoflurane compared with propofol.[302] The plasma concentrations of a biochemical marker of atherosclerotic plaque instability (pregnancy-associated plasma protein A) were also lower in sevoflurane-treated patients compared with those receiving propofol 72 hours after surgery (Fig. 28-18). In addition, sevoflurane-induced

alterations in genetic regulatory control of myocardial energy metabolism appeared to be favorably modified in such a way that postoperative cardiac function may be relatively preserved in OP-CAB patients receiving the volatile anesthetic compared with propofol.[302] Other studies also verified that sevoflurane and isoflurane may be used with equivalent protective efficacy in patients undergoing OP-CAB.[303,304]

Despite the generally compelling nature of the previously mentioned findings, the results of a number of other investigations have failed to show that volatile anesthetics exert any substantial myocardial protection in patients undergoing CABG with or without cardiopulmonary bypass. The effects of sevoflurane-remifentanil and propofol-remifentanil anesthesia adjusted to equivalent bispectral index values on intraoperative hemodynamics and postoperative myocardial necrosis (troponin I and CK-MB release) were examined and compared in two studies of patients undergoing OP-CAB.[305,306] No differences in these end points were observed between groups, although both studies were most likely underpowered to exclude β error from the analysis. Piriou and colleagues[307] randomized 72 patients to receive 1.0 MAC sevoflurane for 15 minutes followed by a 15-minute elimination period before cardiopulmonary bypass or placebo. Sevoflurane APC did not decrease postoperative troponin I release, nor did it affect the activities of several key protein kinases previously implicated in volatile anesthetic–induced myocardial protection, including ecto-5′-nucleotidase, PKC, PTK, and p38 MAPK, which were measured in atrial tissue biopsies. Fewer patients exposed to sevoflurane APC had reduced postoperative cardiac output, but the number of patients requiring inotropic support was similar between groups.[307] In the largest single-center, randomized clinical trial of its kind conducted to date, De Hert and colleagues[308] compared the effects of desflurane, sevoflurane, and propofol-based anesthesia on myocardial necrosis and long-term outcome in 414 patients undergoing CABG using cardiopulmonary bypass.[308] Maximal troponin T release and 1-year mortality were similar between groups, but hospital length of stay was shorter in patients receiving volatile anesthetic compared with total intravenous anesthesia. Postoperative troponin I release, intensive care unit and hospital length of stays, and short-term and long-term morbidity and mortality were also similar in a study of 100 patients undergoing CABG randomized to receive sufentanil with isoflurane or propofol.[309] Interpretation of these results requires qualification because naturally occurring (e.g., morphine) and synthetic opioids (e.g., fentanyl, sufentanil) also may be capable of producing myocardial protection in humans independent of volatile anesthetics or other medications implicated in pharmacologic preconditioning.[310,311] Peak troponin release and 1-year mortality were similar in 100 patients with coronary artery disease receiving continuous sevoflurane compared with propofol anesthesia for mitral valve surgery.[312] These data supported the findings of an earlier study demonstrating that desflurane APC (conducted using a 30-minute exposure before cardiopulmonary bypass) did not exert a selective myocardial protective effect compared with propofol in patients without coronary artery disease undergoing mitral valve surgery.[313]

Three meta-analyses emphasized that use of a volatile anesthetic during cardiac surgery most likely reduces the severity of myocardial necrosis associated with the procedure in contrast to intravenous anesthesia, but whether such a beneficial effect translates into an improvement in long-term clinical outcome was not definitively established. Symons and Myles[314] examined 27 clinical trials including 2979 patients undergoing CABG.[314] Postoperative troponin I release was decreased and cardiac index after cardiopulmonary bypass was greater, whereas the requirement for inotropic medications was diminished in patients receiving volatile compared with intravenous anesthetics, but no differences in the incidence of myocardial ischemia, postoperative myocardial infarction, intensive care unit length of stay, or hospital mortality were observed between groups. Yu and Beattie[315] analyzed 32 studies in which 2841 patients had been enrolled and confirmed that use of a volatile anesthetic during CABG surgery reduces postoperative troponin I release compared with an intravenous anesthetic technique.[315] Despite this observation, these authors were also unable to provide substantial evidence to support the hypothesis that a volatile anesthetic technique is linked to improved clinical outcome. In general, the overall conclusions of these two meta-analyses[314,315] concurred with the results of several large-scale clinical trials documenting the safety of volatile anesthetics compared with opioid-based anesthesia in cardiac surgical patients published more than 2 decades ago[282,283] in response to the isoflurane and coronary steal controversy. These latter studies continue to be vitally important because their results emphasized that anesthetic technique per se is not an important determinant of outcome in the setting of cardiac surgery.

In direct contrast to conclusions drawn by the two previously discussed meta-analyses,[314,315] another meta-analysis of 22 studies with 1922 patients undergoing cardiac surgery suggested that use of volatile anesthetics were, in fact, associated with significant reductions in the incidence of postoperative myocardial infarction (2.4% versus 5.1%; $P = .008$) and mortality (0.4% versus 1.6%; $P = .02$) compared with intravenous anesthesia.[316] The reasons for these divergent conclusions are unclear, especially considering that many of the same original clinical trials were included in all three meta-analyses. Nevertheless, two other studies have provided additional, albeit rather indirect, evidence that use of a volatile anesthetic may be capable of enhancing long-term outcome compared with intravenous anesthetic techniques. A longitudinal, risk-adjusted analysis of 64 Italian cardiac surgery centers examined whether a correlation existed between the use of volatile anesthetics and a decline in 30-day mortality in 34,310 patients undergoing CABG.[317] The authors concluded that use of a volatile anesthetic was weakly but significantly correlated with a decline in 30-day mortality ($r^2 = .07$; $P = .035$). The study's uncontrolled, retrospective design and the statistical methods used to estimate, rather than directly measure, 30-day mortality limited interpretation of the results. Nevertheless, the data suggest that there may be a positive relationship between the use of a volatile anesthetic and perioperative outcome in CABG patients. Similarly, a retrospective study of 10,535 patients also suggested that sevoflurane anesthesia was

associated with lower 30-day mortality in patients who had not suffered a recent myocardial infarction or did not have unstable angina (which mimics the beneficial effects of IPC) compared with a propofol-based anesthetic technique (2.28% versus 3.14%; $P = .015$).[318] However, no differences in 30-day mortality or the incidence of postoperative myocardial infarction were observed between groups when the entire cohort was examined as a whole.

Collectively, the results of these clinical trials and meta-analyses suggest that use of a volatile anesthetic during cardiac surgery may be associated with a reduction in the magnitude of myocardial necrosis and relative preservation of postoperative LV function compared with an intravenous anesthetic technique. Some evidence of clinical myocardial protection using an acute preconditioning strategy has been presented in the literature, but these data are certainly less convincing than the major findings from studies in which a volatile anesthetic was administered continuously throughout cardiac surgery. Whether delayed APC or APostC strategies have beneficial effects in cardiac surgical patients has yet to be examined. Perhaps most notably, few data have been presented to date directly indicating that use of a volatile anesthetic improves short-term or long-term outcome or decreases the incidence of major adverse cardiac events in patients undergoing cardiac or noncardiac surgery. When considered from the latter perspective, the recent American College of Cardiology Foundation and American Heart Association (ACCF/AHA) guidelines advocating the use of volatile anesthetics for myocardial protection in patients at risk for myocardial ischemia, including those undergoing noncardiac surgery,[319] may appear to be somewhat premature.[320,321] Whether such a strict interpretation of the accumulated data is truly valid will now be discussed in further detail.

Several reasons explain why the clearly advantageous protective effects of volatile anesthetics observed in laboratory settings of ischemia-reperfusion injury do not necessarily translate into equally robust clinical benefits.[322] First, volatile anesthetics may substantially alter the determinants of myocardial O_2 supply and demand through their direct and indirect effects on systemic, pulmonary, and coronary hemodynamics and autonomic nervous system activity in a dose-related manner. These changes may reduce myocardial O_2 consumption and ischemic burden under controlled conditions, but such beneficial effects may be offset or overcome in patients who are subjected to the profound stress associated with cardiac surgery and exposure to cardiopulmonary bypass. Most patients undergoing cardiac surgery are elderly and suffer from multiple coexisting diseases (e.g., hypertension, diabetes mellitus, hypercholesterolemia) that may cause abnormal cardiovascular homeostasis. Indeed, age[52] and diabetes[29] have been shown to attenuate or abolish APC in laboratory animals. Cardiac surgical patients are very often chronically treated with a variety of medications to manage their comorbid disease states and, in addition, receive other anesthetics, analgesics, and other vasoactive drugs that may influence the potentially salutary actions of volatile anesthetics during cardiac surgery. Coronary collateral blood flow, a key factor in determining the tolerance of susceptible regions of myocardium to ischemic stress, is relatively easy to quantify in experimental models of ischemia-reperfusion injury, but these alternative routes of myocardial perfusion are highly variable and are quite difficult to quantify in patients with coronary artery disease.

The relative amount of myocardium at risk for ischemic injury is probably the most important explanation why clinical investigations conducted to date have yet to demonstrate that volatile anesthetics favorably affect outcome in patients undergoing cardiac surgery. The intentional production of severe ischemia-reperfusion injury and the observation of its pathologic consequences without any intervention to mitigate them are characteristic features of virtually all laboratory studies. For example, a prolonged coronary artery ligation followed by several hours of reperfusion is commonly used to produce a large myocardial infarction in intact hearts, the size of which often exceeds more than 50% of the LV area at risk. This experimental model provides a clear, easily measured end point (infarct size) that may be used to discriminate whether administration of a volatile anesthetic reduces the magnitude of injury. Other commonly used models (e.g., Langendorff preparation, atrial or ventricular myocytes in vitro) may use other end points to quantify damage, but these models share the common feature that the heart or its cellular constituents are exposed to profound ischemic or hypoxic insult followed by reperfusion or reoxygenation. In contrast, substantially less myocardium is typically at ischemic risk during elective cardiac surgery unless an unanticipated intraoperative coronary artery occlusion occurs. This is the case because systemic and topical hypothermia, intermittent or continuous administration of antegrade and retrograde cardioplegia, and myocardial decompression are routinely used to minimize global ischemic damage during cardiopulmonary bypass in patients undergoing conventional CABG or valve surgery. Similarly, maintenance of coronary perfusion pressure with intravenous fluids or vasoactive medications during changes in cardiac position and use of intracoronary shunts to provide continuous coronary blood flow during construction of distal anastomoses are common techniques that also maintain global and regional myocardial integrity during OP-CAB or MID-CAB operations. The role of the vigilant anesthesiologist also cannot be overemphasized in these procedures because active prevention, prompt recognition, and immediate, aggressive treatment of myocardial ischemia are central objectives when caring for a patient undergoing cardiac surgery who is at risk for such an event. More subtle clinical end points (e.g., biochemical assays of myocardial necrosis or function, use of vasoactive medications, duration of intensive care unit or hospital stay) are also used to measure generally less intense ischemic injury.

The large differences in the amount of myocardium at risk for ischemia between experimental and clinical studies are emphasized when the following studies are considered. Peak and sustained troponins I and T release clearly predicted infarct size, LV dysfunction, and long-term clinical outcome in patients with acute ST-segment elevation myocardial infarction after an occluded coronary artery was reperfused in the cardiac catheterization laboratory.[323] Notably, the peak troponin I and

T concentrations (~450 and 4.7 ng/mL, respectively) observed in these patients with acute myocardial infarction after percutaneous coronary intervention[323] were at least several orders of magnitude greater than those that occur during sevoflurane or propofol anesthesia in patients undergoing CABG. For example, peak troponin I and T concentrations of approximately 6 and 1 ng/mL, respectively, were reported 24 hours after elective CABG in patients anesthetized with propofol.[286,308] These data clearly demonstrate that the amount of myocardium that may sustain ischemic damage during CABG surgery is relatively limited compared with evolving infarction. Under such circumstances, it may be very difficult, if not virtually impossible, to extrapolate small but statistically significant decreases in myocardial necrosis observed with volatile anesthetics into demonstrable improvements in short-term or long-term outcome without a well-conducted, large-scale, propensity-matched, randomized clinical trial in which thousands of patients are enrolled. The results of a recent study demonstrating that remote IPC combined with APC fails to provide additional myocardial protection in patients undergoing CABG may also be attributed to such an explanation because so little myocardium is actually at risk from the outset.[324] Alternatively, the general consensus of clinical data indicates that volatile anesthetics are capable of reducing injury and producing modest short-term benefits, even when only a small amount of myocardium is at risk.[320,321] Thus, when combined with the very clear conclusions of laboratory experiments, the observations of small clinical trials conducted to date provide compelling, albeit circumstantial, evidence suggesting that volatile anesthetics may indeed exert important protective effects and thereby improve outcome when larger areas of myocardium sustain ischemia-reperfusion injury. From this standpoint, the ACCF/AHA Guidelines appear to be justifiable based on this circumstantial evidence. Nevertheless, additional research will be required in the operating room to convincingly answer whether volatile anesthetics do indeed exert clinically relevant antiischemic effects by reducing the incidence and severity of major adverse cardiac events in patients undergoing cardiac or noncardiac surgery.

NEURAL CONTROL OF THE CIRCULATION

Volatile anesthetics have been shown to depress baroreceptor reflex control of arterial pressure in experimental animals to varying degrees. This inhibition of baroreceptor reflex activity occurs as a result of depression of central nervous system integration of afferent baroreceptor input, attenuation of efferent autonomic nervous system activity, and reductions in ganglionic transmission and end-organ response. Volatile anesthetics increased resting afferent nerve traffic and enhanced the sensitivity of arterial baroreceptors by a Ca^{2+}-dependent mechanism. These anesthetic-induced increases in baroreceptor sensitivity and discharge frequency tonically reduce overall sympathetic nervous system activity and attenuate sympathetic responses to declines in arterial pressure. Isoflurane, halothane, and enflurane inhibited preganglionic sympathetic efferent activity at clinically relevant concentrations in vivo. Volatile anesthetics reduced postganglionic sympathetic nerve activity, suggesting that attenuation of ganglionic transmission represents a major mechanism by which these medications depress sympathetic nerve traffic. Reduction of sympathetic outflow caused by volatile anesthetics has also been suggested by examination of endogenous plasma norepinephrine kinetics. Isoflurane and halothane decreased plasma concentrations of norepinephrine to varying degrees by causing a more pronounced decrease in norepinephrine spillover than clearance. Volatile anesthetics may also attenuate parasympathetic nervous system function. Halothane depressed vagal nerve efferent activity by direct measurement of parasympathetic nerve activity. These findings were supported by the results of several other studies demonstrating that volatile anesthetics inhibit reflex bradycardia in response to increases in arterial pressure. Parasympathetic and sympathetic nervous system outflows appear to be depressed to equivalent degrees during halothane or isoflurane anesthesia.

The effects of volatile anesthetics on neural control of the cardiovascular system have been incompletely examined in healthy humans and have not been described in patients with autonomic nervous system dysfunction. Halothane and enflurane produced greater attenuation of baroreceptor reflex regulation of heart rate than equivalent MAC concentrations of isoflurane. Depression of baroreceptor function by the older volatile anesthetics may be more profound compared with fentanyl, diazepam, and N_2O anesthesia. Baroreceptor-mediated control of peripheral arteriolar tone was also attenuated in young volunteers during halothane anesthesia. Steady-state anesthetic concentrations of sevoflurane were shown to cause greater depression of sympathetic nerve activity measured directly with microneurography in contrast to desflurane at equivalent levels of hypotension. These findings paralleled results demonstrating pronounced sympathetic hyperactivity during rapid increases in inspired desflurane concentration in humans. Importantly, the actions of volatile anesthetics on baroreceptor reflex control of the circulation may be profoundly altered during autonomic dysfunction in elderly patients or those with essential hypertension, diabetes mellitus, or heart failure.

NITROUS OXIDE AND CARDIOVASCULAR FUNCTION

CARDIOVASCULAR FUNCTION

Myocardial Contractility and Left Ventricular Diastolic Function

Experiments in papillary muscle and isolated heart preparations consistently demonstrated that N_2O produces a direct negative inotropic effect, but conflicting results about the influence of N_2O on contractility were observed in experimental animals and healthy volunteers. Several problems have contributed to apparently contradictory results in vivo. Observed changes in contractility may be influenced by the actions of N_2O on the systemic circulation or by autonomic nervous system reflex effects

because N_2O may increase sympathetic nervous system tone. Studies using N_2O alone are difficult to perform and interpret because the gas does not produce complete anesthesia at partial pressures less than 1 atm. The effects of N_2O on contractility also may be influenced by different baseline anesthetics. Furthermore, lack of use of load-insensitive measures of myocardial contractility has allowed only qualitative assessment of the effects of N_2O on intrinsic inotropic state in the intact heart.

Preload recruitable stroke work was used to demonstrate that N_2O depressed myocardial contractility in dogs anesthetized with isoflurane or sufentanil in the absence of autonomic nervous system activity. Seventy percent N_2O decreased this index of contractility by 28% and 41% during sufentanil and isoflurane anesthesia, respectively. Thus, 70% N_2O decreased contractility to approximately the same extent as 1 MAC isoflurane. Similar findings were reported using LV end-systolic pressure-dimension relations in acutely instrumented dogs. N_2O-induced myocardial depression may be offset by simultaneous increases in sympathetic nervous system tone. The negative inotropic effects of N_2O may be more pronounced in the presence of preexisting LV dysfunction. Moreover, N_2O-induced depression of contractile function appeared to overcome the mild sympathomimetic effect of the anesthetic gas in patients with coronary artery or valvular heart disease and LV dysfunction because increases in baseline sympathetic nervous system activity were not further augmented by N_2O under these clinical conditions.

The actions of N_2O on LV diastolic function have been incompletely studied. Modest increases in maximal lengthening velocity and maximal rate of decline of force were observed in ferret papillary muscle concomitant with decreases in contractile state. No changes in the rate of isometric or isotonic relaxation were observed, indicating that N_2O does not substantially modify myocardial relaxation. N_2O modestly increased indices of LV chamber stiffness and reduced early LV filling in acutely instrumented dogs. These findings were supported by evidence indicating that N_2O may produce LV diastolic dysfunction after cardiopulmonary bypass in patients undergoing CABG surgery. N_2O caused dose-related reductions in the intracellular Ca^{2+} transient in vitro. This finding indicated that N_2O-induced depression of myocardial contractility was related to decreases in Ca^{2+} availability for contractile activation. N_2O did not affect myofibrillar sensitivity to Ca^{2+} or Ca^{2+} uptake and release from the SR. In addition, the diastolic Ca^{2+} transient was unaffected by N_2O, suggesting that this anesthetic gas does not fundamentally alter myocardial relaxation kinetics.

Hemodynamics

Assessment of the hemodynamic effects of N_2O in humans is often complicated by administration of volatile anesthetics, opioids, or other medications in the presence or absence of cardiovascular disease. Typical clinical concentrations of N_2O (e.g., 40% to 70%) caused modest increases in heart rate in healthy volunteers. Small increases in heart rate also occurred when hyperbaric concentrations of N_2O were administered or when the gas was added to a volatile anesthetic. Declines in heart rate were observed with N_2O in patients with coronary artery disease anesthetized with isoflurane. Modest reductions in heart rate were reported in patients anesthetized with morphine or fentanyl undergoing cardiac surgery. Sixty percent N_2O caused small increases in arterial pressure in humans. Increases in arterial pressure also occurred under hyperbaric conditions or during volatile anesthesia in volunteers, consistent with a mild sympathomimetic effect. Other studies indicated that partial substitution of N_2O for a volatile anesthetic either did not affect or modestly increased arterial pressure during isoflurane or desflurane anesthesia in experiments conducted at constant MAC. In contrast, reductions in arterial pressure were observed in patients with coronary artery disease receiving N_2O in the presence and absence of opioids.

Small increases in cardiac output and stroke volume were noted during administration of 60% N_2O in O_2 in volunteers, but cardiac output remained unchanged in the presence of hyperbaric N_2O. Cardiac output was greater in volunteers anesthetized with N_2O and halothane than in those receiving halothane alone concomitant with increases in sympathetic nervous system outflow. The addition of N_2O to isoflurane or desflurane anesthesia also modestly increased cardiac output. In contrast, N_2O reduced cardiac output and stroke volume in healthy volunteers and patients with cardiac disease receiving opioids. Hyperbaric N_2O (1.5 MAC) caused a modest reduction in systemic vascular resistance. In contrast, systemic vascular resistance was higher during administration of a volatile anesthetic in the presence versus the absence of N_2O. Pretreatment with a ganglionic blocker attenuated the relative increase in systemic vascular resistance observed during administration of halothane and N_2O compared with halothane alone, findings that may be consistent with a reduction in sympathetic nervous system tone. N_2O-induced increases in systemic vascular resistance were reported in volunteers and patients with cardiac disease anesthetized with opioids.

N_2O increased venous tone and decreased venous capacitance in conscious volunteers. The gas also modestly increased pulmonary artery pressures and pulmonary vascular resistance in patients with coronary artery disease anesthetized with morphine and diazepam or a volatile anesthetic. Thus, the combined effects of enhanced venous return, elevated pulmonary vascular resistance, and depressed contractile function probably contributed to the increases in central venous pressure observed with N_2O in humans. Hyperbaric N_2O also enhanced central venous pressure in association with increases in pulmonary vascular resistance. N_2O inhibited norepinephrine uptake by the lung and subsequent increases in plasma norepinephrine levels detected in the pulmonary vasculature may be partially responsible for the characteristic increases in pulmonary vascular resistance observed during administration of this gas. N_2O-induced increases in pulmonary vascular resistance may be more pronounced in adults with pulmonary hypertension and children with increased pulmonary blood flow. Elevations in pulmonary artery pressures and vascular resistance were described during administration of N_2O in neonatal lambs. Such increases in pulmonary vascular resistance may potentially enhance right-to-left atrial or

ventricular shunts and thereby compromise arterial oxygenation in patients with congenital heart disease.

CARDIAC ELECTROPHYSIOLOGY

Reversible atrioventricular dissociation was reported in humans anesthetized with N_2O and volatile or opioid-based anesthetics. Addition of N_2O to halothane lowered the threshold at which arrhythmias occur. This observation may result from a combination of sympathetic nervous system stimulation by N_2O and myocardial sensitization by halothane. The incidence of arrhythmias was reduced during combined N_2O-opioid anesthesia compared with halothane alone.

CORONARY CIRCULATION

N_2O does not produce direct effects on the coronary vasculature in vitro. The gas altered coronary blood flow in parallel with changes in MVo_2 in dogs. N_2O decreased myocardial segment shortening, increased postsystolic shortening, and redistributed transmural coronary blood flow preferentially to the subepicardium (decreased endo/epi ratio) in experimental models of coronary artery disease. N_2O decreased the recovery of contractile function of canine stunned myocardium, and, in contrast to the findings with isoflurane, did not reduce myocardial infarct size in rats.[325] These data suggested that administration of N_2O before or during transient or prolonged coronary artery occlusion and reperfusion is not associated with myocardial protection. N_2O-induced sympathetic nervous system activation and imbalances of myocardial O_2 supply and demand represented potential mechanisms for the absence of a beneficial effect during reversible or irreversible ischemic injury. In the presence of a volatile anesthetic, N_2O decreased MVo_2 and myocardial O_2 extraction and may exacerbate myocardial ischemia during concomitant reductions in arterial pressure in patients with coronary artery disease. However, the addition of N_2O to volatile or opioid anesthetics did not increase the incidence of new regional wall motion abnormalities as assessed using transesophageal echocardiography in this patient population.

NEURAL CONTROL OF THE CIRCULATION

N_2O caused pupillary dilation, diaphoresis, and increases in systemic vascular resistance, central blood volume, and forearm vascular resistance in volunteers during volatile anesthesia, suggesting that N_2O activates the sympathetic nervous system. A subsequent study demonstrated that N_2O increases sympathetic nerve traffic measured using sympathetic microneurography in human volunteers, especially during the first 15 to 30 minutes of exposure to the gas. Baroreceptor reflex–mediated control of heart rate was impaired during administration of N_2O, but regulation of sympathetic outflow to peripheral blood vessels was preserved. This finding suggested N_2O does not alter sympathetic vasoconstrictor-induced maintenance of arterial pressure and may be partially responsible for the relative stability of hemodynamics during N_2O anesthesia.

XENON

In 1939, Behnke and Yarbrough reported that United States Navy divers developed "stupefaction," "mental fogginess," and neuromuscular impairment while breathing mixtures of argon or krypton and O_2 under hyperbaric conditions.[326] These seminal observations were the first to suggest that noble gases had the potential to produce anesthesia. Subsequent experiments with Xe conducted shortly after the end of World War II confirmed this hypothesis in mice[327] and human volunteers.[328] Xe has a very low blood-gas solubility coefficient (0.115) and produces rapid induction of and emergence from anesthesia. Xe is not teratogenic, does not undergo biotransformation, and exerts anesthetic and analgesic effects under normal atmospheric pressure conditions (1.0 MAC = 71%).[15] Xe is derived from α particle decay of radioactive heavy metals such as uranium and thorium. Xe naturally occurs in the atmosphere in trace amounts (1:11.5 million [8.7×10^{-6} %]) and is extracted from liquefied air by sequential cryogenic fractional distillation. Thus, Xe does not affect the ozone layer, unlike N_2O and volatile anesthetics. This latter effect may be particularly important because currently used inhaled anesthetics have been identified as strong greenhouse gases that contribute to total anthropogenic radiative forcing of global climate change.[329] Xe is expensive to produce because of its rarity; only a finite amount is available for use as a general anesthetic. Total world production of Xe is estimated to be approximately 9 to 12 million liters per year. Despite its relative scarcity and high production costs, Xe was approved for clinical use in Russia, Germany, France, and the United Kingdom during the past decade. A closed-circuit anesthetic technique using a relatively simple modification of a conventional anesthesia machine and a new miniature cryogenic waste gas recycling system have recently been described that may eventually make the use of Xe more cost-effective and competitive with other inhaled anesthetics.[330,331]

Unlike volatile anesthetics and N_2O, which produce diverse hemodynamic actions in the absence or presence of heart disease, Xe is essentially devoid of major cardiovascular effects.[15,332] For example, Xe did not alter the amplitudes of Na^+, L-type Ca^{2+}, and inward-rectifier K^+ channel currents over a range of voltages in the isolated cardiac myocyte nor did the anesthetic noble gas affect indices of cardiac function in a Langendorff heart preparation (Figs. 28-19 and 28-20).[333] No changes in the inotropic response to Ca^{2+}, isoproterenol, or increased stimulation rate were observed during administration of Xe in isolated ventricular myocytes.[334] In contrast to the equivalent MAC of halothane and isoflurane, Xe did not affect voltage-gated Ca^{2+} currents and caused minimal inhibition of transient outward K^+ currents in human atrial myocytes in vitro.[335] Xe anesthesia also did not adversely affect the circulatory response to moderate hypoventilation in vivo.[336] Administration of Xe did not alter invasively derived indices of LV systolic and diastolic function or systemic hemodynamics in isoflurane-anesthetized dogs before and after the development of congestive heart failure. Xe also produced minimal hemodynamic effects and did not affect

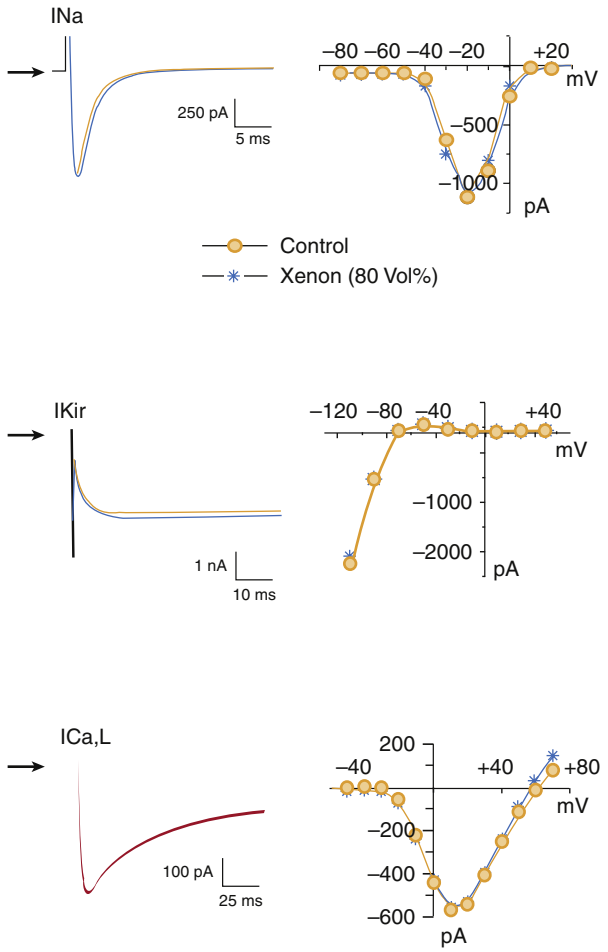

Figure 28-19. Effects of 80 vol% xenon on cardiac ionic currents in single cardiac myocytes *(left)*. Sample current traces recorded from three different myocytes were monitored at test potentials of –20 mV for I_{Na}, –110 mV for I_{Kir}, and +10 mV for $I_{Ca,L}$. Holding potentials were –110 mV for I_{Na}, –40 mV for I_{Kir}, and –50 mV for $I_{Ca,L}$. Corresponding current-voltage relationships for I_{Na}, I_{Kir}, and $I_{Ca,L}$ are shown. *(From Stowe DF, Rehmert GC, Kwok WM, et al: Xenon does not alter cardiac function or major cation currents in isolated guinea pig hearts or myocytes,* Anesthesiology *92:516-522, 2000.)*

contractile function in a rabbit model of myocardial infarction and chronic LV dysfunction.[337] In agreement with these experimental findings, the results of several clinical studies have also documented that Xe anesthesia is associated with remarkable cardiovascular stability in patients with or without heart disease. Xe anesthesia was shown to produce minimal effects on coronary blood flow dynamics and regional cerebral perfusion evaluated using positron emission tomography in healthy volunteers.[338,339] LV function assessed using transesophageal echocardiography was unchanged during 65% Xe-O_2 anesthesia in patients undergoing abdominal surgery. Systemic hemodynamics were unchanged and recovery from anesthesia was faster in patients who received 60% Xe-O_2 compared with 60% N_2O–0.5% isoflurane during elective surgery.[340] Similarly, mean arterial pressure was maintained at conscious values during Xe-remifentanil but not propofol-remifentanil anesthesia in another study of patients undergoing elective surgery.[341] Maintenance of autonomic nervous system–mediated regulation of the circulation during Xe anesthesia was most likely a major contributing factor to this preservation of hemodynamics.[342] Mean arterial pressure and LV function were preserved during Xe anesthesia in patients with coronary artery disease undergoing noncardiac surgery[343] and those with congestive heart failure in whom a cardioverter-defibrillator was implanted.[344] A phase I clinical trial further demonstrated the cardiovascular safety of Xe in patients undergoing CABG using cardiopulmonary bypass.[345]

When considered within the context of these laboratory and clinical findings, the ability of Xe to protect myocardium against ischemic injury is particularly striking. Preckel and associates[346] first demonstrated that administration of 70% Xe during the initial 15 minutes of reperfusion after prolonged coronary artery occlusion (postconditioning) reduced myocardial infarct size in rabbits.[346] Because Xe does not substantially affect the cardiovascular system, alterations in electrophysiology, inotropic state, coronary blood flow, and the hemodynamic determinants of myocardial O_2 supply-demand relations were most likely not responsible for the observed protective effects.[346] Another study demonstrated that administration of 75% Xe before and after brief coronary artery occlusion and reperfusion enhanced the functional recovery of stunned myocardium independent of changes in systemic hemodynamics and coronary collateral perfusion.[347] Weber and associates[348] subsequently demonstrated that three cycles of brief (5-minute) exposure to 70% Xe-O_2 interspersed with 5-minute periods of 70% N_2-O_2 before prolonged coronary occlusion and reperfusion reduced myocardial infarct size in vivo.[348] The magnitude of the myocardial protection resulting from this Xe preconditioning (XePC) was similar to that produced by IPC and APC. The authors further demonstrated that pretreatment with PKC or p38 MAPK inhibitors abolished XePC. In addition, Xe caused posttranslational modification and translocation of PKC-ε from the cytosol to the sarcolemmal membrane in a p38 MAPK–dependent fashion consistent with enzyme activation (Fig. 28-21). These results were also similar to findings observed during IPC and APC.

Additional evidence supports the hypothesis that the mechanisms responsible for XePC are indeed very similar to those of other forms of preconditioning. For example, two important downstream targets of p38 MAPK—MAPKAPK-2 and Hsp27—were shown to be essential for the beneficial effect of APC and XePC.[86] MAPKAPK-2 phosphorylates Hsp27, thereby promoting its translocation to, and facilitating its stabilization of, the actin cytoskeletal structure of the cardiac myocyte. Like APC, XePC phosphorylated MAPKAPK-2 and Hsp27, and these actions were abolished by pretreatment with PKC or p38 MAPK inhibitors. Furthermore, XePC also enhanced Hsp27 translocation, increased F-actin polymerization, and colocalized phospho-Hsp27 and F-actin. Thus, XePC was linked to the cytoskeleton through p38 MAPK-mediated activation of MAPKAPK-2 and Hsp27. These data implicated selective transportation of specific proteins to unique cellular locations to facilitate myocardial protection during XePC. Essential roles for mitochondrial K_{ATP} and other signaling kinases known to be of central importance in other forms

Figure 28-20. of preconditioning and postconditioning also have been demonstrated in XePC. For example, a selective mitochondrial K_{ATP} antagonist blocked XePC-induced reductions in infarct size, phosphorylation of PKC-ε, and membrane translocation of PKC-ε in vivo.[349] Furthermore, a selective PI3K antagonist not only abolished myocardial protection produced by XePC but also inhibited phosphorylation of Akt and another PI3K-related enzyme.[350,351] XePC directly enhanced phosphorylation and translocation of ERK1/2 from the cytosol to the nucleus, whereas pretreatment with an antagonist of an upstream activator of this enzyme abolished XePC-induced protection against infarction.[350] Notably, XePC did not phosphorylate the stress-activated p46/p54 MAPK (also known as c-Jun-N-terminal kinases 1/2 and 3 [JNK 1/2 and 3]), nor did a specific inhibitor of this enzyme complex abolish reductions in infarct size produced by the noble gas. These findings suggested that not only is Xe capable of selectively activating some signaling kinases while leaving others unaffected, but also at least one important difference exists between XePC and IPC in which the involvement of p46/p54 was previously implicated.[350,352] Despite this relatively minor difference in signal transduction between XePC and IPC, Xe directly inhibited Ca^{2+}-induced mPTP opening in isolated ventricular mitochondria,[351] similar to the findings with APC[108] and IPC.[105] As mentioned earlier, mPTP is considered a primary end-effector of preconditioning and postconditioning phenomena. Thus, preservation of mitochondrial integrity appears to be of central importance during XePC, as well (Fig. 28-22).

Xe may cause myocardial protection against reversible or irreversible ischemic injury by favorably modulating endothelium-neutrophil interaction. The effects of Xe on cell adhesion molecule expression were examined in isolated human neutrophils in the absence or presence of known stimulants of enhanced neutrophil activity.[353] Xe decreased neutrophil expression of the adhesion molecules P-selectin glycoprotein ligand-1 (a regulator of neutrophil rolling on the endothelial surface) and L-selectin. Xe also inhibited exogenous stimulant-induced augmentation of L-selectin but not β_2-integrin (CD11a and CD11b) expression. Selectins initiate neutrophil-endothelial cell contact, whereas β_2-integrins are required for tight adhesion of neutrophils and their subsequent migration through endothelium. Thus, Xe may attenuate adhesion of neutrophils to endothelium, but the noble gas does not appear to affect their migration during ischemia-reperfusion injury.[353] Nevertheless, the results of another study failed to support these conclusions, because Xe did not affect cytokine and cell adhesion molecule expression in neutrophils activated by exposure to cardiopulmonary bypass.[354] More recently, the effects of Xe on TNF-α–induced cell adhesion molecule and NF-κB expression were studied in human umbilical vein endothelial cells.[28] Similar to the findings with volatile anesthetics, Xe blocked stimulated cell adhesion molecule expression by TNF-α and attenuated transcriptional activity of NF-κB, suggesting that Xe may protect against ischemic injury by favorably modulating these factors in vascular endothelium. In addition, Xe and isoflurane caused reductions in plasma TNF-α and IL-6 concentrations of similar magnitude in a porcine model of RV infarction.[355]

Like volatile anesthetics, Xe also causes delayed preconditioning in vivo. Weber and colleagues[356] demonstrated that a single 15-minute exposure to 70% Xe-O_2 performed 24 hours before prolonged coronary artery occlusion and reperfusion protects myocardium against infarction.[356] The magnitude of reductions in myocardial necrosis observed during this late XePC were similar to those observed during acute XePC.[348] Analogous to the findings during late APC,[170] pretreatment with a selective COX-2 antagonist blocked delayed XePC.[356] An increase in COX-2 activity was also shown to mediate late XePC. It is highly likely that other signaling molecules, protein kinases, and transcription factors previously implicated in delayed APC and IPC also play important roles in late XePC, but further studies will be required to confirm this hypothesis.

The mechanism(s) by which Xe selectively interacts with biologically active molecules to produce myocardial protection against ischemia-reperfusion injury remains a mystery.[15,332] Xe is not entirely inert despite completely filled electron orbitals and may be ionized or form covalent bonds in the presence of very strong oxidizing agents at low temperatures,[357] but the noble gas is essentially nonreactive under normal physiologic conditions. Intraatomic dipole formation within the outer electron orbitals ($[Kr]5s^2 4d^{10} 5p^6$) of the relatively large Xe atom may account for its ability to interact with ion channels, enzymes, or receptors, but this theory fails to account for

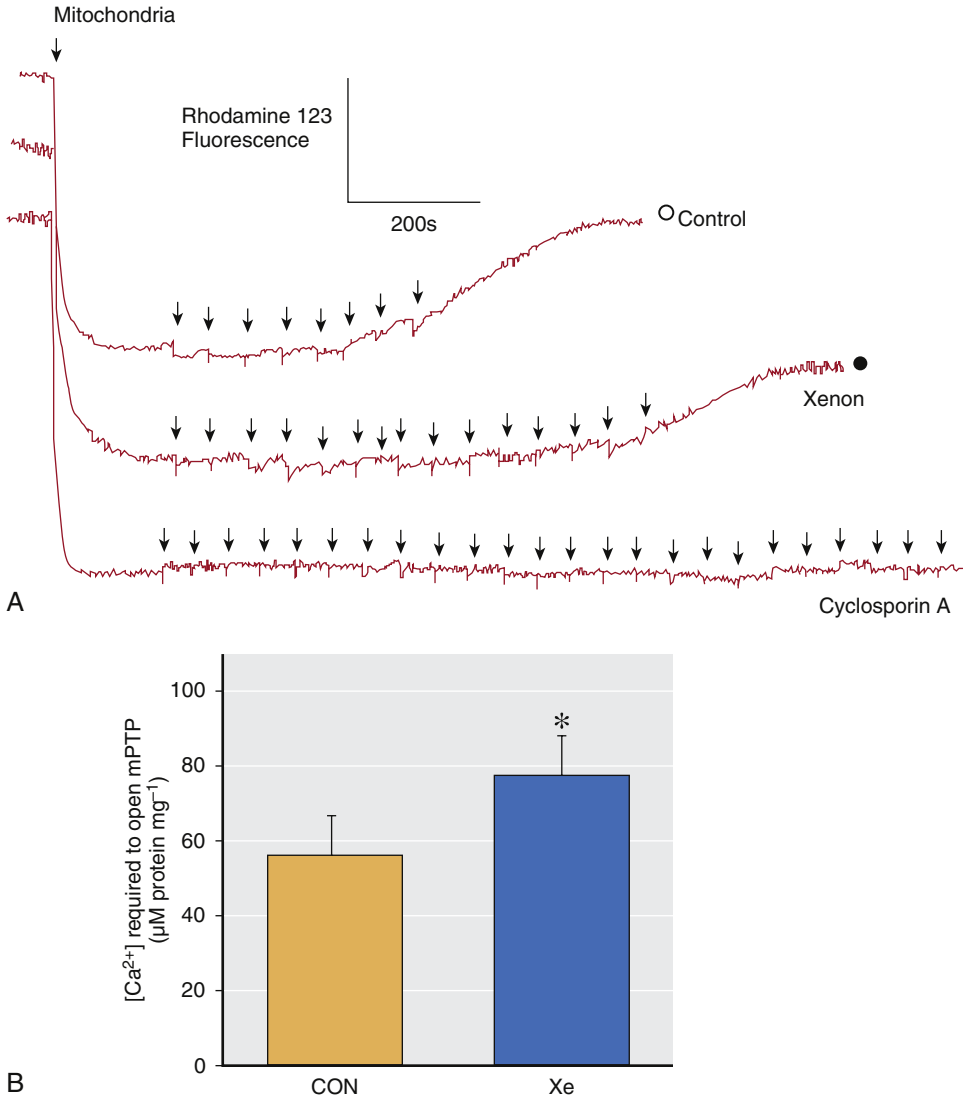

Figure 28-22. Effect of xenon preconditioning on isolated mitochondrial permeability transition pore *(mPTP)* opening. **A,** Typical chart recording showing mitochondrial membrane potential at state 2 with increasing calcium concentration ([Ca^{2+}]). The *arrows* denote the addition of Ca^{2+} in 5-μM increments. Depolarization was detectable by opening mPTP and releasing Ca^{2+} from mitochondria through the mPTP with sequential Ca^{2+} loading. Xe preconditioning delayed depolarization, indicating inhibition of mPTP opening. *Open circle,* Control; *solid circle,* Xe preconditioning. Depolarization was not observed in the presence of mPTP inhibitor cyclosporin A. **B,** Histograms summarizing the results. *CON,* Control; *Xe,* xenon preconditioning (n = 6 per group). *(From Mio Y, Shim YH, Richards E: Xenon preconditioning: the role of prosurvival signaling, mitochondrial permeability transition and bioenergetics in rats,* Anesth Analg *108:858-66, 2009.)*

the selectivity with which such an interaction may occur. Other nonanesthetic noble gases (e.g., helium, neon) have been shown to exert protective effects against myocardial ischemia-reperfusion injury,[358] and their electron orbital structures are not conducive to intraatomic dipole formation. X-ray crystallography studies demonstrated that the catalytic sites of several serine proteases contain specific binding cavities for Xe. Many of the prosurvival signaling kinases implicated in XePC are serine proteases that display conserved structural homology among species. These observations suggest a plausible mechanism by which Xe may activate protein kinases to mitigate ischemic injury. Nevertheless, extrapolation of x-ray crystallography findings to the intact heart may be difficult because the crystallography experiments were conducted using crystallized proteins under hyperbaric conditions (Xe pressures between 8 and 20 atm). Xe and N_2O were shown to occupy the heme pocket of CYP450 monooxygenase and competitively inhibit the enzyme's catalytic activity under standard atmospheric pressure conditions. However, only Xe, and not N_2O, is capable of producing myocardial protection.[325] Molecular modeling and electrophysiology studies suggested that Xe and isoflurane selectively inhibit the *N*-methyl-D-aspartate (NMDA) receptor by binding to its glycine agonist site[359] through the phenylalanine 758 residue.[360] These data suggested that Xe was capable of selectively interacting with a complex protein in vitro. However, it is unclear why Xe may activate some kinases or receptors while leaving others unaffected. As discussed, ERK1/2, but not c-Jun N-terminal kinases, mediated XePC in vivo,[350] whereas both kinase types are known to play roles in IPC. Thus, the precise biochemistry of selective Xe-protein interaction remains elusive, but strong pharmacologic evidence shows that Xe protects myocardium against ischemia-reperfusion injury by activating many of the same signaling pathways that are responsible for other forms of preconditioning and postconditioning. Whether Xe produces myocardial protection in humans is currently unknown and will require clinical trials to determine.

SUMMARY

Volatile anesthetics exert profound effects on the cardiovascular system by altering the inotropic, chronotropic,

dromotropic, and lusitropic state of the heart. Volatile anesthetics also produce significant actions on both the preload and afterload systems. These pharmacologic effects cause dramatic changes in hemodynamics that may be accentuated in patients with underlying cardiovascular disease. Less profound but equally important effects are observed with N_2O and Xe. Volatile anesthetics and Xe, but not N_2O, have been shown to cause myocardial protection, thereby directly reducing the sequelae of ischemia and reperfusion injury. The use of inhaled anesthetics requires a clear understanding of their complex cardiovascular pharmacology.

Chapter 29

Inhaled Anesthetics: Delivery Systems

STEVEN G. VENTICINQUE • J. JEFFREY ANDREWS

Acknowledgment: The editors and publisher would like to thank Dr. Russell C. Brockwell for contributing a chapter on this topic to the prior edition of this work. It has served as the foundation for the current chapter.

Key Points

- If there is any possibility that the workstation or the breathing circuit is a potential cause of difficulty with ventilation or oxygenation, switching to a self-inflating resuscitation bag is an appropriate decision. *Ventilate and oxygenate first — troubleshoot later.*
- The most important part of the preuse anesthesia workstation checkout procedure is verifying the presence of a self-inflating resuscitation bag.
- The Diameter Index Safety System (DISS) is designed to prevent the misconnection of hospital gas supply lines to the anesthesia workstation. The Pin Index Safety System (PISS) is designed to prevent incorrect gas cylinder connections in the anesthesia workstation. Neither system is immune from failure.
- If the hospital pipeline becomes crossed or contaminated, two actions must be taken. The backup oxygen cylinder valve must be opened, and the wall supply sources must be disconnected. Otherwise, hospital pipeline gas will continue to flow to the patient.
- Fail-safe valves and proportioning systems help minimize delivery of a hypoxic mixture, but they are not always effective. Delivery of a hypoxic mixture can result from (1) the wrong supply gas, (2) a defective or broken safety device, (3) leaks downstream from these safety devices, (4) administration of a fourth inert gas (e.g., helium), and (5) dilution of the inspired oxygen concentration by high concentrations of inhaled anesthetic agents (e.g., desflurane).
- The low-pressure section (LPS) of the gas supply system is a highly vulnerable area of the anesthesia machine because it is subject to breakage and leaks. The LPS is located downstream from all safety features of anesthesia machines, except the breathing circuit oxygen analyzer, and it is the portion of the machine that is missed if an inappropriate LPS leak test is performed.
- The LPS must be checked for leaks before an anesthetic agent is administered because leaks in the LPS can cause delivery of a hypoxic mixture or an inadequate concentration of anesthetic agent that could result in a patient's awareness during anesthesia (see also Chapter 44).
- Because many older Datex-Ohmeda anesthesia machines and some modern GE Healthcare machines have a one-way check valve in the LPS, a negative-pressure leak test is required to detect leaks in the LPS on these machines. On machines without a check valve in this location, manual positive-pressure testing or automated testing is used to test the LPS for leaks.
- Internal vaporizer leaks can be detected only when the vaporizer is turned on. This is true even during machine self-tests. The GE/Datex-Ohmeda Aladin cassette vaporizer and the Maquet FLOW-i anesthesia workstation vaporizer are exceptions to this rule.
- Saturated vapor pressure is a physical property of a liquid, and it depends on temperature. It is not affected by barometric pressure.
- The main purpose of the temperature compensation device within variable bypass vaporizers is to compensate for the liquid cooling that results from evaporation of volatile anesthetic liquid.
- Because of desflurane's low boiling point and high vapor pressure, controlled vaporization of desflurane is not possible using a variable bypass vaporizer.

Key Points—cont'd

- Misfilling a variable bypass vaporizer with desflurane could theoretically be catastrophic and potentially cause delivery of a hypoxic mixture and a massive overdose of inhaled desflurane.
- Increasing the fresh gas flow rate into the circle breathing system causes less rebreathing of volatile anesthetic gas and more waste gas.
- Before an anesthetic agent is administered, the circle system must be checked for leaks and flow. To test for leaks, the circle system should be pressurized to 30 cm H_2O, and the circle system airway pressure gauge should be observed (static test). An automated test may perform this function on many modern machines. To check for appropriate flow, to rule out obstruction and faulty valves, the ventilator or the breathing bag and a test lung (another breathing bag) can be used (dynamic test).
- Inhaled anesthetic agents can interact with carbon dioxide absorbents and produce potentially harmful degradation products. During sevoflurane anesthesia, compound A can be formed, particularly at low fresh gas flow rates. During desflurane anesthesia, carbon monoxide can be produced, particularly with desiccated absorbents (see also Chapter 26). The minimization of strong bases in absorbents decreases this risk.
- Anesthesia ventilators with ascending bellows (bellows ascending during the expiratory phase) are safer than descending bellows because disconnections are readily manifested by failure of ascending bellows to refill.
- Piston ventilators and descending bellows ventilators can potentially draw room air into the breathing circuit if a leak is present.
- With machines that do not have a fresh gas decoupling feature, oxygen flushing during the inspiratory phase can cause volutrauma or barotrauma, or both (particularly in pediatric patients) (see also Chapter 93). Therefore, the oxygen flush should never be activated during the inspiratory phase of mechanical ventilation.
- On older-generation anesthesia machines, tidal volume and airway pressure during positive-pressure ventilation are increased by increases in fresh gas flow rate. Most newer-generation machines compensate for changes in fresh gas flow rate. Obviously, anesthesia providers should know whether their machines compensate for these changes.
- Workstations that use bellows ventilators that scavenge gas from both the patient and the ventilator drive have substantially increased volumes of scavenged gas. Thus, the scavenging systems must be set appropriately (e.g., adequate vacuum) to accommodate the increased volume, or pollution of the operating room environment could result.
- Obstruction of the scavenging system transfer tubing (segment between the breathing circuit and the scavenging interface) can result in increased breathing circuit pressure and barotrauma.
- An inadequate vacuum to an open scavenging interface can cause leakage of anesthetic gases into the room.
- The American Society of Anesthesiologists *Recommendations for Pre-Anesthesia Checkout Procedures (2008)* serves as an excellent template for the creation of machine-specific checkout procedures. However, it is not a one-size-fits-all checklist.

Modern anesthesia delivery systems have evolved from the ether-soaked sponges and rags used in the mid-1800s. During that era, spontaneous breathing was the only mode of ventilation, no safety features existed besides vigilance, and the norm was uncertainty regarding the delivered anesthetic concentration. Today, anesthesia workstations are capable of safely delivering controlled concentrations of volatile anesthetic agents and other gases, along with providing positive-pressure ventilation, scavenging waste anesthetic gas, and monitoring for hazardous conditions or output failures. Newcomers to the specialty often find the anesthesia machine to be both mysterious and

intimidating, even though these practitioners often have some experience with other ventilation equipment, such as the intensive care unit (ICU) ventilator. The following requirements highlight the unique demands placed on the anesthesia workstation and help explain why it functionally differs from its ICU counterpart.

- Deliver volatile anesthetic gas at precise concentrations.
- Allow rebreathing of the exhaled anesthetic gases after removing carbon dioxide.
- Individually meter oxygen and two or more other breathing gases, and continuously enrich the inhaled gas with these vapors.
- Provide a manual mode of breathing ("bag" ventilation) with adjustable breathing circuit pressure control.
- Eliminate ("scavenge") excess gas from the patient's breathing circuit, and remove this gas from the room.
- Continuously measure the inspired oxygen concentration.
- Prevent hypoxic gas mixtures caused by operator error or gas supply failure.
- Provide a breathing circuit manual oxygen flush feature.
- Possess a backup supply of oxygen.
- Display gas pipeline and backup tank supply pressures.

Anesthesia workstations undergo steady innovation and change that make maintaining a current knowledge base difficult for many practitioners to achieve. Understanding anesthetic equipment is important because the workstation is one of the most essential pieces of equipment used by anesthesia care providers. Some design and engineering changes enhance ease of use and efficiency, and some enhance patients' safety. In fact, closed claims analysis of adverse anesthetic outcomes related to the anesthesia delivery system have declined and now account for only approximately 1% of the claims in the American Society of Anesthesiologists (ASA) closed claims database.[1] However, although claims related to the medical gas delivery system are infrequent, when they do occur they are usually severe, involving death or permanent brain injury.[2]

Although anesthesia workstation engineering advances may decrease the incidence of mishaps and injuries to patients, adverse events will never be eliminated. In addition, with new technologies come new potential problems. To prevent mishaps, providers must be aware of the operational characteristics and functional anatomy of their anesthesia workstations. Many workstations and their components share very similar characteristics, but the variation among them is growing. Similarly, the operational and preuse checkout procedures are becoming more divergent, thus mandating device-specific familiarity. Unfortunately, a lack of knowledge pertaining to the anesthesia workstation and a lack of understanding and application of a proper preuse check are common.[3-8] The increasing diversity in the design and function of these machines could potentially worsen the anesthesia provider's knowledge deficit. The safe use of today's anesthesia workstation requires a solid generic understanding, as well as knowledge of machine-specific features and checkout procedures.

Because anesthesia workstations consist of numerous subsystems, it is useful to learn about the machine in a manner that addresses each subsystem individually and as they relate to the system as a whole. This functional anatomy approach is familiar and useful. The chapter is therefore arranged as follows:

1. Standards and guidelines for anesthesia workstations
2. Functional anatomy sections
   a. Gas supply system
   b. Anesthetic breathing circuits
   c. Anesthetic vaporizers
   d. Waste gas scavenging systems
3. Anesthesia machine preuse checkout

For several decades, anesthesia workstation design remained fairly similar, barring some differences in subsystem design. In particular, the circle breathing circuits were virtually identical, and the schematic was requisite knowledge for the anesthesiology consultant. With moderate effort, a comprehensive understanding of the entire machine was attainable. Today, these workstations have increasing numbers of differences in terms of features and design nuance. Variability is now the norm. The ASA's current *Recommendations for Pre-Anesthesia Checkout* states more clearly than earlier versions that the checkout serves as a guide for users to *create their own machine-specific checkout procedures*, whereas the previous version could be more universally applied.[9,10] Earlier machines also tended to be more mechanical and less electronic. Further, with older machines the components were more exposed and therefore were easier to see and functionally understand. Newer workstations are more modular, and many of the components are concealed from view. An obvious analogy is the automobile. Arguably, our generic understanding and ability to troubleshoot issues with automobiles have diminished as a result of their increasing complexity, diversity, and component concealment.

Providing a detailed description of each gas system, subsystem component, and patient's breathing circuit is not practical within the scope of a single chapter. However, because anesthesia workstations must adhere to basic standards, a generic approach to learning is a suitable starting point. Although several subsystems are described in detail in this chapter, anesthesia providers must acquire a functional understanding of their own workstations and ensure that their local preuse checkout procedures are suitable for their machines.

STANDARDS AND GUIDELINES FOR ANESTHESIA WORKSTATIONS

Standards for medical devices and anesthesia workstations provide guidelines for manufacturers regarding device minimum performance, design characteristics, and safety requirements. For the anesthesia workstation, many of these requirements are outlined in the standards of ASTM International (formerly known as the American Society for Testing and Materials). ASTM International is a developer of international voluntary consensus standards.[11] The current standards are defined within the

Standard Specification for Particular Requirements for Anesthesia Workstations and Their Components F1850-00, found within ASTM volume 13.02, September 2012, *Medical and Surgical Materials and Devices*.[12] Additional ASTM International standards address anesthesia breathing systems, anesthetic gas scavenging systems, and alarm signals. ASTM International standards also apply the International Electrotechnical Commission (IEC) 60601-1 standards, which pertain to medical electrical equipment safety. The IEC 60601-1 serves as parent standards for numerous medical device standards. Additional key standards for machine subsystems arise from the Compressed Gas Association (CGA) and the Institute of Electrical and Electronics Engineers (IEEE), although other standards may directly or indirectly affect workstation design.[12]

The ASTM International specification describes the anesthesia workstation as a "system for administration of anesthesia to patients" consisting of "the anesthesia gas supply device, anesthesia ventilator, monitoring devices, and protection devices."[12] The standards define numerous aspects of design and construction, including protection against common hazards, protection against incorrect machine output, monitoring standards, alarm standards, and the requirements for several other safety systems. Although these standards are too long to describe here comprehensively, several of them are addressed in this chapter as they pertain to various subsystems.

The ASA publishes several guidelines pertaining to the anesthesia workstation.[9] The *Recommendations for Pre-Anesthesia Checkout,* which was updated last in 2008, serves as a general guideline for individual departments and practitioners to design preanesthesia checkout procedures specific to their anesthetic delivery systems.[9] The ASA *Guidelines for Determining Anesthesia Machine Obsolescence* helps to assist anesthesia providers and other health care personnel, administrators, and regulatory bodies determine when an anesthesia machine is obsolete by applying both absolute and relative criteria.[9] Finally, the ASA also publishes *Standards for Basic Anesthetic Monitoring,* which outlines minimal monitoring standards pertaining to oxygenation, ventilation, circulation, body temperature, and the requirements for the presence of anesthesia personnel. Standards and recommendations pertaining to the anesthesia workstation are published by several other national anesthesiology societies.[13,14]

FUNCTIONAL ANATOMY OF THE ANESTHESIA WORKSTATION

GAS SUPPLY SYSTEM

Regardless of the increasing electronic complexity of the anesthesia machine, it remains a fundamentally pneumatic device. Central to its function is the safe delivery and metering of the breathing gases, particularly oxygen, from the gas supply sources to the vaporizers and finally to the patient's breathing circuit. These are the functions of the gas supply system. Figures 29-1 and 29-2 demonstrate typical anesthesia workstation gas supply systems. The gas supply system of the workstation is usually concealed from view, with the exception of the pipeline gas inlets, the gas tanks and their mounts, the flowmeters, the vaporizers, and the oxygen flush button. Despite being cloaked within the anesthesia workstation, this section of the anesthesia machine contains numerous key pneumatic safety features. Although some diversity in gas supply systems exists among workstations, these systems do retain many similarities because of required safety standards and performance expectations.

The overview of the gas supply system is as follows: Oxygen and the other breathing gases flow from the hospital pipeline sources to the flow control valves, through the flowmeters (or flow sensors), and through or past an anesthetic vaporizer. From there they are introduced into the patient breathing circuit through a fresh gas supply line. Throughout this course, safeguards are present to detect low oxygen supply pressure and prevent a hypoxemic gas mixture from being delivered to the patient regardless of the flows selected by the user. Machine-mounted gas cylinders can be used as an alternate source of oxygen or of other gases. Permanent safeguards are in place to prevent connecting the wrong gas to the wrong inlet or connecting the wrong gas tank to the wrong tank receptacle. The machine can directly and rapidly flush 100% oxygen into the patient's breathing circuit, and oxygen is usually available from an auxiliary flowmeter. These two features are usually available even when the machine is not turned on.

The gas supply system can be divided functionally into high-pressure, intermediate-pressure, and low-pressure sections. The *high-pressure* section involves the segments exposed to the high pressures within the E-cylinder auxiliary gas tanks (e.g., ≤2000 pounds per square inch gauge [psig] for air and oxygen). This section extends from the tanks to the primary or high-pressure regulators. The *intermediate-pressure* section includes the segments exposed to hospital pipeline pressures (50 to 55 psig) and lower pressures in the range of 15 to 30 psig when secondary pressure regulators are used. The *low-pressure* section of the gas supply system extends from the flow control valves, through the flowmeters (or flow sensors), through the anesthetic vaporizers, and out the fresh gas supply line. This description begins with the gas supply source inlets and moves through to the fresh gas line that leads to the patient's breathing circuit.

High-Pressure Section

Auxiliary E-Cylinder Inlet. During normal operating conditions, the hospital's central gas supply system serves as the primary gas source for the anesthesia machine. However, it is a requirement to have at least one attachment for an oxygen cylinder to serve as a backup source of oxygen in case of failure of the hospital supply source. Many machines have up to three and sometimes four E-cylinder attachment points to accommodate oxygen, air, and nitrous oxide. Some machines have attachments for two oxygen tanks, and some rare systems can accommodate carbon dioxide or helium tanks used for special applications. The cylinders are mounted to the anesthesia machine by the hanger yoke assembly, as seen in Figure 29-3. The hanger yoke assembly orients and safely supports the cylinder, provides

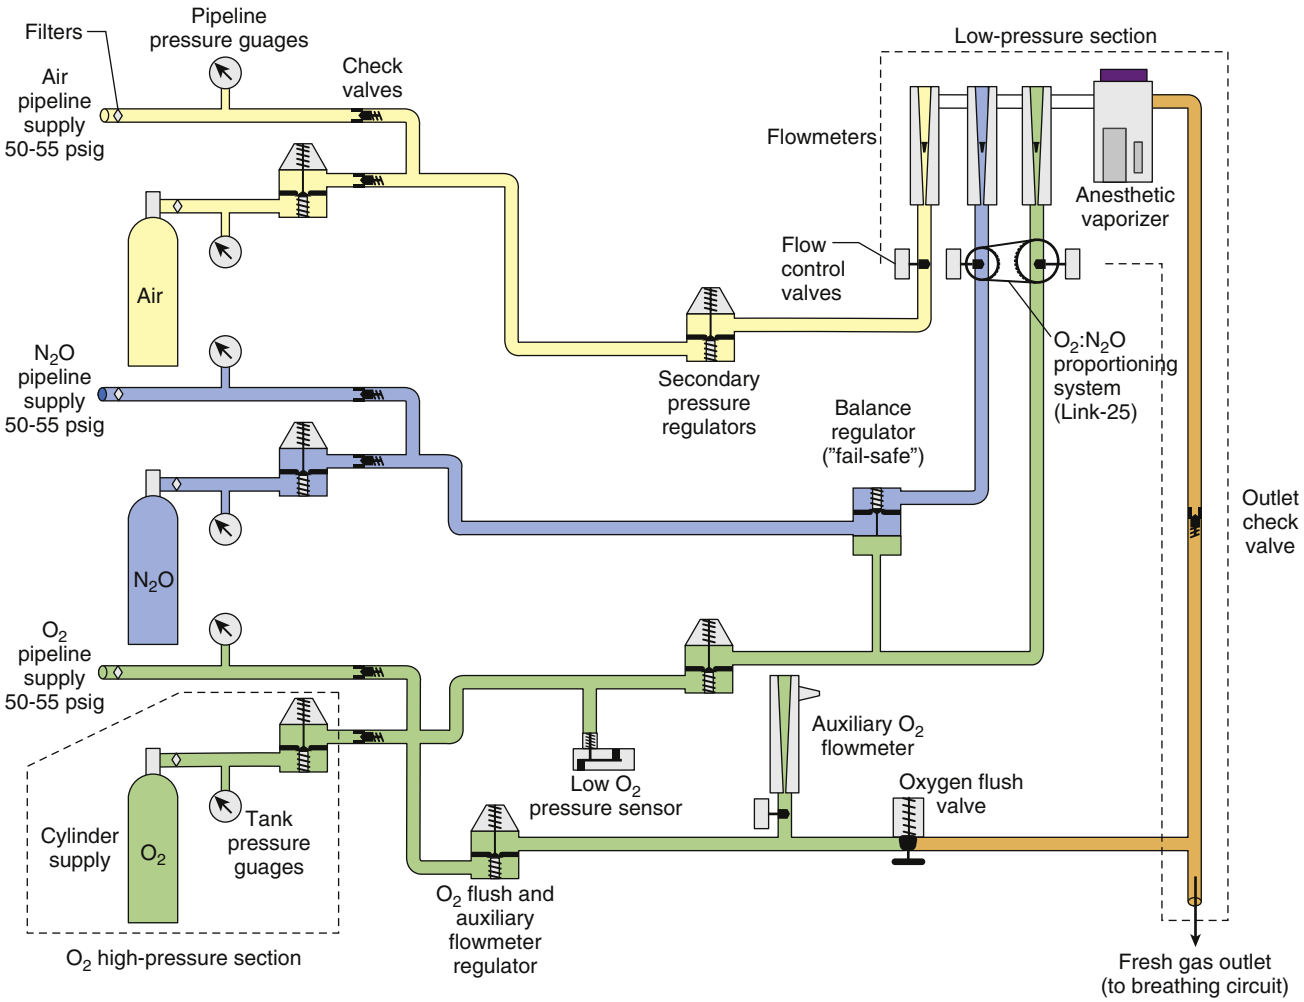

Figure 29-1. Anesthesia workstation gas supply system represented by the GE Healthcare Aespire anesthesia workstation. The high-pressure system extends from the gas cylinders to the high-pressure regulators (*dashed lines* around 0_2 high-pressure section). The intermediate-pressure section extends from the high-pressure regulators to the flow control valves and also includes the tubing and components originating from the pipeline inlets. The low-pressure section (*dashed lines*) extends from the flow control valves to the breathing circuit. See text for additional details. *(From Datex-Ohmeda:* S/5 Aespire anesthesia machine: technical reference manual, *Madison, Wis., 2004, Datex-Ohmeda.)*

a gas-tight seal, and ensures unidirectional flow of gases into the machine.[15] Each yoke assembly must have a label designating which gas it is intended to accept. Each hanger yoke is also equipped with the Pin Index Safety System (PISS), which is a safeguard to reduce the risk of a medical gas cylinder error caused by interchanging cylinders. Two metal pins on the yoke assembly are arranged to project precisely into corresponding holes on the cylinder head–valve assembly of the tank. Each gas or combination of gases has a specific pin arrangement.[16] Although infrequent, failures of the PISS have been reported, and like all safety systems, the PISS should be considered partial protection. Conditions in which failure occurred have included the following: excessive seating (jamming) of the pins back into the hanger yoke; the presence of bent or broken pins; and an excessive use of washers between the cylinder and the yoke that can override pin alignment, yet allow for a gas-tight seal.[17-19] Medical gas cylinder errors can have tragic outcomes, so it is critical to ensure that the proper gas is being connected to the proper inlet by also checking the tank and yoke labels.[20]

Once a gas cylinder valve is opened by the operator, gas flows first through a filter to entrap any particulate matter from the tank inflow. The maximum pressure in the E-cylinders ranges from approximately 750 psig for nitrous oxide, approximately 2000 psig for air, and approximately 2000 psig for oxygen. This pressure is much higher than the normal hospital pipeline supply pressure of 50 to 55 psig. Each cylinder supply source line must therefore have a pressure-reducing mechanism known as the *high-pressure regulator*, which reduces the variable high pressures present in the cylinders to a lower, nearly constant pressure suitable for use in the anesthesia machine (see Figs. 29-1 and 29-2). The high-pressure regulators are adjusted to provide gas from the E-cylinders at a pressure of approximately 45 psig (but it can be as low as 35 psig).[15,16,21] Although this specific value may vary among machines, the principle is to keep high-pressure regulator output pressure lower than the normal pipeline supply pressures. This approach ensures that the hospital's central gas supply will serve as the main supply of gas to the machine if a cylinder is open as long as the hospital supply line

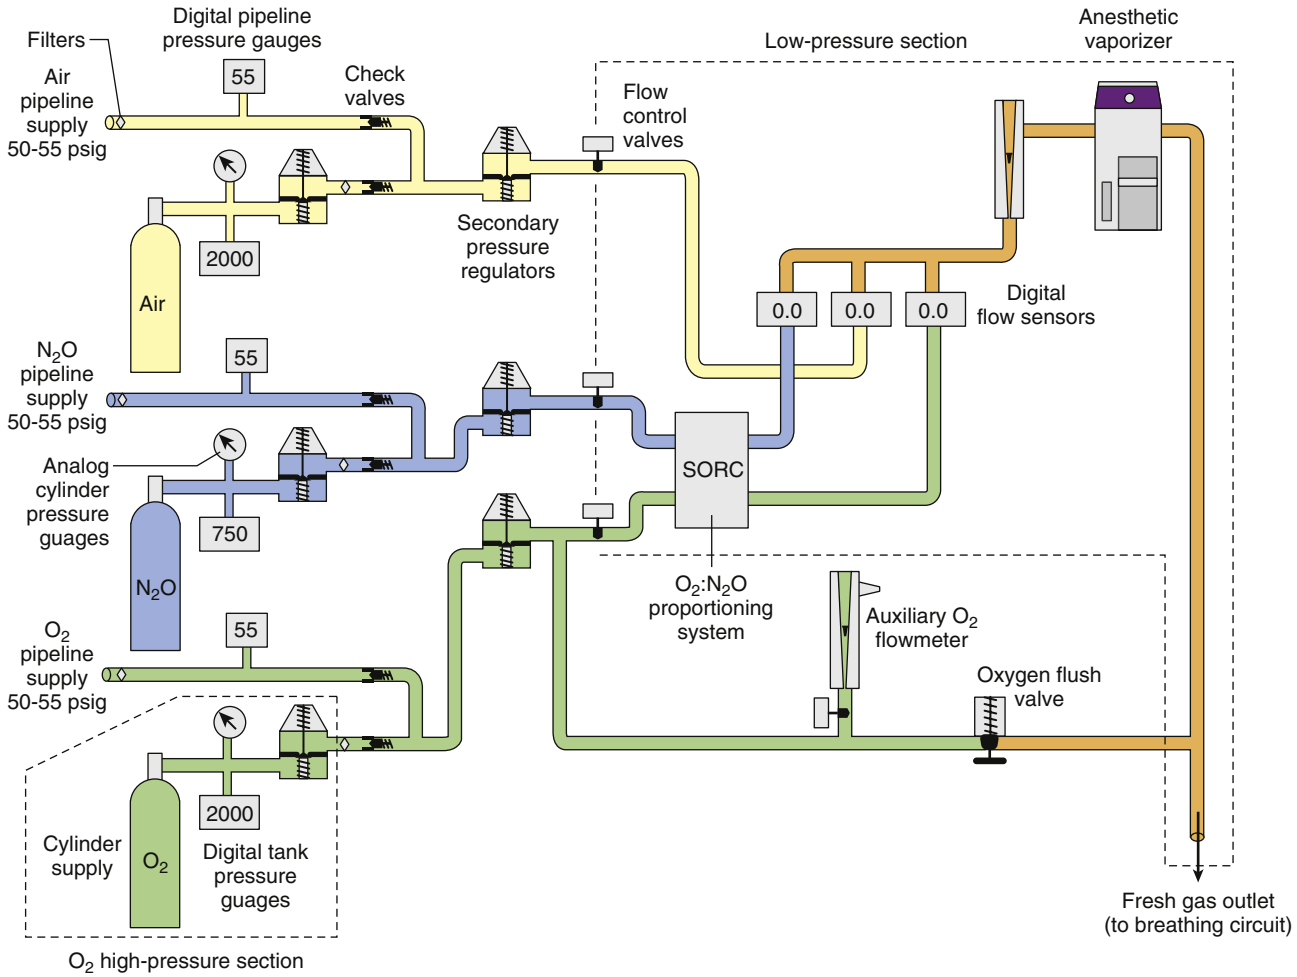

Figure 29-2. Anesthesia workstation gas supply system represented by the Dräger Apollo anesthesia workstation. The high-pressure system extends from the gas cylinders to the high-pressure regulators (*dashed lines* around 0_2 high-pressure section only). The intermediate-pressure section extends from the high-pressure regulators to the flow control valves and also includes the tubing and components originating from the pipeline inlets. The low-pressure section (*dashed lines*) extends from the flow control valves to the breathing circuit. See text for additional details. *(From Dräger Medical:* Instructions for use: Apollo, *Telford, Pa., 2012, Dräger Medical.)*

pressure remains higher than the regulator output pressure. In other words, the E-cylinders, even when open, will not provide gas to the anesthesia machine if the hospital supply line pressure is within or higher than the normal range. Therefore, in a case of known or suspected hospital pipeline oxygen supply contamination or pipeline crossover, in which oxygen is substituted for another gas but pipeline pressure maintained, only by *disconnection* of the oxygen pipeline source hose from the wall outlet will the machine be able to use E-cylinder oxygen.

After the high-pressure regulator, cylinder gas flows through a one-way valve called the cylinder check valve, which prevents any backflow of machine gas out through an empty yoke or back into a nearly empty cylinder (see Figs. 29-1 and 29-2). On some older machines, the yoke check valve is located before the high-pressure regulator. With this arrangement, and when two oxygen tanks could be mounted on the machine on a common manifold, the yoke check valve also (1) minimizes the transfer of gas from a cylinder at high pressure to one with lower pressure, (2) allows an empty cylinder to be exchanged for a full one while gas flow continues from the other cylinder into the machine, and (3) minimizes leakage from an open cylinder to the atmosphere if one cylinder is absent.[15,21] Note the location of the cylinder pressure gauges and pressure sample sites in Figures 29-1 and 29-2. Auxiliary tank pressure gauges (or electronic displays) must be located in plain sight on the front of the machine. In the gas supply system seen in Figure 29-2, electronic transducers relay tank pressure (when their valves are opened) to a display on the front of the machine.

Although gas usually does not flow from the open tanks when pipeline supply pressures are normal, the gas supply cylinder valves should be closed when they are not in use, except during the preoperative machine checkout. If the cylinder supply valves are left open, the reserve cylinder supply can be silently depleted if pressure inside the machine decreases to a value lower than the regulated cylinder pressure. For example, oxygen pressure within the machine can decrease to less than 45 psig with oxygen flushing or possibly even during use of a pneumatically driven ventilator, particularly at high

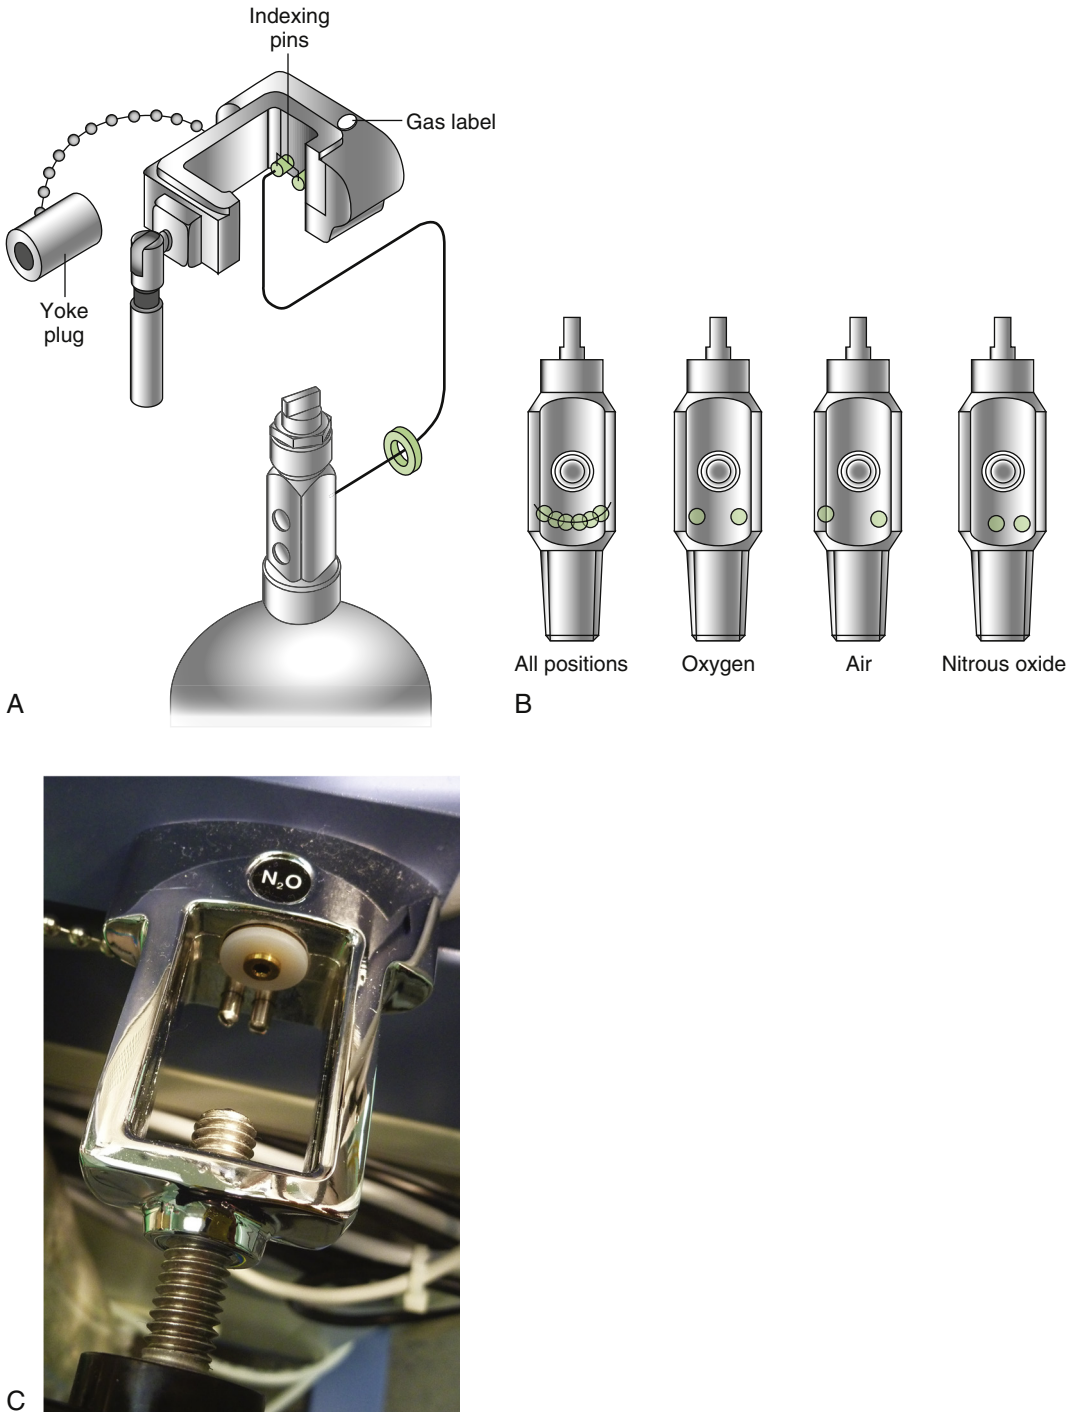

Figure 29-3. E-cylinder hanger yoke assembly. **A,** Standard E-cylinder hanger yoke assembly highlighting the gas-specific indexing pins, sealing gasket, and yoke plug. The yoke plug should be inserted when a tank is not in place. **B,** Pin Index Safety System holes machined into the cylinder head–valve mechanism of the compressed gas cylinders. **C,** Nitrous oxide yoke with indexing pins. Compare the image with the nitrous oxide pattern in **B.** *(**A** and **B,** From Yoder M: Gas supply systems. In* Understanding modern anesthesia systems, *Telford, Pa., 2009, Dräger Medical.)*

inspiratory flow rates. Additionally, the pipeline supply pressures of all gases can fall to less than 45 psig if problems exist in the central piping system. If the cylinders are left on when this occurs, they will eventually become depleted, and no reserve supply may be available if a pipeline failure occurs.[15,21] Moreover, the yoke hanger seal is vulnerable to leakage.

Intermediate-Pressure Section

Pipeline Inlet: Hospital Central Gas Supply Source. The main supply source of oxygen in a large hospital is usually a massive cryogenic bulk oxygen storage system, although some sites may use smaller cryogenic storage units or large H-type oxygen cylinders connected by manifold. Centrally supplied nitrous oxide arises from a bank

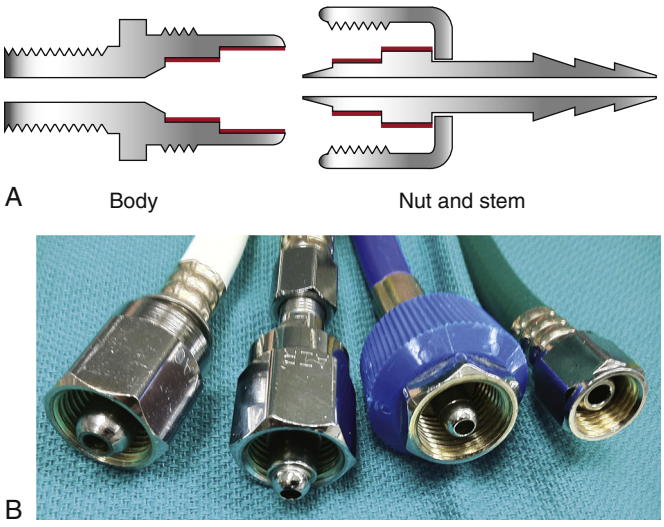

Figure 29-4. Diameter Index Safety System (DISS). DISS connectors are used for noninterchangeable, removable medical gas connections at pressures less than 200 psig. They are also used for suction and waste gas connections. Indexing is accomplished through differing diameters of the connection components, resulting in keylike fitting when matched connectors come together. The oxygen connector is additionally distinguished from the other gas connectors by a unique threaded fitting diameter and a unique thread count. **A,** DISS connector cross section. **B,** Nut and stem connectors for (*left* to *right*) vacuum, air, nitrous oxide, and oxygen. (***A,*** *Modified from Yoder M: Gas supply systems. In* Understanding modern anesthesia systems, *Telford, Pa., 2009, Dräger Medical.)*

of H-type cylinders. On-site compressors supply medical air, which is stored in holding tanks until needed. From these sources, a piping system delivers these gases to outlet points within patient care areas. The pipeline pressure for oxygen, medical air, and nitrous oxide in the United States is 50 to 55 psig.

The medical gas outlets throughout patient care areas in the hospital may have a variety of gas-specific connector types. However, medical gas from the hospital's central supply always enters the anesthesia machine through Diameter Index Safety System (DISS) connectors, as seen in Figure 29-4.[12] The purpose of these connectors is to prevent the connection of the wrong gas to the wrong inlet. DISS connectors work by matching the shoulders of the stem assembly on the end of the supply hose to the bores of the appropriate inlet receptacle on the anesthesia machine.[16] Once the gas enters the machine through the DISS connector, it encounters a filter followed by a pipeline check valve. This one-way valve prevents the reverse flow of machine gas from the machine into the medical gas pipeline system or into the atmosphere from an open inlet. Interposed between the DISS inlet and the pipeline check valves is a sample port to measure pipeline oxygen pressure by gauge or transducer. The pipeline pressure must always be clearly visible on the front of the machine.

Oxygen Flush Valve. The oxygen flush valve is probably one of the oldest safety features on the machine, and it remains a machine standard today.[12,22] The valve provides manual delivery of a high flow rate of 100% oxygen directly to the patient's breathing circuit. Flow from the oxygen flush valve bypasses the anesthetic vaporizers (see Figs. 29-1 and 29-2). The intermediate-pressure segment of the gas supply system feeds the valve, which remains closed until the operator opens it. The feature is usually available even when the machine is not turned on because the valve is usually located upstream from the machine's pneumatic power switch. Flow from the oxygen flush valve enters the low-pressure circuit downstream from the vaporizers at a rate between 35 and 75 L/minute, depending on the machine and the segment operating pressure.[12,22]

Several hazards have been reported with the oxygen flush valve. A defective or damaged valve can stick in the fully open position and result in barotrauma.[23] A valve sticking in a partially open position can result in a patient's awareness because oxygen flow from the incompetent valve dilutes the inhaled anesthetic.[24,25] Improper use of normally functioning oxygen flush valves also can cause problems. Overzealous intraoperative oxygen flushing can dilute inhaled anesthetic agents. Oxygen flushing during the inspiratory phase of positive-pressure ventilation can produce barotrauma if the anesthesia machine does not incorporate a fresh gas decoupling feature or an appropriately adjusted inspiratory pressure limiter. Fresh gas decoupling prevents the fresh gas inflow from either the flowmeters or the oxygen flush valve from increasing the delivered ventilator tidal volume presented to the patient's lungs (see the section on fresh gas decoupling). With most older anesthesia breathing circuits, excess volume could not be vented during the inspiratory phase of mechanical ventilation because the ventilator relief valve was closed and the breathing circuit adjustable pressure-limiting (APL) valve was either out of circuit or closed.[26]

The oxygen flush valve can potentially provide a high-pressure, high-flow oxygen source at the machine's fresh gas outlet suitable for jet ventilation, but it has potential limitations. First, on many modern anesthesia machines, the fresh gas outlet is no longer easy to access. Next, even on machines with accessible fresh gas outlets, not all are necessarily capable of generating pressures at the outlet that are sufficient to deliver jet ventilation.[27,28] If jet ventilation is going to be considered a contingency, it would be prudent to investigate whether it can be supported by the machine's oxygen flush function. If not, an alternate source of high-flow oxygen should be sought.

Pneumatic Safety Systems. The pneumatic safety devices within the gas supply system are engineered to help delivery of a hypoxemic gas mixture to the patient. Oxygen is the primary gas within the gas supply system circuitry, and it influences the flow of all other gases. On much older anesthetic delivery devices, the oxygen and nitrous oxide flows existed as independent entities, and they were not pneumatically or mechanically interfaced. Therefore, abrupt or insidious oxygen pressure failure had the potential to deliver a hypoxic gas mixture or possibly nitrous oxide alone. One of the primary safety goals of contemporary anesthesia machines is to prevent delivery of a hypoxemic gas mixture, and in particular to guard against the potential of delivering an excessive

concentration of nitrous oxide relative to oxygen. ASTM standards state the following: "The anesthesia gas supply device shall be designed so that whenever oxygen supply pressure is reduced to below the manufacturer specified minimum, the delivered oxygen concentration shall not decrease below 19% at the common gas outlet."[12] Gas supply systems have several safety devices that minimize the risk of delivery of a hypoxic gas mixture in case the oxygen pressure were to decrease significantly.

Oxygen Supply Failure Alarm Sensor. Within the oxygen circuit of the intermediate-pressure section of the machine is a sensor that will provide an audible and visual warning to the clinician if the oxygen pressure drops below a manufacturer-specified minimum (see Fig. 29-1). The alarm is an ASTM requirement, and it cannot be silenced until the pressure is restored to the minimum value.[12] An example is a loss or significant decrease of pipeline pressure, or a nearly empty oxygen tank if the machine were using the tank as an oxygen source. During normal operation, an alarm signal serves as a prompt for the operator to open the oxygen E-cylinder on the machine and troubleshoot the oxygen pipeline source. Numerous types of pneumatic-electrical switches can serve as this sensor. Because pipeline pressure standards vary significantly throughout the world, the minimum threshold pressure for an alarm condition differs among manufacturers and models. For example, early Dräger Narkomed (Dräger Medical, Lubeck, Germany) machines had a set point of 37 psig because they were designed for line pressures of 50 to 55 psig (the U.S. standard). However, Dräger Fabius series machines, which are sold internationally, are set to alarm at 20 psig to accommodate fluctuations in normal operating pressures as low as 41 psig, which can be seen in other countries.[22] The gas supply system seen in Figure 29-2 has no separate oxygen supply failure sensor component. The pipeline and tank electronic pressure transducers send information to a central processor, which will create an alarm if pressures drop below predetermined minimums.[22]

Oxygen Failure Protection Devices or Fail-Safe Valves. The so-called fail-safe valves are safeguards intended to link the flow of other gases in the gas supply system to the pressure of oxygen. They are present within some anesthesia workstations, but not all. Controlled by the oxygen supply pressure in the intermediate-pressure segment, the fail-safe valves shut off or proportionally decrease the flow of the other breathing gases before the flow control valves (e.g., nitrous oxide, air, helium) as the oxygen supply pressure decreases. Fail-safe valves either are binary (from open to closed at a threshold pressure) or close proportionally as the oxygen supply pressure decreases. Figure 29-1 demonstrates a proportioning-type fail-safe valve used on the nitrous oxide pathway within the GE Aespire (GE Healthcare, Little Chalfont, United Kingdom) gas supply system (called the "balance regulator" by the manufacturer). Unfortunately, the term *fail-safe* as it pertains to these valves is a misnomer and has led to the misconception that they can independently prevent the administration of a hypoxic mixture. In fact, if a gas other than oxygen adequately pressurizes the oxygen circuit as a result of hospital pipeline contamination or crossover, the fail-safe valves will remain open. In such a case, only the inspired oxygen concentration monitor and clinical acumen would protect the patient.

Auxiliary Oxygen Flowmeter. Although auxiliary oxygen flowmeters are not mandatory, they are commonly encountered. During normal operation, the auxiliary flowmeter is a convenience feature that allows the use of low-flow oxygen for devices independent of the patient's breathing circuit. Similar to the oxygen flush feature, oxygen flow from the flowmeter is usually accessible even when the machine is not turned on, because the flowmeter is typically fed before the pneumatic power switch in the intermediate-pressure section. Therefore, the auxiliary oxygen flowmeter can also serve as a safety feature because it allows the use of an oxygen delivery source (e.g., a manually powered self-inflating resuscitation bag) even in the case of a system power failure as long as oxygen is available from the pipeline inlet or from an attached E-cylinder. The auxiliary oxygen flowmeter may potentially serve as gas source for a jet ventilation contraption; however, not all machines can generate sufficient working pressure.[27]

The operator should be aware that the source of oxygen for the auxiliary flowmeter is the same as for the other oxygen flow control valves (see Figs. 29-1 and 29-2). This is an important consideration in cases of suspected hospital oxygen pipeline contamination or crossover. If the pipeline oxygen supply line is connected to the machine and the pressure is sufficient, the gas source will be the pipeline source even if the auxiliary oxygen tank valve is opened (described earlier). In a simulation experiment, a nitrous oxide–oxygen pipeline crossover situation was created whereby the inspired oxygen concentration became alarmingly low, and the "patient" became hypoxemic after turning the nitrous oxide flow off. Researchers noted that many study participants tried to make inappropriate use of the auxiliary oxygen flowmeter and oxygen E-cylinders on the machine as an external source of oxygen without disconnecting the pipeline source.[29] The participant's suboptimal management was attributed to a lack of knowledge of the anesthesia machine and its gas supply.

Second-Stage Pressure Regulators. Many machines have second-stage regulators located downstream from the gas supply sources in the intermediate-pressure circuit (see Figs. 29-1 and 29-2). These regulators supply constant pressure to the flow control valves and the proportioning system regardless of potential fluctuations in hospital pipeline pressures. They are adjusted to lower pressure levels than the pipeline supply, usually between 14 and 35 psig, depending on the workstation.[16,30-32]

Low-Pressure Section

The low-pressure section of the gas supply system begins at the flow control valves and ends at the outlet of the fresh gas line (see Figs. 29-1 and 29-2). Key components include the flow control valves, the flowmeters or flow sensors, the vaporizer manifold, and the anesthetic vaporizers. The low-pressure section is the most vulnerable section to leaks within the gas supply system.

Flowmeter Assemblies. The flowmeter assembly consists of the flow control valves and the flowmeters, and its purposes are precise control and measurement of gas flow traveling to the common gas outlet (Fig. 29-5). The valves themselves represent an important anatomic landmark within the anesthesia workstation because they separate the intermediate-pressure section from the low-pressure section. The operator regulates flow entering the low-pressure circuit by adjusting the flow control valves. Flow control valves have historically been controlled mechanically; however, on many newer workstations they are controlled by electronic interface. The oxygen and nitrous oxide flow control valves are either linked mechanically or affiliated pneumatically to a proportioning system to help prevent inadvertent delivery of a hypoxic mixture involving excess nitrous oxide (see the later section on proportioning systems). After leaving the flowmeters, the mixture of gases travels through a common manifold and may be directed through an anesthetic vaporizer if selected. The total fresh gas flow and the anesthetic vapor then travel toward the common gas outlet.[15,21]

Flow Control Valves. The flow control valve assembly consists of a flow control knob, a tapered needle valve, a valve seat, and a pair of valve stops.[15] The inlet pressure to the assembly is determined by the pressure characteristics of the intermediate-pressure segment of the respective machine. As described earlier, secondary pressure regulators are often used before the flow control valves to provide stable input pressure despite fluctuations in hospital pipeline supply pressure. The location of the needle valve in the valve seat changes to establish different orifices when the flow control valve is adjusted. Gas flow increases when the flow control valve is turned counterclockwise, and it decreases when the valve is turned clockwise. Because their use is frequent and the consequences of damage are significant, the controls must be constructed so extremes of rotation will not cause disassembly or disengagement. Some newer machines have a fully digital interface in which the control of flow is performed remote from the valve; however, even these workstations possess a backup manual oxygen flow control and valve flowmeter in case of system or electrical failure.[33,34]

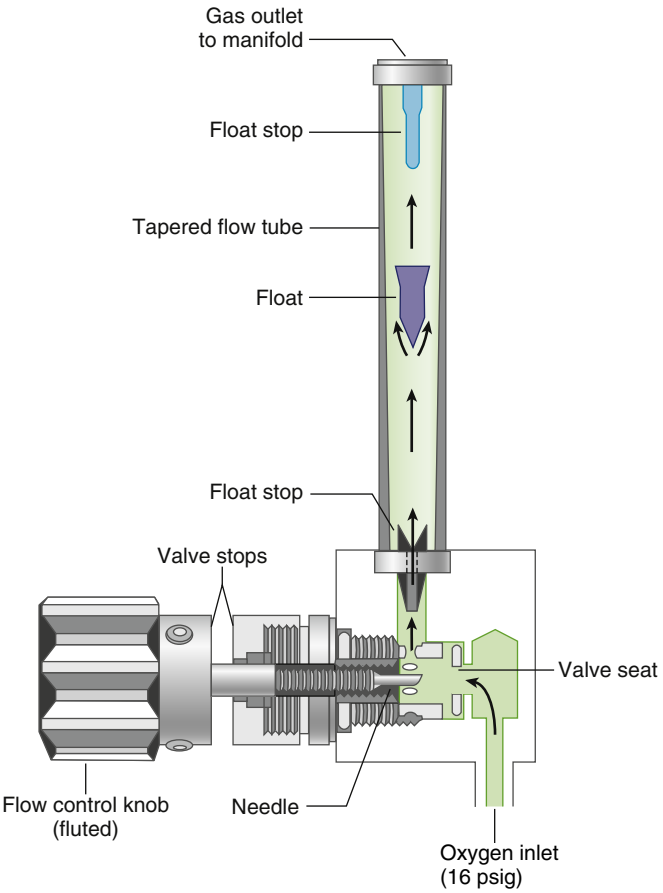

Figure 29-5. Oxygen flowmeter assembly. The oxygen flowmeter assembly is composed of the flow control valve assembly and the flowmeter subassembly. See text for details. *(From Bowie E, Huffman LM: The anesthesia machine: essentials for understanding, Madison, Wis., 1985, Ohmeda, BOC Group.)*

Safety Features. Contemporary flow control valve assemblies have numerous safety features. The oxygen flow control knob must be physically distinguishable from the other gas knobs. It is distinctively fluted, may project beyond the control knobs of the other gases, and is larger in diameter than the flow control knobs of other gases. All knobs are color coded for the appropriate gas, and the chemical formula or name of the gas must be permanently marked on each knob. Flow control knobs are recessed or protected with a shield or barrier to minimize inadvertent change from a preset position. If a single gas has two flow tubes, the tubes are arranged in series and are controlled by a single flow control valve.[12]

Flow Tubes. Although electronic flowmeters are becoming increasingly common, calibrated flow tubes historically have been the means of measuring gas flows on the anesthesia workstation and are still frequently encountered. With a traditional flowmeter assembly, the flow control valve regulates the amount of flow that enters a tapered, transparent flow tube known as a variable orifice flowmeter. A mobile indicator float inside the calibrated flow tube indicates the amount of flow passing through the associated flow control valve. The quantity of flow is indicated on a scale associated with the flow tube.[15,21] Referred to as *variable orifice area flow tubes* or *Thorpe tubes,* these glass tubes are narrowest at the bottom and widen vertically. An indicator float is housed within the tube that is free to move vertically. Opening the flow control valve allows gas to travel through the space between the float and the flow tube. This space is known as the *annular space,* and it varies in size depending on the position of the indicator in the tube (Fig. 29-6). The indicator float hovers freely in an equilibrium position in the tube where the upward force resulting from gas flow equals the downward force on the float resulting from gravity at a given flow rate. The float moves to a new equilibrium position in the tube when flow is changed. These flowmeters are commonly referred to as *constant-pressure* flowmeters because the decrease in pressure across the float remains constant for all positions in the tube.[15,35,36]

Flow through the annular space can be laminar or turbulent, depending on the gas flow rate (Fig. 29-7). The characteristics of a gas that influence its flow rate through a given constriction are viscosity (laminar flow)

and density (turbulent flow). Because the annular space behaves as a tube at low flow rates, laminar flow is present, and *viscosity* determines the gas flow rate. Conversely, at high flow rates the annular space behaves like an orifice with turbulent gas flow in which the *density* of the gas predominantly influences the flow. Because the viscosity and density of the gas affect flow through annular space around the float, the calibrated flow tubes are gas specific. The tube, the float, and the scale are inseparable. Although temperature and barometric pressure can influence gas density and viscosity, under normal clinical circumstances flow tube accuracy is not significantly affected by mild changes in temperature or pressure.

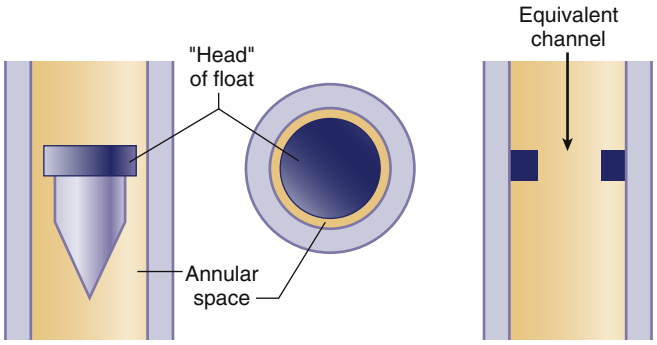

Figure 29-6. The annular space. The clearance between the head of the float and the flow tube is known as the annular space. It can be considered equivalent to a circular channel of the same cross-sectional area. *(Redrawn from Macintosh R, Mushin WW, Epstein HG, editors:* Physics for the anaesthetist, *ed 3, Oxford, 1963, Blackwell Scientific.)*

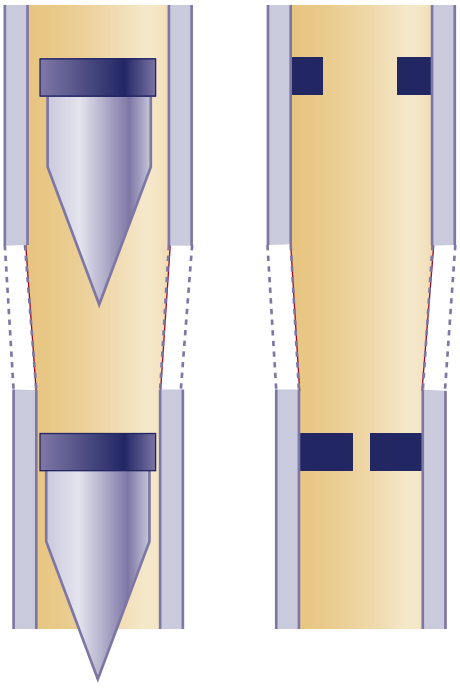

Figure 29-7. Flow tube constriction. The *lower pair* of illustrations represents the lower portion of a flow tube. The clearance between the head of the float and the flow tube is narrow. The equivalent channel is tubular because its diameter is less than its length. Viscosity is dominant in determining the gas flow rate through this tubular constriction. The *upper pair* of illustrations represents the upper portion of a flow tube. The equivalent channel is orificial because its length is less than its width. Density is dominant in determining the gas flow rate through this orificial constriction. *(Redrawn from Macintosh R, Mushin WW, Epstein HG, editors:* Physics for the anaesthetist, *ed 3, Oxford, 1963, Blackwell Scientific.)*

The float or bobbin within the flow tube is usually constructed so that it rotates to indicate that gas is flowing and that the indicator is not stuck in the tube. A stop at the top of the flowmeter tube prevents the float from occluding the outlet. Two flowmeter tubes are sometimes placed in series, with a fine flow tube displaying low flows and a coarse flow tube indicating higher flows.

Electronic Flow Sensors. As mentioned earlier, newer anesthesia workstations are increasingly equipped with electronic flow sensors instead of flow tubes with either conventional control knobs or an electronic interface to control gas flow. Flows can be displayed numerically or sometimes graphically in the form of a virtual, digitalized flowmeter. Numerous types flow sensor technologies can be applied, such as hot-wire anemometers, a differential pressure transducer method, or mass flow sensors. An example of an electronic mass flow sensor is seen in Figure 29-8. The illustrated device relies on the principle of specific heat to measure gas flow.[16] As gas streams through a heated chamber of known volume, a specific amount of electricity is required to maintain the chamber temperature. The amount of energy required to maintain the temperature is proportional to the flow of the gas and the gas's specific heat. Regardless of the mechanism of flow measurement, these systems depend on electrical power to provide a display of gas flow. When system electrical power is totally interrupted, some backup mechanical means usually exists to control (mechanical flow control) and display (flow tube) oxygen gas flow.

Problems with Flowmeters

Leaks. Flow tube leaks are a potential hazard because the flowmeters are located downstream from antihypoxemia safety devices, except the breathing circuit oxygen analyzer.[37] Leaks can occur at the O-ring junctions between the glass flow tubes and the metal manifold or from cracked or broken glass flow tubes, so these tubes have historically been a very fragile pneumatic component of the workstation. Even though gross damage to conventional glass flow tubes is usually apparent, subtle

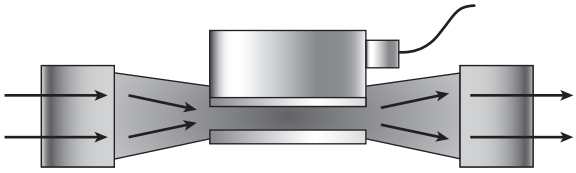

Figure 29-8. Electronic mass flow sensor. Gas flows past a heated chamber of known volume. The amount of heat (electrical energy) that is required to maintain a set chamber temperature is proportional to the specific heat of the gas and its rate of flow through the chamber. Because the specific heat of the gas is relevant to the calculation, each gas must have its own mass flow sensor. Flow is accurately extrapolated from the energy required to keep the chamber at a constant temperature. *(Modified from Yoder M: Gas supply systems. In* Understanding modern anesthesia systems, *Telford, Pa., 2009, Dräger Medical.)*

cracks and chips may be overlooked and can cause in errors in delivered flow.[38] The use of electronic flowmeters and removal of conventional glass flow tubes from many modern anesthesia workstations may help eliminate this potential source of leaks.

In the 1960s, investigators established that in the presence of a flowmeter leak, a hypoxic mixture is less likely to occur if the oxygen flowmeter is located downstream from all other flowmeters.[36,39] Figure 29-9 illustrates this potential problem. In the examples given in Figure 29-9, the unused air flow tube has a large leak, and the nitrous oxide and oxygen flow rates are assumed to be set at a ratio of 3:1. A potentially dangerous arrangement is shown in Figure 29-9, *A* and *B,* because the nitrous oxide flowmeter is located in the downstream position. A hypoxic mixture can occur because a substantial portion of the oxygen flow passes through the leak in the air flow tube, and mainly nitrous oxide is directed to the common gas outlet. Safer configurations are shown in Figure 29-9, *C* and *D,* in which the oxygen flowmeter is located in the downstream position. A portion of the nitrous oxide flow escapes through the leak, and the remainder goes toward the common gas outlet. A hypoxic mixture is less likely because all the oxygen flow is advanced by the nitrous oxide (this principle is known as the Eger flow sequence). ASTM standards state that "where oxygen and other gases are delivered by their respective flow indicators into a common manifold, the oxygen should be delivered downstream of all other gases."[12]

A leak in the oxygen flow tube may result in creation of a hypoxic mixture even when oxygen is located in the downstream position (Fig. 29-10).[37,38] Oxygen escapes through the leak, and nitrous oxide continues to flow toward the common outlet, particularly at high ratios of nitrous oxide to oxygen flow.

Inaccuracy. Flow measurement error can occur even when flowmeters are assembled properly with appropriate components. Dirt or static electricity can cause a float to stick, and the actual flow may be higher or lower than that indicated. Sticking of the indicator float is more common in the low-flow ranges because the annular space is smaller. A damaged float can cause inaccurate readings because the precise relationship between the float and the flow tube is altered. Backpressure from the breathing circuit can cause a float to drop so that it reads less than the actual flow. Finally, if flowmeters are not aligned properly in the vertical position (plumb), readings can be inaccurate because tilting distorts the annular space.[15,38,40]

Proportioning Systems. The proportioning system is probably the most important pneumatic safety component within the gas supply system of the machine. Manufacturers equip anesthesia workstations with proportioning systems in an attempt to prevent the creation and delivery of a hypoxic gas mixture. The ASTM standard states that the "the anesthesia workstation shall be provided with a device to protect against an *operator selected* delivery of a mixture of oxygen and nitrous oxide having an oxygen concentration below 21% oxygen (v/v%) in the fresh gas or in the inspiratory gas."[12] In other words, no matter how high the operator attempts to turn up the nitrous oxide, or how low the operator tries to turn down the oxygen flow when nitrous oxide is running, the machine will automatically limit the amount of nitrous oxide flow so that a hypoxemic gas mixture will not be delivered. This is accomplished by a pneumatic-mechanical interface between the oxygen and nitrous oxide flows or by mechanically linking the oxygen and nitrous oxide flow control valves. The specific devices used to accomplish this control vary among manufacturers in design. Two examples are discussed here.

North American Dräger Sensitive Oxygen Ratio Controller System. The North American Dräger sensitive oxygen ratio controller system (SORC) is a pneumatic-mechanical, oxygen–nitrous oxide interlock system designed to maintain a ratio of no less than 25% oxygen to 75% nitrous oxide flow into the breathing circuit by limiting the nitrous oxide flow when necessary.[22] The SORC is located between the flow control valves and the electronic flow sensors. A schematic of the SORC is shown in Figure 29-11. The SORC consists of an oxygen chamber with a diaphragm, a nitrous oxide chamber with a diaphragm, and a nitrous oxide proportioning valve. All are

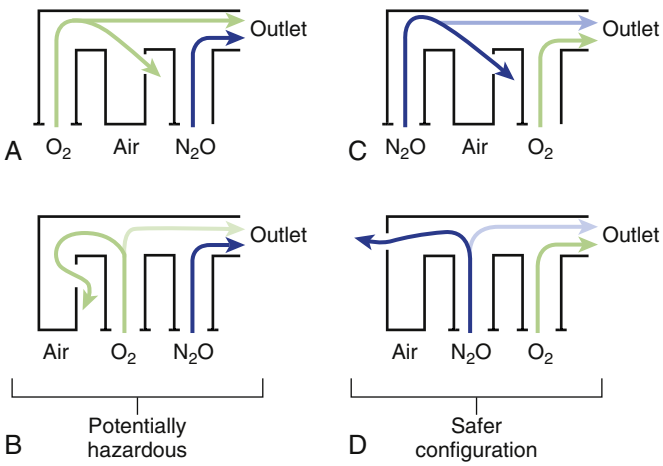

Figure 29-9. The flowmeter sequence is a potential cause of hypoxia. In the event of a flowmeter leak, a potentially dangerous arrangement exists when nitrous oxide is located in the downstream position (**A** and **B**). A safer configuration exists when oxygen is located in the downstream position (**C** and **D**). See text for details. *(Modified from Eger EI II, Hylton RR, Irwin RH, et al: Anesthetic flowmeter sequence: a cause for hypoxia,* Anesthesiology *24:396, 1963.)*

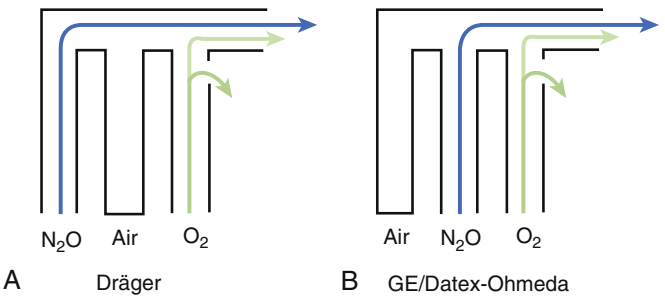

Figure 29-10. An oxygen leak from the flow tube can produce a hypoxic mixture regardless of the arrangement of the flow tubes (**A** shows a Dräger [Dräger Medical, Telford, Pa.] system, and **B** shows a GE Healthcare/Datex-Ohmeda [Datex Ohmeda, Madison, Wis.] system).

interconnected by a mobile horizontal shaft. Pneumatic input into the device comes from the oxygen and nitrous oxide flow control valves.

As oxygen flows out of the SORC, it encounters a resistor that creates backpressure. This backpressure is transmitted to the oxygen chamber diaphragm, which causes the diaphragm to move to the right, thereby opening the nitrous oxide proportioning valve. As the oxygen flow is increased, so too is the backpressure and the rightward motion of the shaft. If the nitrous oxide flow is now turned on, it will also flow into the SORC, through the proportioning valve, and past its resistor to create backpressure that will press on the diaphragm in its respective chamber. The counterbalance between the two gas flows (backpressures) determines the positioning of the nitrous oxide proportioning valve.[22] If the oxygen is turned down too low (<25% of the nitrous oxide flow), the shaft will move to the left and thus limit the nitrous oxide flow. If the operator tries to turn up the nitrous oxide too high relative to the oxygen flow, the SORC will limit the nitrous oxide flow regardless of how far the flow control valve is opened. If the oxygen flow is decreased to less than 200 mL/minute, the proportioning valve will close completely (see Fig. 29-11, *B*).[41]

Datex-Ohmeda Link-25 Proportion-Limiting Control System. A mechanical proportioning system that remains in use today on many conventional and modern anesthesia machines is the GE/Datex-Ohmeda Link-25 system (Datex-Ohmeda, Madison, Wis.). The system is based on a mechanical integration of the nitrous oxide and oxygen flow control valves and a difference in the taper of the needles of the oxygen and nitrous oxide flow control valves. It allows independent adjustment of either valve, yet it automatically intercedes to maintain a minimum oxygen concentration with a maximum nitrous oxide–oxygen flow ratio of 3:1. The Link-25 automatically increases oxygen flow when then nitrous oxide flow is increased to more than a certain point relative to oxygen flow to prevent delivery of a hypoxic mixture.

Figure 29-12 illustrates the Link-25 system. A 15-tooth sprocket is attached to the nitrous oxide flow control valve, and a 29-tooth sprocket is attached to the oxygen flow control valve. A chain physically links the sprockets. When the nitrous oxide flow control valve is turned through two revolutions, or 28 teeth, the oxygen flow control valve will revolve once because of the 2:1 gear ratio (see Fig. 29-12, *A*). The final 3:1 flow ratio results because the flow control valve needle for nitrous oxide

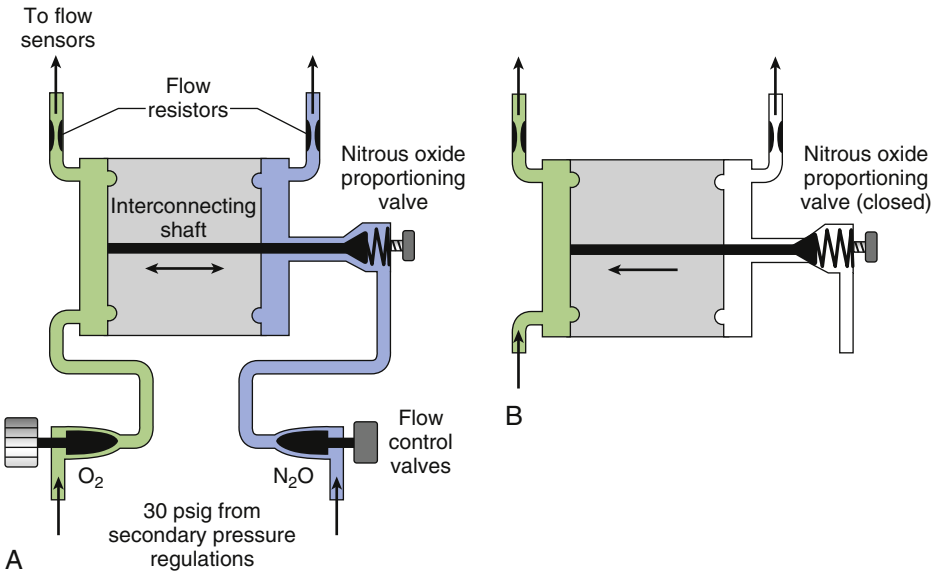

Figure 29-11. North American Dräger sensitive oxygen ratio controller system (SORC) (Dräger Medical, Telford, Pa.). The SORC is a pneumatic-mechanical interlock system designed to maintain a ratio of no less than 25%/75% nitrous oxide regardless of operator input. **A,** Main components. Differential oxygen and nitrous oxide flows and the resultant chamber backpressures determine the position of the nitrous oxide proportioning valve. See text for details**. B,** Complete closure of the proportioning valve when the oxygen flow is decreased to less than 200 mL/minute. *(Modified from Yoder M: Gas supply systems. In* Understanding modern anesthesia systems, *Telford, Pa., 2009, Dräger Medical.)*

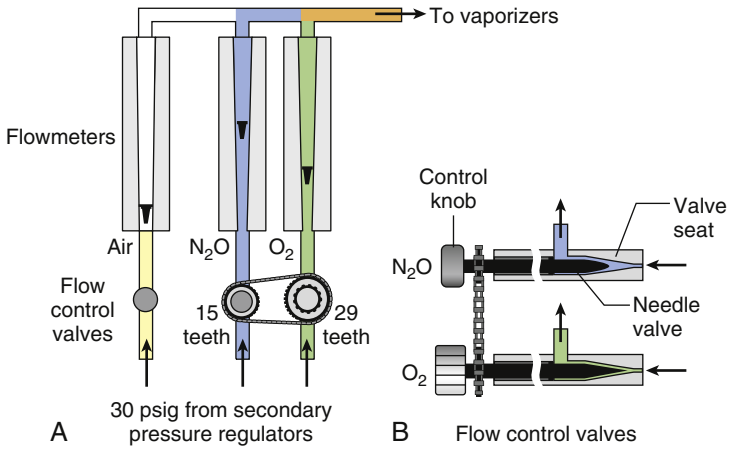

Figure 29-12. GE/Datex-Ohmeda Link-25 nitrous oxide: oxygen proportioning system. The system prevents the operator from selecting more than a 75% nitrous oxide–25% oxygen (3:1) mixture by two separate but interdependent means. **A,** Mechanical linkage of the control valves maintains no more than a 2:1 ratio. **B,** A faster taper of the nitrous oxide valve needle allows more gas flow through the valve per turn relative to flow through the oxygen valve per turn, thus resulting in the maximal 3:1 ratio. A stable and equal pressure supply to the valves is provided by the secondary pressure regulator for oxygen and a balance regulator for nitrous oxide. See text for additional details. *(Personal communication, GE Healthcare, Little Chalfont, United Kingdom, 28 February, 2013.)*

has a faster taper than does the oxygen valve needle (see Fig. 29-12, *B*). This situation results in more nitrous oxide flow per turn relative to flow through the oxygen valve per turn. Earlier versions of the system relied on a differential supply pressure to the valves rather than different needle tapers. With the current version, the pressure supplied to the valves is equal. Oxygen is supplied by a secondary regulator at 30 psig, and nitrous oxide is supplied by a balance regulator that is piloted by the oxygen supply pressure (see Fig. 29-1). If the oxygen pressure were to decrease, the nitrous oxide pressure would decrease by an equal amount. In this way, the balance regulator is also acting as a fail-safe valve. The Link-25 proportioning system can be thought of as a system that increases oxygen flow when necessary to prevent delivery of a fresh gas mixture with an oxygen concentration of less than 25%. In contrast, pneumatic systems such as the SORC work by limiting nitrous oxide flow.

Limitations. Proportioning systems are not immune from failure, and workstations equipped with proportioning systems can still deliver a hypoxic mixture under certain conditions. The following sections briefly present some situations in which this can occur.

Proportioning System Malfunction. Reports of proportioning system malfunction have described failures that resulted in an inability to administer oxygen without nitrous oxide or to increase oxygen flow or allowed creation of a hypoxic mixture.[42-46]

Wrong Supply Gas. Both mechanical and pneumatic proportioning systems can be defeated if a gas other than oxygen is present in the oxygen pipeline. If the pressure in the oxygen circuit is adequate, then the only device that will save the patient from experiencing a hypoxemic gas mixture is the oxygen analyzer within the patient's breathing circuit.

Leaks Downstream. Proportioning systems function at the level of the flow control valves. A leak downstream from these devices, such as a broken oxygen flow tube (see Fig. 29-10), can result in delivery of a hypoxic mixture to the common gas outlet. In this situation, oxygen escapes through the leak, and the predominant gas delivered is nitrous oxide. The inspired oxygen monitor is the only machine safety device that can detect this problem.

Dilution of Inspired Oxygen Concentration by Volatile Inhaled Anesthetic Agents. Volatile inhaled anesthetic agents are added to the mixed gases downstream from both the flowmeters and the proportioning system. Concentrations of less potent inhaled anesthetic agents such as desflurane may account for a larger percentage of the total fresh gas composition than is the case with more potent agents. This situation can be seen when the maximum vaporizer dial settings of the various volatile agents are examined (e.g., a desflurane maximum dial setting of 18% versus an isoflurane maximum dial setting of 5%). Because significant percentages of these inhaled anesthetic agents may be added downstream of the proportioning system, the resulting gas-vapor mixture may contain an inspired oxygen concentration less than 21% despite a functional proportioning system. The anesthesia care provider must be aware of this possibility, particularly when high concentrations of less potent volatile inhaled anesthetic agents are used.

Vaporizer Mount and Interlock System

Vaporizer Mounting Systems. Modern vaporizer mounts allow for detachment and replacement of the anesthetic vaporizers by the workstation operator. The benefits of detachable vaporizer mountings include ease of maintenance, the need for fewer vaporizer positions on the workstation, and the ability to remove the vaporizer in the setting of malignant hyperthermia.[47] The problems associated with detachable mounting systems stem from an increased potential for low-pressure systems leaks or fresh gas flow obstruction as a result of an inappropriately seated vaporizer or other connection-related failures.[47-51] After adding a vaporizer to the anesthesia machine, the operator should make sure it is properly and securely seated and cannot be removed once locked. The operator should then perform a low-pressure system leak test.[47] With all but the Datex-Ohmeda Anesthesia Delivery Unit (ADU) vaporizer and the Maquet (Maquet Critical Care, Solna, Sweden) vaporizer, the operator will need to turn the vaporizer on to test it for a leak.

Vaporizer Interlock Devices. All anesthesia workstations must prevent fresh gas from flowing through more than one vaporizer at time.[12] The design of vaporizer interlock devices varies significantly. Operators should be aware that these devices are not immune from to failure, and anesthetic overdose is the potential consequence.[52-55]

Outlet Check Valve. Many older Datex-Ohmeda anesthesia machines and a few contemporary workstations (e.g., GE/Datex-Ohmeda Aestiva and Aespire) have a one-way check valve located between the vaporizer and the common gas outlet in the mixed-gas pipeline (see Fig. 29-1). The purpose of this valve is to prevent backflow into the vaporizer during positive-pressure ventilation, thereby minimizing the effects of intermittent fluctuations in downstream pressure on the concentration of inhaled anesthetic (see the discussion of intermittent backpressure in the section on vaporizers). The presence or absence of this check valve historically influenced which *manual* preoperative leak test of the low-pressure system was indicated because it precluded positive-pressure tests to detect for leaks upstream of the valve (see the section on checking anesthesia workstations).

ANESTHETIC VAPORIZERS

In 1846, William T. G. Morton performed the first public demonstration of ether anesthesia using an ingenious, yet simple inhaler (Fig. 29-13).[56-58] Although the device was effective in delivering anesthetic vapor, Morton's ether inhaler had no means of regulating its output concentration or compensating for changes in temperature caused by vaporization of the liquid anesthetic and the ambient environment. These two issues were central to the subsequent development and evolution of modern anesthetic vaporizers. Modern variable bypass–type vaporizers are temperature compensated and can maintain desired outputs accurately over a wide range input gas flow rates. In 1993, with the introduction of desflurane to the clinical

Figure 29-13. Morton's ether inhaler: A replica of the inhaler used by William T.G. Morton during his public demonstration of ether anesthesia in October of 1846 at Massachusetts General Hospital in Boston. *(Courtesy the Wood Library–Museum of Anesthesiology, Park Ridge, Ill.)*

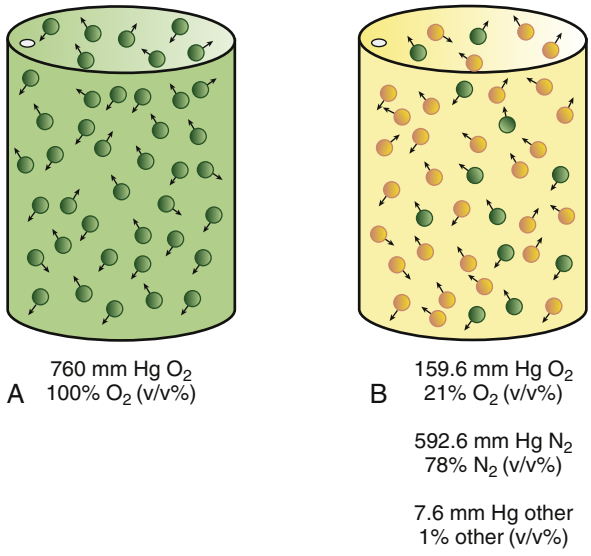

Figure 29-14. Partial pressures. **A,** Theoretical chamber containing 100% oxygen by volume at ambient pressure, which in this case is 1 atm (760 mm Hg). The oxygen molecules within the container account for the entirety of the wall tension. $P_{total} = P_{oxygen} = 760$ mm Hg. **B,** Pure oxygen is replaced with air, and now the sum of the nitrogen, oxygen, and the other molecules present in air accounts for the wall tension. $P_{total} = P_{oxygen} + P_{nitrogen} + P_{other} = 760$ mm. See text for more details.

setting, a unique and even more sophisticated vaporizer was introduced to handle the unique physical properties of this agent. Vaporizers blending both old technology and new computerized control technology also emerged in "cassette" vaporizer systems. An injection-type vaporizer has also been reintroduced. This vaporizer sprays precise amounts of liquid anesthetic agent into the fresh gas stream. Before discussing any of these systems, certain physical principles are briefly reviewed to facilitate an understanding of the operating principles, construction, and design of contemporary anesthetic vaporizers.

Physics

Dalton's Law of Partial Pressures. When a gas exists within a container, the gas molecules bombard the container walls and create a pressure that is proportional to the number of molecules of gas present within the space. The units usually used to express this pressure when describing the anesthetic breathing gases are millimeters of mercury (mm Hg) or kilopascals (kPa). In Figure 29-14, *A,* oxygen fills a theoretical container that is open to the ambient environment through a very small hole. The pressure in the container is equal to the ambient pressure, which in this case is 760 mm Hg. The oxygen molecules create all the wall tension within the space. In Figure 29-14, *B,* the container has now been filled with air, and the sum of the oxygen and nitrogen molecules creates the wall tension. If the container were to be sealed and only the oxygen molecules were removed, the pressure in the container would become subatmospheric, represented only by the pressure created by the nitrogen molecules (≈593 mm Hg). When a mixture of gases exists in a space such as the example container, each gas creates its own pressure, which is the same pressure as if it occupied the container alone (Dalton's law of partial pressures).[59] The individual gas tensions exerted by each of the constituent gases are referred to as *partial pressures*.

$$\text{Pressure}_{total} = P_1 + P_2 + P_3 + \ldots$$

In the context of describing the breathing gases in anesthesiology, the sum total of the partial pressures of the constituent gases is equal to the ambient or atmospheric pressure. At sea level, the ambient pressure is 760 mm Hg, which can also be expressed as 1 atm or 101.325 kPa.

Evaporation and Vapor Pressure. Inhaled anesthetic agents are termed volatile because, like other volatile liquids, they possess a high propensity to evaporate, or *vaporize*. When a liquid such as an inhaled anesthetic agent is exposed to air or other gases, molecules at the fluid surface that have sufficient energy escape from the liquid phase and enter the vapor phase. This process is known as evaporation, which is purely a surface phenomenon. If this process occurs within a contained environment, such as the vaporizing chamber of a variable bypass anesthetic vaporizer, the number of molecules entering the vapor phase will eventually equal those returning to the liquid phase (Fig. 29-15). The concentration of molecules in the vapor then remains constant, and the vapor is said to be "saturated" with anesthetic. At this point of evaporative equilibrium, the anesthetic molecules in the vapor phase are bombarding the walls of the container and creating a partial pressure known as the *saturated vapor pressure*, or simply *vapor pressure*. Substances with a high propensity to evaporate generate higher vapor pressures.

Vapor pressure is a physical property of a substance, with each substance having its own unique value at any

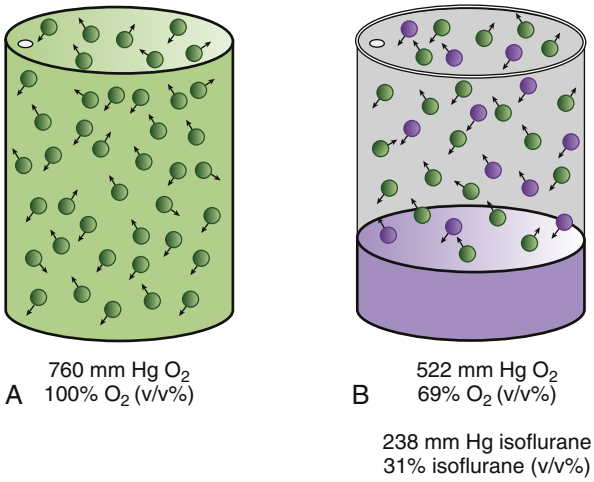

Figure 29-15. Evaporation (vaporization) and vapor pressure. **A,** Theoretical chamber containing 100% oxygen at 1 atm (760 mm Hg). The oxygen molecules within the container account for the entirety of the wall tension. $P_{total} = P_{oxygen} = 760$ mm Hg. **B,** Isoflurane is added to the container, and the temperature is maintained at 20° C (68° F). Evaporation commences, and isoflurane molecules begin to displace oxygen molecules out of the container. Once as many isoflurane molecules reenter the solution as leave it, the gas space above the liquid is said to be "saturated" with the vapor. The partial pressure of the isoflurane at this point is called the saturated vapor pressure (SVP), which at this temperature equals 238 mm Hg. $P_{total} = P_{oxygen} + P_{isoflurane} = 760$ mm.

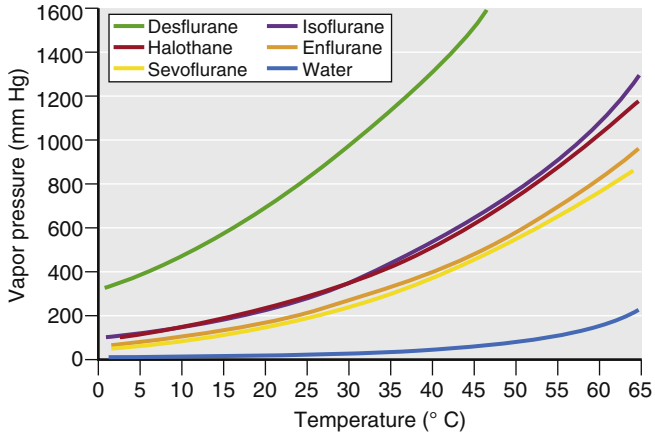

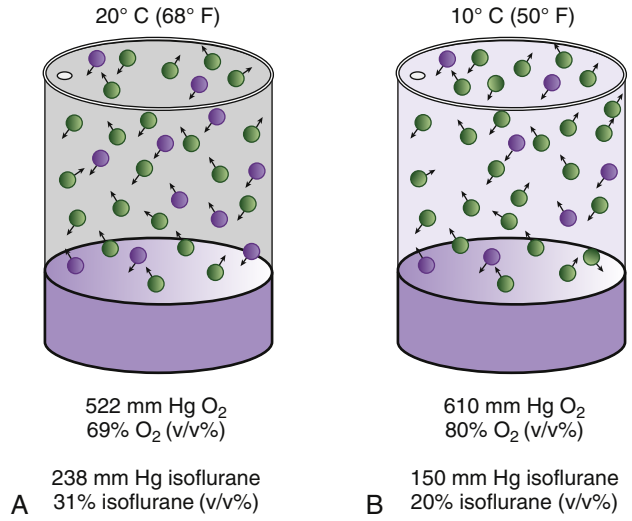

Figure 29-16. Vapor pressure–versus-temperature curves for desflurane, isoflurane, halothane, enflurane, sevoflurane, and water. Note that the vapor pressure curve for desflurane differs dramatically from that of the other contemporary inhaled anesthetic agents. Also note how the vapor pressure curves of the volatile agents compare with that of water *(From inhaled anesthetic package insert equations and Susay SR, Smith MA, Lockwood GG: The saturated vapor pressure of desflurane at various temperatures,* Anesth Analg *83:864-866, 1996.)*

$$P_{total} = P_{oxygen} + P_{isoflurane} = 760 \text{ mm Hg}$$

Figure 29-17. The impact of temperature on vapor pressure. **A,** Chamber containing oxygen and isoflurane at its SVP at 20° C (68° F). At evaporative equilibrium, the SVP of isoflurane in the container represents 31% of the entire gas composition by volume (v/v%). **B,** Decreasing the temperature by 10° C (16° F) to 10° C (50° F) substantially decreases the isoflurane vapor pressure to 150 mm Hg and causes isoflurane to represent only 20% of the entire gas volume (v/v%). This example assumes that some oxygen can enter the container to replace the liquefied isoflurane molecules.

given temperature (Fig. 29-16). Vapor pressure is temperature dependent and is *not* affected by changes in atmospheric pressure.[60] As illustrated in Figure 29-17, if the temperature of a liquid, such the anesthetic agent isoflurane, is decreased, evaporation is diminished because fewer molecules possess the energy to enter the vapor phase. Conversely, if the liquid temperature increases, evaporation is enhanced, and vapor pressure increases. Although ambient temperatures can alter liquid anesthetic vapor pressure, the cooling influence of evaporation has a far more pronounced and dynamic effect. The impact of evaporative temperature change on vaporizer and anesthetic inhaler output has been recognized since the mid-1800s, and addressing this phenomenon has been one of principal factors in the evolutionary design of anesthetic vaporizers.

Because vapor pressure values are unique to each liquid anesthetic agent, anesthetic vaporizers must be constructed in an agent-specific manner. If agent-specific vaporizers are inadvertently misfilled with incorrect liquid anesthetic agents, the resulting mixtures of volatile agents may demonstrate properties uniquely different from those of the individual component agents. The altered vapor pressure and other physical properties of the resulting azeotropic mixtures caused by combining various agents may change the output of the anesthetic vaporizer (see the discussion of misfilling in the section on variable bypass vaporizers).[61,62]

Expressing Gas Concentrations and Minimum Alveolar Concentration. When describing the proportion of a single gas in a sample containing a mixture of gases, we can refer to the individual gas in terms of its *partial pressure* (mm Hg) or by its percentage by volume relative to the sum volume of the all the gases present, which is known as *volume percent* or *volume-volume percent* (v/v%)[63]:

$$\text{Volume percent} = \frac{\text{Volume of gas } x}{\text{Total gas volume}}$$

The volume that a gas occupies at a given temperature and pressure is related to the number of molecules of gas present, not the size (type) of the molecules;

this is know as the *Avogadro Hypothesis*. Therefore, because partial pressure is directly proportional to the number of molecules of a gas that are present in the sample, we can also use partial pressure as a means to calculate the volume percent of any constituent gas[64]:

$$\text{Volume percent} = \frac{\text{Partial pressure of a gas (mm Hg)}}{\text{Atmospheric pressure (mm Hg)}}$$

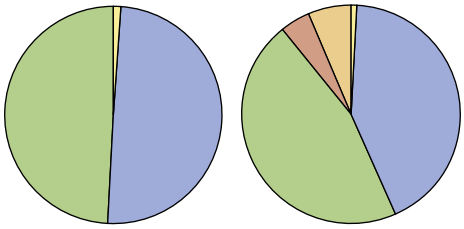
Using air at sea level as an example:

Partial pressures

760 mm Hg ≈ 160 mm Hg oxygen + 592 mm Hg nitrogen + 8 mm Hg other gases

Volume percent (v/v%)

100 % air ≈ 21 % oxygen + 78 % nitrogen + 1 % other gases



When anesthesiologists describe inhaled and exhaled anesthetic concentrations, they typically do so using volume percent. All anesthesiology practitioners understand the meaning of 1% isoflurane, but providing the value as 7.6 mm Hg isoflurane (the same amount at sea level) is typically out of context:

$$1\,\%\ \text{isoflurane} = \frac{7.6\ \text{mm Hg isoflurane}}{760\ \text{mm Hg (sea level)}}$$

The amount of oxygen and nitrous oxide in the breathing gas is also typically described in terms of volume percent. However, breathing gas carbon dioxide content (e.g., Et_{CO_2}) is usually displayed as a partial pressure (mm Hg). This was probably adopted because of the relatively close correlation between Et_{CO_2} and Pa_{CO_2}, and the latter's common expression as a partial pressure. Figure 29-18 illustrates a theoretical composition of the breathing gases during anesthesia in terms of concentration (v/v%) and partial pressures.

The minimum alveolar concentration (MAC) is described in terms of volume percent. MAC is the concentration of anesthetic that prevents movement from surgical stimulus in 50% of individuals.[65] MAC is an age-dependent phenomenon, and it can also be affected by other variables. MAC is a clinically useful value given that vaporizer control knobs are marked and calibrated in terms of anesthetic concentration. However, it is actually the anesthetic partial pressure (mm Hg) value in the brain that is responsible for anesthetic depth. MAC is simply an expression of gas concentration (v/v%), with the denominator being the barometric pressure where the MAC experiment was conducted (typically at sea level). The corresponding partial pressure for each MAC value is known as the minimal alveolar partial pressure (MAPP), as listed in Table 29-1.[66] When discussing anesthetic vaporizers, it is useful to think about their output in terms of partial pressure and how it relates to volume percent and MAC, especially when considering changes in ambient pressure. The impact of barometric pressure on vaporizer output is discussed later.

Latent Heat of Vaporization. When a molecule of liquid evaporates into the gaseous phase, energy is required because the molecules of a liquid are cohered. The amount of energy that is consumed by a specific liquid when it is converting to a vapor is referred to as the *latent heat of vaporization*. It is more precisely defined as the number of

	Inhalation		Exhalation	
Gas	mm Hg	v/v%	mm Hg	v/v%

Oxygen	378	49.75	323.2	42.5
N_2O	372.5	49	347.2	45.8
CO_2	–	–	35	4.5
H_2O	–	–	47*	6.2
Total	760	100	760	100

*Saturated vapor pressure of water at body temperature.

Figure 29-18. Common units of measure for breathing circuit gases: theoretical values for an oxygen-nitrous oxide-sevoflurane anesthetic. Anesthetic agent, oxygen, and nitrous oxide concentrations are typically expressed in volume percent (v/v%). Carbon dioxide is commonly described as a partial pressure (mm Hg).

calories required to change 1 g of liquid into vapor without a change in temperature. The energy for vaporization must come from the liquid itself, and in the absence of an outside energy source the temperature of the liquid decreases during vaporization. This energy loss can lead to significant decreases in temperature within the remaining liquid, which will reduce vapor pressure and subsequent vaporization.[47,60,67] Unless the evaporative cooling effect of the liquid anesthetic agent is mitigated and compensated for, vaporizer output will decrease.

Boiling Point. The *boiling point* of a liquid is defined as the temperature at which vapor pressure equals atmospheric pressure and the liquid begins to boil.[47,67] In Table 29-1, note the boiling points for the various anesthetic agents at 1 atm. Desflurane boils at 22.8° C, and the other four inhaled anesthetic agents boil at between 45° C and 60° C. Whereas evaporation is a surface phenomenon, boiling occurs throughout the body of the liquid. Unlike vapor pressure, the boiling point is directly proportional to atmospheric pressure. A liquid's boiling point is inversely related to its volatility. The lower the boiling point, the more likely a liquid is to vaporize. For comparison, the boiling point for water at sea level is 100° C (212° F), far in excess of the boiling point of the volatile anesthetic agents.

In reviewing the boiling points of contemporary volatile anesthetic agents, it becomes clear that under most clinical situations, the boiling point is not a functional issue. Desflurane, however, boils at 22.8° C (73° F), which is a temperature encountered in clinical settings. This unique physical characteristic, along with its high saturated vapor pressure, mandates a special vaporizer design to control the delivery of this agent (see the section on the desflurane vaporizer). Isoflurane and halothane could theoretically boil at high altitudes and very high temperatures. At least one manufacturer lowers its vaporizer's

TABLE 29-1 **PHYSICAL PROPERTIES OF INHALED VOLATILE ANESTHETIC AGENTS**

Property	Halothane	Isoflurane	Sevoflurane	Desflurane
SVP* @ 20° C (mm Hg)	243	238	157	669
SVC† @ 20° C at 1 atm‡ (v/v%)	32	31	21	88

v/v%, Volume percent.
*SVP, Saturated vapor pressure. From anesthetic prescribing information.
†SVC, Saturated vapor concentration: the percentage of anesthetic agent relative to ambient pressure within an equilibrated (saturated) container (SVP/ambient pressure).
‡1 atm, 1 atmosphere = ambient pressure at sea level (760 mm Hg).
§MAC, Minimum alveolar concentration: the alveolar concentration that produces immobility in response to a noxious stimulus in 50% of subjects.[65] The denominator is approximately sea level pressure (760 mm Hg).
¶MAPP, Minimum alveolar partial pressure. The alveolar partial pressure that produces immobility in response to a noxious stimulus in 50% of subjects (the numerator in the MAC calculation).[66] Not affected by altitude. Calculated as MAC (fraction) × 760 mm Hg (i.e., for isoflurane = 0.012 × 760 mm Hg).

maximum temperature operating range for these anesthetic agents.[68]

Specific Heat. The *specific heat* of a substance is the number of calories required to increase the temperature of 1 g of a substance by 1° C.[47,67] The concept of specific heat is important to the design, operation, and construction of vaporizers because it is applicable in two ways. First, the specific heat for an inhaled anesthetic agent is important because it indicates how much heat must be supplied to the liquid to maintain a constant temperature when heat is being lost during vaporization. Second, manufacturers select vaporizer component materials that have high specific heat because these materials better resist temperature changes associated with vaporization.

Thermal Conductivity. Thermal conductivity is a measure of the speed at which heat flows through a substance. The higher the thermal conductivity, the better the substance will conduct heat.[47] Vaporizers are constructed of metals that have relatively high thermal conductivity, which helps them maintain a uniform internal temperature during evaporation by allowing them to absorb environmental heat more effectively.

Modern Vaporizer Types

Generic vaporizer nomenclature can be somewhat confusing, especially if the historical context of vaporizer, workstation, and breathing circuit evolution is not considered. Vaporizers are first designated as *in-circuit* or *out-of-circuit*, which describes their relationship to the patient's breathing circuit. Virtually all modern vaporizers are located outside the patient's breathing circuit, and their controlled output is introduced into the breathing circuit through a fresh gas line. In-circuit vaporizers are found mainly within the so-called *draw-over* anesthesia systems, which are of great historical significance in anesthesiology and are still used in some settings.

The second designation involves the specific types of vaporizers, and these currently include the *variable bypass vaporizer*, the *dual-circuit vaporizer* (e.g., classic desflurane vaporizer), *the cassette vaporizer* (e.g., Datex-Ohmeda Aladin cassette), the *injection vaporizer* (e.g., the Maquet vaporizer), and the now historical *measured-flow vaporizer* (e.g., Copper Kettle). Variable bypass vaporizers can be subcategorized as *plenum type,* which are located out of the breathing circuit and have relatively high internal flow resistance, or *draw-over type,* which are located within the breathing circuit (in-circuit) and have low internal resistance. Within most modern clinical settings, variable bypass vaporizers are *plenum type* and are located out of the breathing circuit, like those seen in Figures 29-1 and 29-2. Draw-over–type variable bypass vaporizers are used with draw-over anesthesia circuits, which are very uncommon today. Variable bypass vaporizers are associated with some additional designations such as *agent-specific*, *flow-over*, *temperature-compensated*, and *pressure-compensated*, which are discussed later.

Variable Bypass Vaporizers. When volatile anesthetic agents evaporate, their resultant saturated gas concentrations greatly exceed those used clinically, so these concentrations must be diluted to safe ranges (Table 29-1). *Variable bypass* refers to the method of carefully regulating the concentration of vaporizer output by diluting gas fully saturated with anesthetic agent with a larger flow of gas. A diagram of a variable bypass vaporizer is shown in Figure 29-19, *A*. Basic vaporizer components include a vaporizer inlet port (fresh gas inlet), the concentration control dial, the bypass chamber, the vaporizing chamber, the vaporizer outlet port, and the filling assembly. The maximum safe level of the vaporizer corresponds to the filling port, which is situated to minimize the chance of overfilling. A concentration control dial determines the ratio of gas that flows through the bypass chamber and the vaporizing chamber, and a temperature-compensating device further adjusts that ratio. Vaporizer concentration control dials are labeled to set vaporizer output in terms of volume percent (v/v%), and the vaporizers are calibrated at sea level.

Figure 29-20 illustrates volatile anesthetic equilibrium concentrations within a theoretical vaporizing chamber of a variable bypass vaporizer. As can be seen, the anesthetic concentration within the chamber (21% sevoflurane) far exceeds the clinical concentration. Figure 29-20 also depicts the volume of anesthetic vapor that is added to the gas stream as it flows through the chamber. Although this example and others in the chapter imply that the gas flowing through the vaporizing chamber becomes fully saturated with anesthetic vapor, this is actually not

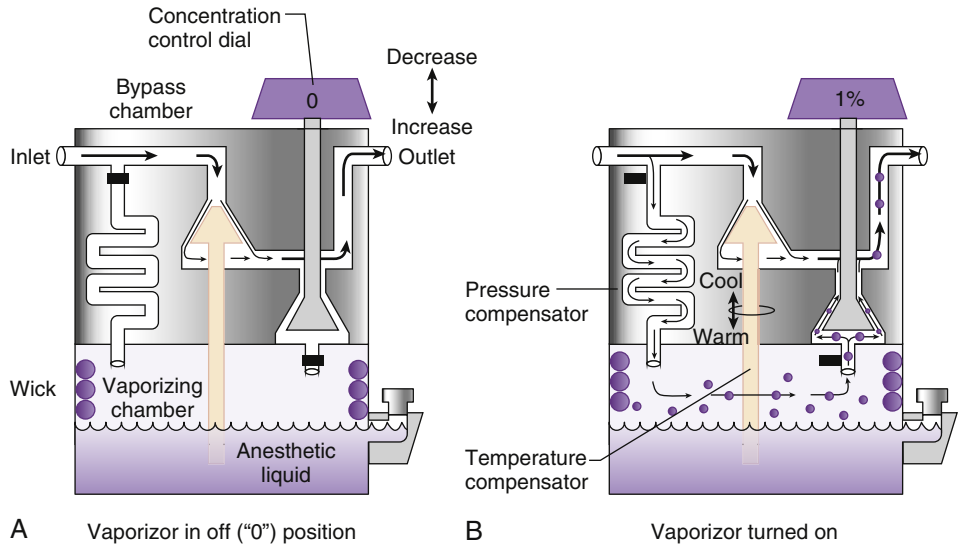

Figure 29-19. Variable bypass vaporizer. **A,** Basic component parts. Vaporizer in the off or "0" position. Fresh gas from the flowmeter assembly enters the vaporizer and then flows through the bypass chamber, around the temperature compensator, and out the vaporizer without passing through the vaporizing chamber. **B,** Selecting a vaporizer output (turning the vaporizer "on") diverts an agent-specific ratio of gas through the pressure-compensating labyrinth, into the vaporizing chamber where it becomes saturated with anesthetic vapor, and then past the concentration cone where it reunites with the fresh gas stream. The temperature compensation device further adjusts the ratio of bypass to vaporizing chamber flow, to compensate for changes in anesthetic vapor pressure resulting from temperature changes. As the liquid anesthetic cools by evaporation, more gas is diverted to the vaporizing chamber to compensate for the decrease in anesthetic vapor pressure. The pressure-compensating labyrinth compensates for pressure fluctuations within the vaporizer from the gas supply side and the breathing circuit side to stabilize vaporizer output. It is *not* present to compensate for changes in atmospheric pressure. Please see text for additional details.

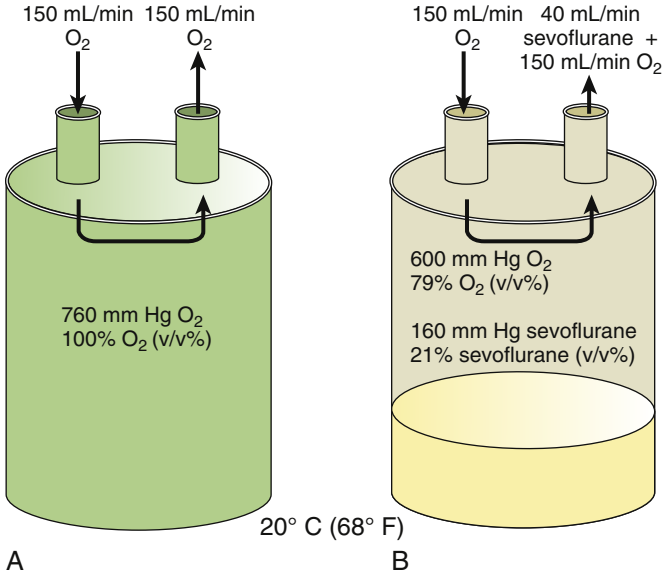

Figure 29-20. Theoretical vaporizing chamber demonstrating the volume of anesthetic gas added to the gas flow stream as a result of evaporation: **A,** 150 mL/minute of oxygen flows through the chamber at 1 atm (760 mm Hg) and 68° F (20° C). Oxygen represents 100% of chamber volume and output. **B,** Liquid sevoflurane is added to the chamber and evaporates to saturated vapor pressure SVP (160 mm Hg), which dilutes the oxygen to 79% of the chamber gas (600 mm Hg). The amount of gaseous sevoflurane that has been added to the chamber output can be calculated by simple equilibrium proportions: Step 1: 150 mL O_2/79% of container gas = *x* mL sevoflurane/21% of container gas Step 2: rearrange to solve for *x*: (150 mL/0.79) × 0.21 = *x* mL sevoflurane $x \approx 40$ mL sevoflurane.

the case. Vaporizing chamber gas becomes partly saturated as a result of constant gas flow.[69] However, for the purposes of this discussion, it is useful to assume that full saturation occurs.

Figure 29-21 illustrates a modern variable bypass vaporizer set to deliver 2% sevoflurane. Note how the majority of fresh gas flows straight through the bypass chamber. Figure 29-21 also illustrates how bypass flow and vaporizing chamber output combine to create the output concentration selected by the practitioner. The fresh gas that is diverted to the vaporizing chamber becomes saturated with anesthetic gas by flowing over liquid agent and the wicking system, hence the designation *flow-over*. The specific ratio of fresh gas flow divided between the bypass chamber and the vaporizing chamber is determined by the concentration control dial setting and the temperature compensation device (see the later discussion of temperature compensation). Because the physical properties and clinical concentrations of each agent are unique, the concentration-specific diverting ratios are specific to each agent, hence the vaporizer designation *agent specific*. The approximate variable bypass diverting or "splitting ratios" for the common anesthetic agents at 20° C are shown in Table 29-2. Variable bypass vaporizers can be used to deliver halothane, isoflurane, and sevoflurane, and older agents, but not desflurane, because of this agent's unique physical properties (see section on the desflurane vaporizer). Most variable bypass vaporizers are used in applications whereby their output is introduced into the patient's breathing circuit through a fresh gas line, hence the designation *out-of-circuit*. When these

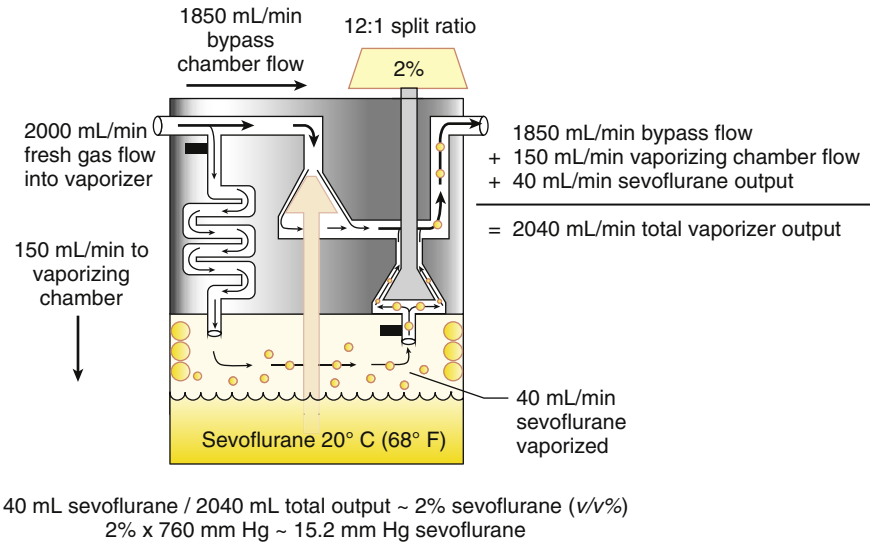

Figure 29-21. Vaporizer set to deliver 2% sevoflurane at 1 atm (760 mm Hg): 2% sevoflurane requires a splitting ratio of 12:1 (see Table 29-2). At 2000 mL/minute inflow, 1850 mL/minute flows through the bypass chamber and 150 mL/minute flows through the vaporizing chamber. The evaporation of sevoflurane contributes approximately 40 mL/minute of vapor:
Step 1: 150 mL O_2/79% of vaporizing chamber gas = *x* mL sevoflurane/21% of vaporizing chamber gas
Step 2: rearrange to solve for *x*: (150 mL/0.79) × 0.21 = *x* mL sevoflurane
$x \approx 40$ mL sevoflurane
Total vaporizer output is 2040 mL/minute. Sevoflurane represents ≈ 2% of that output.

TABLE 29-2 VARIABLE BYPASS VAPORIZER SPLITTING RATIOS

Concentration Control Dial Setting (v/v%)	Bypass Chamber–to–Vaporizing Chamber Splitting Ratios at 20° C (68° F)*		
	Halothane	Isoflurane	Sevoflurane
1	46:1	45:1	25:1
2	23:1	22:1	12:1
3	15:1	14:1	8:1

v/v%, Volume percent.
*Ratio of fresh gas flowing through the bypass chamber relative to the vaporizing chamber for the listed output concentrations. The temperature compensation device may alter the actual ratio. This applies to variable bypass vaporizers only. Calculated from: % volatile agent output = 100 × P_V × F_V / F_T (P_A – P_V) where P_A = atmospheric pressure, P_V = vapor pressure at 20° C, F_V = Flow of fresh gas through vaporizing chamber (mL/min), and F_T = total fresh gas flow (mL/min).
From Prescribing information Forane [isoflurane, USP]. *Deerfield, IL, 2009, Baxter Healthcare.*

agents are physically located within the patient's breathing circuit, they are designated as *in-circuit*, or *draw-over*.

Virtually all variable bypass vaporizers are classified as *temperature compensated*. Each of these vaporizers is equipped with an automatic temperature-compensating device that helps maintain constant vaporizer output over a wide range of operating temperatures by automatically altering the ratio of gas flowing to the bypass and vaporizing chambers. A representative temperature-compensating system is illustrated in Figure 29-19, *B*. Temperature compensation is accomplished by an expansion-contraction element, as seen in the image, or a bimetallic strip, that directs a greater proportion of gas flow through the vaporizing chamber as the liquid anesthetic cools from evaporation or a low ambient temperature, or both. In the example in Figure 29-19, *B*, as the liquid anesthetic agent cools, the temperature-compensating cone moves upward, which restricts bypass flow and diverts more gas to the vaporizing chamber. Cooler liquid anesthetic results in lower vapor pressure, so the net effect of temperature compensation is the maintenance of relatively stable vaporizer output. The inverse is also true, in that higher anesthetic temperatures result in lowering of the cone and less flow to the vaporizing chamber. The major temperature effect on vaporizers results from the evaporative cooling of the liquid anesthetic. The faster it evaporates, the more it cools. Rub some isopropyl alcohol on your skin, and feel your skin cool as the alcohol rapidly turns to vapor. Imagine the effect of this type of cooling on anesthetic agent vapor pressure! This knowledge has influenced vaporizer design for more than a century. Variable bypass vaporizers are also constructed from materials with high specific heat for temperature stability and high thermal conductivity to transfer ambient heat energy rapidly. Additionally, the wick systems previously mentioned are placed in contact with the metal wall of the vaporizer to absorb environmental heat better.

Factors That Influence Variable Bypass Vaporizer Output. An ideal variable bypass vaporizer at a given setting would maintain a constant concentration output regardless of varied conditions such as the fresh gas flow rate, temperature changes, intermittent backpressure from the breathing circuit, changes in carrier gas composition, and barometric pressure changes. ASTM standards state that the average output should not deviate from the dial setting by +30% or –20% or more than +7.5% or –5% of the maximum setting (ASTM). Although modern vaporizers generally have excellent performance characteristics, it is important to understand how these challenges could potentially influence vaporizer output.

Impact of Gas Flow Rate. Vaporizer output can vary with the rate of gas flowing through the vaporizer. As can be

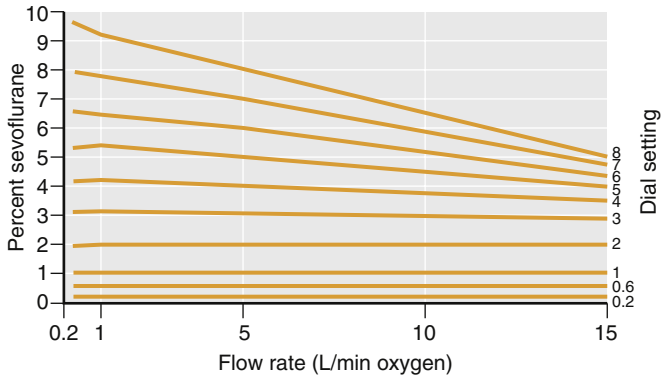

Figure 29-22. Effect of flow rate on vaporizer output. See text for explanation. *(From Datex-Ohmeda:* Tec 7 vaporizer: user's reference manual, *Madison, Wis., 2002, Datex-Ohmeda.)*

seen in Figure 29-22, this variation is notable only at the extremes of flow rates and at higher dial settings. The output of variable bypass vaporizers tends to be slightly less than the dial setting at low flow rates (<250 mL/minute) because of the relatively high density of volatile inhaled anesthetic agents. Insufficient turbulence is generated in the vaporizing chamber at low flow rates to advance the vapor molecules upwardly. At extremely high flow rates, such as 15 L/minute, the output of most variable bypass vaporizers is somewhat less than the dial setting at high anesthetic concentrations. This discrepancy is multifactorial, including cooling during rapid evaporation, incomplete mixing, and failure to saturate the carrier gas in the vaporizing chamber. In addition, the resistance characteristics of the bypass chamber and the vaporizing chamber can vary as flow increases.[68,70]

Impact of Temperature Change. Despite the impact of evaporative cooling and ambient conditions, modern vaporizer concentration output remains fairly linear over a wide range of vaporizer temperatures. Automatic temperature-compensating mechanisms in the bypass chamber strive to maintain constant vaporizer output with varying temperatures, although the linear change in these compensatory mechanisms does not correlate precisely with the shape of the vapor pressure curves.[21,68] As a result, a slight correlation between delivered concentration and vaporizer temperature may remain. This correlation is mainly apparent at higher temperatures and higher concentrations. A dangerous but highly unlikely circumstance could occur if the boiling point of a volatile agent within a variable bypass vaporizer were reached. In this situation, the vaporizer output would be impossible to control by any compensatory mechanism. Although it would be rare indeed to reach the ambient temperatures required at sea level to boil halothane, isoflurane, or sevoflurane, at higher altitudes, where boiling points are lower, isoflurane and halothane are theoretically vulnerable. In fact, the Dräger Vapor 2000 user's manual decreases the high-altitude operating specification for the vaporizer from 9880 to 4800 feet if halothane or isoflurane is used at higher ambient temperatures. Manufacturers' published vaporizer operating temperatures range from 10° C to 40° C (50° C to 104° F), although the specific ranges vary.[68,70-74]

Impact of Intermittent Backpressure. The intermittent backpressure that results from either positive-pressure ventilation or use of the oxygen flush valve may lead to higher than expected vaporizer output. This phenomenon, known as the *pumping effect*, is more pronounced at low flow rates, low dial settings, and low levels of liquid anesthetic in the vaporizing chamber.[47,68,75-77] Additionally, the pumping effect is increased by rapid respiratory rates, high peak inspired pressures, the use of anesthesia machines without fresh gas decoupling, and rapid drops in pressure during expiration.[47,60,67,68,78,79] Although contemporary variable bypass vaporizers are not highly vulnerable to the pumping effect, the proposed mechanism of the phenomenon and preventative design features should be understood. The pumping effect is caused by retrograde transmission of pressure from the patient circuit to the vaporizer during the inspiratory phase of positive-pressure ventilation or use of the oxygen flush function. Gas molecules are compressed in both the bypass and vaporizing chambers. When the backpressure is suddenly released during the expiratory phase of positive-pressure ventilation, vapor exits the vaporizing chamber both through the vaporizing chamber outlet and in the retrograde direction through the vaporizing chamber inlet because the output resistance of the bypass chamber is lower than that of the vaporizing chamber, particularly at low dial settings. The enhanced output concentration results from the increment of vapor that travels in the retrograde direction to the bypass chamber.[68,76,77,80]

To decrease the pumping effect, modern vaporizing chambers are smaller than those of early variable bypass vaporizers.[77] Therefore, no substantial volumes of vapor can be discharged from the vaporizing chamber into the bypass chamber during the expiratory phase. Additionally, some vaporizers, such as that shown in Figure 29-19, have a long spiral tube or labyrinth that serves as the inlet to the vaporizing chamber[77] (see Fig. 29-19, *B*). When the pressure in the vaporizing chamber is released, some of the vapor enters this tube but does not enter the bypass chamber because of tube length.[60] This serpentine passage also decreases the energy of the gas flow into the vaporizing chamber, thus dampening the pressure fluctuations. It can also compensate for fluctuations in gas supply pressure. Some designs may also include an extensive baffle system in the vaporizing chamber. Finally, a one-way check can be inserted past the vaporizers but before the breathing circuit inlet to minimize the pumping effect (see the discussion of the gas supply system). This check valve attenuates but does not eliminate the increase in pressure because gas still flows from the flowmeters to the vaporizer during the inspiratory phase of positive-pressure ventilation.[47,81] Although intermittent backpressure can result in transient rises in anesthetic concentration at the common gas outlet, dilution within the anesthetic breathing circuit tends to mitigate this effect.[82] The goal of all these pressure-compensating mechanisms is to provide an even flow of gas through the vaporizing chamber despite dynamic changes in outlet and inlet pressure. These devices lend the additional designation *pressure-compensated*. Clearly, these devices do not compensate for changes in ambient pressure, which is what some practitioners mistakenly infer from the term.

Impact of Carrier Gas Composition. Variable bypass vaporizer output can be influenced by the composition

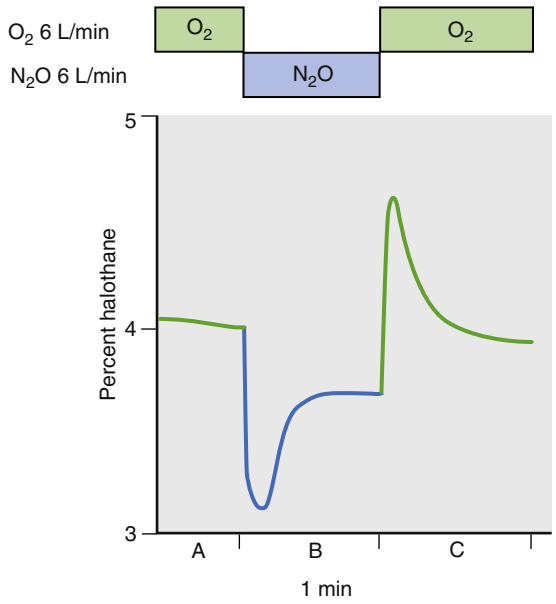

Figure 29-23. Halothane output of a North American Dräger Vapor 19.n vaporizer (Dräger Medical, Telford, Pa.) with different carrier gases. The initial output concentration is approximately 4% halothane when oxygen is the carrier gas at flows of 6 L/min (*A*). When the carrier gas is quickly switched to 100% nitrous oxide (*B*), the halothane concentration decreases to 3% within 8 sec. A new steady-state concentration of approximately 3.5% is then attained within about 1 min. When O_2 flow is reestablished, halothane output increases abruptly and then settles back to baseline (*C*). See text for details. *(Modified from Gould DB, Lampert BA, MacKrell TN: Effect of nitrous oxide solubility on vaporizer aberrance,* Anesth Analg *61:939, 1982.)*

of the fresh gas as a result of differences in solubility of anesthetic vapors in different carrier gas mixtures. This effect is most pronounced when nitrous oxide is introduced or removed as a carrier gas.[68,83-90] In the experimental example seen in Figure 29-23, a change in carrier gas from 100% oxygen to 100% nitrous oxide results in a sudden decrease in volume percent halothane output that is followed by a slow increase to a new steady-state value (see Fig. 29-23, label *B*).[88,89] Because nitrous oxide is more soluble than oxygen in the halogenated liquid within the vaporizer sump, the output from the vaporizing chamber is transiently reduced as some of the nitrous oxide is literally absorbed by the volatile agent, thus decreasing the vaporizing chamber volume output.[88] Once the anesthetic liquid becomes saturated with nitrous oxide, vaporizing chamber output increases, and a new steady state is established.

The explanation for the new steady-state output value is less well understood.[90] Although ongoing absorption of nitrous oxide may be contributory, differences in the density and viscosity of oxygen and nitrous oxide are also responsible. These gas properties can affect the relative amount of flows through the bypass and vaporizing channels within the vaporizer. This may explain difference in seen in the magnitude of this phenomenon when it is assessed using different vaporizers.[86,89,91] Helium, a gas with far lower density than either oxygen or nitrous oxide, has been shown to both decrease and increase vaporizer output, depending on the vaporizer model and study design, although the changes tend to be minimal.[92,93]

Although the carrier gas composition can be demonstrated experimentally to affect vaporizer output, deviations are often within vaporizer-specified accuracy ranges. Vaporizer user's manuals usually specify the anticipated response to a change in carrier gas relative to the calibration gas, which may be air or oxygen, depending on the vaporizer model.[68,70,71,94]

Impact of Barometric Pressure Changes. Understanding the influence of barometric pressure change on variable bypass vaporizer output is probably more important for comprehending vaporizer function than for actual clinical reasons. This is because, from a practical point of view, with *variable bypass* vaporizers the depth of anesthesia at a given dial setting is relatively independent of atmospheric pressure, and no adjustments must be made (Table 29-3).[68]

Hypobaric Conditions. As previously discussed, vapor pressure is not influenced by barometric pressure. Therefore, as altitude increases and the barometric pressure declines, the partial pressure of anesthetic agent in the variable bypass vaporizing chamber remains constant despite a decline in the partial pressures of other constituent breathing gases and the total ambient pressure. This situation results in significantly increased volume percent concentration of anesthetic agent within the vaporizing chamber and at the outlet of the vaporizer (see Table 29-3). However, because anesthetic depth is based on brain *partial pressure,* the clinical impact in minor (see MAPP in Table 29-1). With a constant dial setting of 0.89%, at 1 atm, a well-calibrated isoflurane variable bypass vaporizer would deliver 0.89 v/v% isoflurane, and the partial pressure of isoflurane would be 6.8 mm Hg. Maintaining the same dial setting and lowering the atmospheric pressure to 0.66 atm or 502 mm Hg (roughly equivalent to an elevation of 10,000 feet) would result in an increase in the concentration output to 1.75% (almost double), but the partial pressure would increase to only 8.77 mm Hg (a 29% increase). To put this change into familiar perspective, a similar partial pressure change at sea level, in terms of volume percent, would increase the isoflurane concentration by only 0.2%. To reemphasize, the anesthetic brain partial pressure is what is ultimately responsible for anesthetic depth. The anesthetic concentration (v/v%) is a relative phenomenon.

As described earlier, MAC values for contemporary inhalational anesthetic agents were determined at sea level. Similarly, anesthetic vaporizers are calibrated at sea level, thus ensuring that vaporizer output (v/v%) matches the dial setting. Using sevoflurane as an example, one can therefore see how confusing that using volume percent and MAC can be when considering barometric change. Knowing that sevoflurane MAPP = 12.9 mm Hg:

$$\text{Sevoflurane MAC at sea level (v/v\%)} = \frac{12.9\text{ mm Hg}}{760\text{ mm Hg}} \approx 1.7\%$$

$$\text{Sevoflurane MAC at } 10,000\text{ feet (v/v\%)} = \frac{12.9\text{ mm Hg}}{534\text{ mm Hg}} \approx 2.4\%$$

The MAPP at altitude is the same as at sea level because it is based on partial pressure, whereas the MAC has increased because it is a simple concentration. After viewing the examples in Table 29-3, it becomes clear that the

atm, Atmospheres (1 atm = 760 mm Hg); *v/v%,* volume percent.
*ATA or atmospheres absolute. ATA = atmospheric pressure + water pressure. Hyperbaric oxygen chamber protocols apply ATA. Many protocols use depths from 2.0 to 2.5 ATA, but some conditions such as gas embolus or carbon monoxide poisoning may require depths to 3.0 ATA.[262] 2 ATA ≈ 33 feet of sea water (fsw) ≈ 1520 mm Hg ambient pressure.
Modified from Ehrenwerth J, Eisenkraft J: Anesthesia vaporizers. In Ehrenwerth J, Eisenkraft J, editors: Anesthesia equipment: principles and applications, *St. Louis, 1993, Mosby, pp 69-71.*

partial pressure output of a variable bypass vaporizer changes proportionally less than the volume percent concentration as altitude increases. Because anesthetic partial pressure is what determines anesthetic depth, the operator *does not* need adjust the dial to a higher setting to compensate for barometric pressure change. This holds for variable bypass vaporizers, but it is not the case for the desflurane Tec 6–style vaporizer, which is discussed in section on desflurane vaporizers.

Although anesthesia is sometimes delivered in *hyperbaric conditions,* volatile agents are an unlikely choice in this setting given the advent of intravenous anesthesia. Under hyperbaric conditions, the anesthetic partial pressure in the vaporizing chamber also remains constant despite an increase in ambient pressure and the partial pressure of the other gases. The net theoretical effects on variable bypass vaporizers are a significant decrease in anesthetic concentration (v/v%) and a mild decrease in partial pressure output. However, the partial pressure of halothane was noted to increase slightly with increasing barometric pressure under experimental conditions.[95] Possible explanations for this finding include the effect of increased atmospheric gas density on the flow of gas through the vaporizer and the increased thermal conductivity of air at higher pressure. The clinical significance of these small changes in variable bypass vaporizer partial pressure output under hyperbaric conditions is unclear.

Safety Features and Potential Hazards. Contemporary variable bypass vaporizers incorporate many features that have minimized or eliminated many hazards once associated with these devices. Agent-specific, keyed filling devices help prevent filling a vaporizer with the wrong agent. Overfilling of these vaporizers is minimized because the filler port is located at the maximum safe liquid level. Finally, today's vaporizers are firmly secured to a vaporizer manifold on the anesthesia workstation. Thus, problems associated with vaporizer tipping have become much less frequent. Contemporary interlock systems prevent the administration of more than one inhaled anesthetic agent. However, virtually all safety systems have vulnerabilities, so understanding these potentially hazardous situations is important.

Misfilling. Misfilling of anesthetic vaporizers can result in potentially hazardous volatile agent outputs that can overdose or underdose anesthetic agents.[96,97] Vaporizer output in these circumstances depends on the erroneous agent's saturated vapor pressure and the splitting ratio of the vaporizer. Similarly, mixtures of anesthetic agents can result potentially harmful dosing as well.[61] The potential for misfilling anesthetic vaporizers with the wrong agent has been reduced but not eliminated with the use of agent specific filling devices; however, current standards recommend but do not mandate the use of these devices.[12] A potential for misfilling exists even in vaporizers equipped with keyed fillers, although few recent reports exist.[98-100] The use of breathing circuit gas analysis may alert the user to misfilling. If a variable bypass vaporizer such as an isoflurane or sevoflurane vaporizer is misfilled with desflurane, a substantial overdose could occur because of desflurane's high vapor pressure, particularly at normal operating temperatures.

Contamination. Although unusual and rarely reported, contamination of anesthetic vaporizer contents has occurred as a result of filling an isoflurane vaporizer with a contaminated bottle of isoflurane. A potentially serious incident was avoided because the operator did not use the contaminated vaporizer after detecting an abnormal acrid odor.[101]

Tipping. Tipping of a variable bypass vaporizer can occur when it is incorrectly removed, transported, or replaced. Excessive tipping can allow the liquid agent to enter the bypass chamber and cause an output with an extremely high concentration of agent.[102] Although some vaporizers may be more immune to tipping than others, most vaporizers should not be used until it they have been flushed for a period of time at high flow rates. Manufacturers' instructions differ regarding their

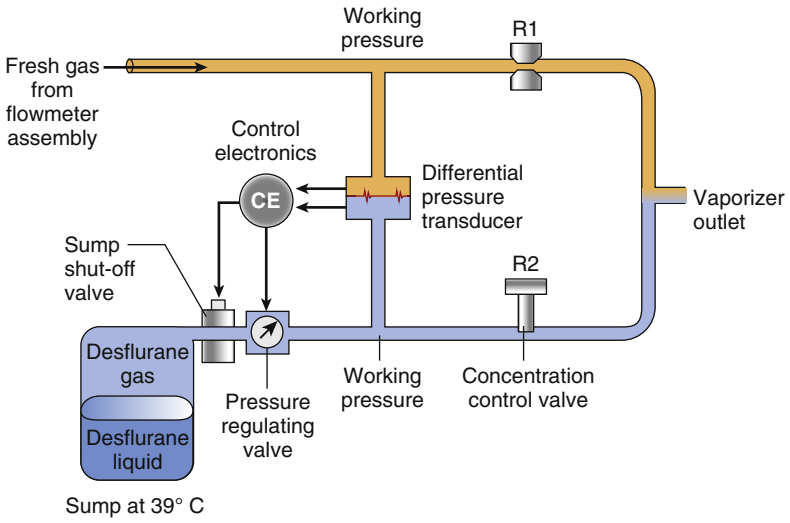

Figure 29-24. Simplified schematic of the Tec 6 desflurane vaporizer (Datex-Ohmeda, Madison, Wis.). Please see text for details. *(From Andrews JJ:* Operating principles of the Ohmeda Tec 6 desflurane vaporizer: a collection of twelve color illustrations, *Washington, D.C., 1996, Library of Congress.)*

posttipping procedures, precluding any generic recommendation.[68,70,71,94] The specific user's manual should be consulted. Following any of these specified procedures, a breathing gas analyzer should be used to assess vaporizer output before patient use. The Dräger Vapor 20.n series vaporizers have a transport ("T") dial setting that isolates the vaporizer chamber from the bypass chamber and eliminates the possibility of internal overflow.[68]

Overfilling. Improper filling procedures combined with failure of the vaporizer sight glass can cause overfilling and patient overdose. If overfilled, liquid anesthetic may enter the bypass chamber, and a harmful dose of vapor concentration can be delivered to the common gas outlet.[103] It is a design requirement that contemporary vaporizers cannot be overfilled when they are used in a normal operating position.[12] Side-fill variable bypass vaporizers, as opposed to top-fill devices, largely prevent overfilling because the maximum safe fill amount is predetermined by the level of the filler port, which is situated to minimize the chance of overfilling. In addition, some vaporizers are equipped with an overflow hole as an additional safeguard.[68] However, despite safeguards, vaporizer overfilling can still occur. Hazardous situations include tipping of the vaporizer while filling, filling of the vaporizer while it is turned on, and air entry at the bottle neck and filler adapter caused by a loose or faulty seal.[103-106] User's manuals for contemporary vaporizers warn specifically about these conditions.[68,70,71,94]

Leaks. Vaporizers and the vaporizer-machine interface are potential sources of gas leaks that can result in a patient's awareness during anesthesia. Loose filler caps, filler plugs, and drain valves are probably the most common sources of vaporizer leaks. Such a leak can be obvious as an audible gas leak with possible spillage of anesthetic agent or a more subtle presentation with lower than expected inhaled agent concentration or the odor of anesthetic gas.[107,108] Another common source of gas leak associated with vaporizers occurs at the junction of the vaporizer and the mounting bracket or manifold, where broken mounting assemblies or foreign bodies can compromise the seal between the vaporizer and its point of attachment.[109-112] Gas leaks can also occur within the vaporizer itself as a result of mechanical failure. Assessment for low-pressure system leaks, including the vaporizer mount, is addressed in the section on 'checking your anesthesia workstation.

Environmental Considerations. Today more than ever, anesthesia care providers are being asked to provide anesthesia to patients outside the operating room. One such location that has sometimes proved difficult to work in is the magnetic resonance imaging (MRI) suite. The presence of a powerful magnet field, significant noise pollution, and limited access to the patient during the procedure all complicate care in this setting. The anesthesia provider must have a clear understanding of the extremely powerful magnetic fields used in these devices and must know that only nonferrous (MRI-compatible) equipment can be used in these settings. Although some anesthesia vaporizers may appear nonferrous by testing with a horseshoe magnet, they may indeed contain substantial internal ferrous components. Inappropriate use of such devices in an MRI suite may potentially turn them into dangerous missiles if they are left unsecured.[113]

Desflurane Vaporizer. Because of its unique physical characteristics, the controlled vaporization of desflurane required a novel approach to vaporizer design. The first such system, the Datex-Ohmeda Tec 6 vaporizer, was released into clinical use in the early 1990s. The Tec 6 is an electrically heated, pressurized device specifically designed to deliver desflurane (Fig. 29-24).[114,115] The vapor pressure of desflurane is three to four times that of other contemporary inhaled anesthetic agents (669 mm Hg at 20° C), and it boils at 22.8° C (73.1° F),[116] which is basically room temperature (see Table 29-1). In 2004, Dräger Medical received approval from the U.S. Food and Drug Administration (FDA) for its own version of the Tec 6 desflurane vaporizer. The operating principles described in the following discussion are applicable to either system, although the discussion refers to the Tec 6 specifically. The

Datex-Ohmeda Aladin cassette vaporizer and the Maquet vaporizers are also capable of delivering desflurane, but their operational principles are different. These vaporizers are discussed in later sections.

Unsuitability of Contemporary Variable Bypass Vaporizers for Controlled Vaporization of Desflurane. Desflurane's high volatility and moderate potency preclude its use with contemporary variable bypass vaporizers for three main reasons[114]

1. Desflurane's high rate of evaporation would require excessive diluting gas (bypass chamber) flow. At 68° F (20° C), the vapor pressure of desflurane is nearly 1 atm. This pressure is significantly higher than the vapor pressure of the other conventional anesthetic agents (see Fig. 29-16 and Table 29-1).[116] If desflurane were placed in a variable bypass vaporizer, tremendous gas flow rates would be required to dilute the vaporizing chamber output to clinical concentrations. For example, at 1 atm and 68° F (20° C), 100 mL/minute passing through the vaporizing chamber would entrain 735 mL/minute of desflurane, as opposed to 29, 46, and 47 mL/minute of enflurane, isoflurane, and halothane, respectively.[114] Under these same conditions, to produce a 1% desflurane output, the amount of bypass flow necessary to achieve sufficient dilution of the large volume of desflurane-saturated anesthetic vapor would be approximately 73 L/minute, in contrast to 5 L/minute or less for the other three anesthetic agents. This would be neither practical nor possible using conventional anesthesia workstations.
2. Desflurane's high rate of evaporation would cause substantial anesthetic cooling. Variable bypass vaporizers require ambient sources heat to stay warm as they cool during vaporization. Although the latent heat of vaporization for desflurane is approximately equal to that of enflurane, isoflurane, and halothane, its MAC is four to nine times higher than those of the other three inhaled anesthetic agents. Thus, the absolute amount of desflurane vaporized over a given period is considerably greater than that of the other anesthetic drugs. Supplying desflurane through a variable bypass vaporizer in equivalent MAC concentrations would lead to excessive cooling of the vaporizer and significantly reduce its output. In the absence of an external heat source, temperature compensation with the traditional mechanical devices would be almost impossible. Because of the broad range of temperatures seen in the clinical setting and because of desflurane's steep vapor pressure–versus-temperature curve (V-P curve), delivery of desflurane in a conventional anesthetic vaporizer would be at best unpredictable.[114]
3. Desflurane is more likely to boil. At temperatures higher than 73° F (22.8° C) at 1 atm, desflurane boils. This temperature is at the higher end of normal operating room temperatures. If the anesthetic agent were to boil within a variable bypass–type vaporizer, the output would be uncontrollable because the amount of vapor produced would be limited only by the heat energy available from the vaporizer because of its specific heat.[114]

Operating Principles of the Tec 6 and Tec 6 Plus. The Tec 6 vaporizer was designed to achieve controlled vaporization of desflurane, and it was the first clinically available vaporizer ever to be electrically heated and pressurized. Although the physical appearance and operation of the desflurane vaporizers and the variable bypass vaporizers are similar, many aspects of their internal design and operating principles are radically different.

Functionally, operation of the Tec 6 is more accurately described as a dual-gas blender than as a vaporizer. A simplified schematic of the Tec 6 is shown in Figure 29-24. The vaporizer has two independent gas circuits arranged in parallel. The fresh gas circuit is shown in *orange,* and the vapor circuit is shown in *blue.* Fresh gas from the flowmeters enters at the fresh gas inlet, passes through a fixed restrictor (R1), and exits at the vaporizer gas outlet. The vapor circuit originates at the desflurane sump, which is electrically heated and thermostatically controlled to 39° C, a temperature much higher than desflurane's boiling point. The heated sump assembly serves as a reservoir of desflurane *vapor*. At 39° C, the vapor pressure in the sump is approximately 1300 mm Hg,[117] or approximately 2 atm. Just downstream from the sump is the shut-off valve. After the vaporizer warms up, the shut-off valve fully opens when the concentration control valve is turned to the "on" position. A pressure-regulating valve located downstream from the shut-off valve down regulates the pressure to approximately 1.1 atm absolute (74 mm Hg gauge) at a fresh gas flow rate of 10 L/minute. The operator controls the output of desflurane by adjusting the concentration control valve (R2), which is a variable restrictor.[114]

The vapor flow through R2 joins the fresh gas flow through R1 at a point downstream from the restrictors. Until this point, the two circuits are physically separated. They are interfaced pneumatically and electronically, however, through differential pressure transducers, a control electronics system, and a pressure-regulating valve. When a constant fresh gas flow rate encounters the fixed restrictor R1, a specific backpressure proportional to the fresh gas flow rate pushes against the diaphragm of the control differential pressure transducer. The differential pressure transducer conveys the pressure difference between the fresh gas circuit and the vapor circuit to the control electronics system. The control electronics system regulates the pressure-regulating valve so that the pressure in the vapor circuit equals the pressure in the fresh gas circuit. This equalized pressure supplying R1 and R2 is the working pressure, and the working pressure is constant at a fixed fresh gas flow rate. If the operator increases the fresh gas flow rate, more backpressure will be exerted on the diaphragm of the control pressure transducer, and the working pressure of the vaporizer will increase.[114]

Table 29-4 shows the approximate correlation of the fresh gas flow rate with working pressure for a typical vaporizer. At a fresh gas flow rate of 1 L/minute, the working pressure is 10 millibars, or 7.4 mm Hg gauge. At a fresh gas flow rate of 10 L/minute, the working pressure is 100 millibars, or 74 mm Hg gauge. Therefore, a linear relationship exists between the fresh gas flow rate and working pressure. When the fresh gas flow rate is increased 10-fold, the working pressure increases 10-fold.[114]

TABLE 29-4 FRESH GAS FLOW RATE VERSUS WORKING PRESSURE

From Andrews JJ, Johnston RV Jr: The new Tec 6 desflurane vaporizer, Anesth Analg *76:1338, 1993.*

The following are two specific examples to demonstrate the operating principles of the Tec 6[114]:

Example A: *Constant fresh gas flow rate of 1 L/minute with an increase in the dial setting.* With a fresh gas flow rate of 1 L/minute, the working pressure of the vaporizer is 7.4 mm Hg. In other words, the pressure supplying R1 and R2 is 7.4 mm Hg. As the operator increases the dial setting, the opening at R2 becomes larger, thereby allowing more vapor to pass through R2. Specific vapor flow values at different dial settings are shown in Table 29-5.

Example B: *Constant dial setting with an increase in fresh gas flow from 1 to 10 L/minute.* At a fresh gas flow rate of 1 L/minute, the working pressure is 7.4 mm Hg, and at a dial setting of 6%, the vapor flow rate through R2 is 64 mL/minute (see Tables 29-4 and 29-5). With a 10-fold increase in the fresh gas flow rate, a concomitant 10-fold increase in the working pressure to 74 mm Hg occurs. The ratio of R2 to R1 resistance is constant at a fixed dial setting of 6%. Because R2 is supplied by 10 times more pressure, the vapor flow rate through R2 increases 10-fold to 640 mL/minute. Vaporizer output is constant because both fresh gas flow and vapor flow increase proportionally.

Factors That Influence Vaporizer Output. Varied altitude and carrier gas composition influence the Tec 6 vaporizer output. Each is discussed in the following paragraphs.

Varied Altitudes. Although ambient pressure changes affect *variable bypass vaporizer* output significantly in terms of volume percent, their effect on anesthetic potency (partial pressure) is minimal. However, the change in variable bypass vaporizer output with altitude is in stark contrast to the response of the Tec 6 style desflurane vaporizer at varied altitudes, as can be seen in Table 29-3. One must remember that the Tec 6 style desflurane vaporizer device is more accurately described as a dual-gas blender than a vaporizer. Regardless of ambient pressure, the Tec 6 will maintain a constant concentration of vapor output (v/v%), *not a constant partial pressure*. This means that at high altitudes, the partial pressure of desflurane will decrease in proportion to the reduction in atmospheric pressure divided by the calibration pressure (normally 760 mm Hg) per the following formula:

$$\text{Required dial setting } (\%) = \text{Normal dial setting} \times \frac{760 \text{ mm Hg}}{\text{Ambient pressure (mm Hg)}}$$

For example, at an altitude of 2000 m, or 6564 feet, where the ambient pressure is 608 mm Hg, the operator must advance the concentration control dial from 10% to 12.5% to maintain the required anesthetic partial pressure. In hyperbaric settings, the operator must decrease the dial setting to prevent delivery of an overdose. At 2 atm or 1520 mm Hg of pressure, the desflurane output in mm Hg is twice that at sea level (91.2 versus 45.6 mm Hg).

Carrier Gas Composition. Vaporizer output approximates the dial setting when oxygen is the carrier gas because the Tec 6 vaporizer is calibrated with 100% oxygen. At low flow rates when a carrier gas other than 100% oxygen is used, however, a clear trend toward reduction in vaporizer output emerges. This reduction parallels the proportional decrease in viscosity of the carrier gas. Nitrous oxide has lower viscosity than does oxygen, so the backpressure generated by resistor R1 (see Fig. 29-24) is less when nitrous oxide is the carrier gas, and the working pressure is reduced. At low flow rates and with nitrous oxide used as the carrier gas, vaporizer output is approximately 20% less than the dial setting. This suggests that at clinically useful fresh gas flow rates, gas flow across resistor R1 is laminar, and the working pressure is proportional to both the fresh gas flow rate and the viscosity of the carrier gas.[118]

Safety Features. Because desflurane's vapor pressure is nearly 1 atm, misfilling contemporary variable bypass vaporizers with desflurane could theoretically result in both desflurane overdose and creation of a hypoxic gas mixture.[119] Like most of its contemporaries, the desflurane vaporizer has a unique, anesthetic-specific filling system to minimize occurrence of this potential hazard. The agent-specific filler of the desflurane bottle, known as the "Saf-T-Fill" adapter, is intended to prevent its use with traditional vaporizers. The filling system also minimizes spillage of liquid or vapor anesthetic by maintaining a closed system during the filling process. Each desflurane bottle has a spring-loaded filler cap with an O-ring on the tip. The spring seals the bottle until it is engaged in the filler port of the vaporizer. Thus, this anesthetic-specific filling system interlocks the vaporizer and the dispensing bottle and thereby prevents loss of anesthetic agent to the atmosphere.

Major vaporizer faults cause the shut-off valve located just downstream from the desflurane sump (see Fig. 29-24) to close and produce a no-output situation. The valve is closed, and a no-output alarm is activated immediately if any of the following conditions occur: (1) the anesthetic level decreases to less than 20 mL,

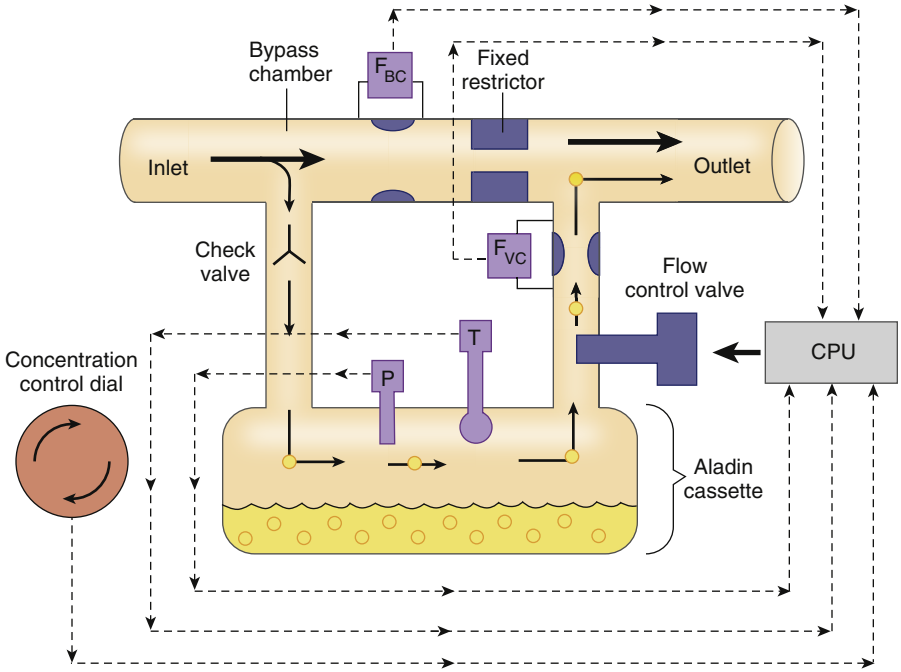

Figure 29-25. Simplified schematic of Datex-Ohmeda Aladin cassette vaporizer (Datex-Ohmeda, Madison, Wis.). The *black arrows* inside the vaporizer represent flow from the flowmeters, and the *yellow circles* represent anesthetic vapor. The heart of the vaporizer is the electronically controlled flow control valve located in the outlet of the vaporizing chamber. *CPU,* Central processing unit; F_{BC}, flow measurement unit that measures flow through the bypass chamber; F_{VC}, flow measurement unit that measures flow through the vaporizing chamber; *P,* pressure sensor; *T,* temperature sensor. Please see text for additional details. *(Modified from Andrews JJ:* Operating principles of the Datex-Ohmeda Aladin cassette vaporizer: a collection of color illustrations, *Washington, D.C., 2000, Library of Congress.)*

(2) the vaporizer is tilted, (3) a power failure occurs, or (4) a disparity between the pressure in the vapor circuit and the pressure in the fresh gas circuit exceeds a specified tolerance. Although such automated safeguards can enhance the patient's safety, they can sometimes have unintended consequences. For example, when a Datex-Ohmeda D-Tec "plus" was used with a new anesthesia machine that, by design, interrupted fresh gas flow during mechanical inspiration in the volume mode as means of fresh gas decoupling, the vaporizer was reported to provide a no output warning during mechanical ventilation.[120] These purposeful fresh gas flow interruptions, which occurred in the volume-mode of ventilation only, were sensed as a fault situation, and the vaporizer output was terminated. Although the vaporizer was subsequently modified, the circumstance serves as a reminder that new technology can bring about new problems.

Summary. The Tec 6 and Dräger D-Vapor vaporizers are electrically heated, thermostatically controlled, constant-temperature, pressurized, electromechanically coupled dual-circuit, gas vapor blenders. The pressure in the vapor circuit is electronically regulated to equal the pressure in the fresh gas circuit. At a constant fresh gas flow rate, the operator regulates vapor flow with a conventional concentration control dial. When the fresh gas flow rate increases, the working pressure increases proportionally. For a given concentration setting, even when varying the fresh gas flow rate, the vaporizer output is constant because the amount of flow through each circuit remains proportional.[114]

Datex-Ohmeda Aladin Cassette Vaporizer. The vaporizer system used in the Datex-Ohmeda S/5 ADU and GE Aisys anesthesia workstations is unique in that a single electronically controlled vaporizer is designed to deliver five different inhaled anesthetic agents, including halothane, isoflurane, enflurane, sevoflurane, and desflurane (Fig. 29-25). The vaporizer consists of a permanent internal control unit housed within the workstation and interchangeable cassettes that contain anesthetic liquid and serve as vaporizing chambers. The Aladin cassettes are color coded for each anesthetic agent, and they are also magnetically coded so the workstations can identify which anesthetic cassette has been inserted. The cassettes are filled using agent-specific fillers.[120]

Operationally, the Aladin cassette vaporizing system is best described, during most circumstances, as a computer-controlled variable bypass vaporizer because it consists of a bypass section and vaporizing chamber. Within the cassette, anesthetic agent vaporizes freely to saturated vapor pressure. A flow control valve, modulated by a central processing unit (CPU), precisely meters the amount of gas flow through the vaporizing chamber or cassette, which then joins the bypass flow after being saturated with anesthetic agent. The CPU receives input from multiple sources, including the concentration control dial, a pressure sensor located inside the vaporizing chamber, a temperature sensor located inside the vaporizing chamber, a flow measurement unit located in the bypass chamber, and a flow measurement unit located in the outlet of the vaporizing chamber. The CPU also receives input from the flowmeters regarding the composition of the carrier gas because this can affect vaporizer output, as described earlier. By using data from these multiple sources, the CPU is able to regulate the flow of fresh gas through the vaporizing chamber precisely with the flow control valve to obtain the desired vapor concentration output.[121]

A fixed restrictor located in the bypass chamber causes gas flow from the vaporizer system inlet to split into two flow streams. One stream passes through the bypass chamber, and the other portion enters the inlet of the vaporizing chamber and passes through a one-way check valve.

The presence of this check valve is unique to the Aladin system. This one-way valve prevents retrograde flow of the anesthetic vapor back into the bypass chamber, and its presence is crucial when delivering desflurane if room temperature is higher than the boiling point of desflurane (22.8° C).[47] A precise amount of vapor-saturated carrier gas passes through the flow control valve, which is regulated by the CPU. This flow then joins the bypass flow and is directed to the outlet of the vaporizer.[47]

As mentioned in the discussion of the Tec 6, controlled vaporization of desflurane presents a unique challenge, particularly when room temperature is higher than the boiling point of desflurane (73° F [22.8° C]). If the desflurane were to boil, the pressure inside the vaporizing chamber would increase to more than ambient pressure. When this pressure exceeds pressure in the bypass chamber, the one-way check valve located in the vaporizing chamber inlet closes to prevent carrier gas from entering the vaporizing chamber. At this point the carrier gas passes straight through the bypass chamber and its flow sensor. Under these conditions, the electronically regulated flow control valve simply meters in the appropriate flow of pure desflurane vapor needed to achieve the desired final concentration selected by the user. The vaporizer then begins functioning as an injector, as opposed to resembling a variable bypass unit. At least one case report has described failure of the vaporizing chamber inlet check valve to function as designed. In this case, an anesthetic overdose occurred as a result of regurgitation of desflurane from the vaporizing chamber in retrograde fashion back into the bypass chamber. Because of this report, ADU users should be cautious of this potential problem, especially when desflurane is used.[121]

During operating conditions in which high fresh gas flow rates or high dial settings (or both) are used, large quantities of anesthetic liquid are vaporized rapidly. As a result, the temperature of the remaining liquid anesthetic and the vaporizer itself decreases because of energy consumption or from the latent heat of vaporization. To offset this cooling effect, the S/5 ADU is equipped with a fan that forces warmed air from an "agent heating resistor" across the cassette (vaporizer sump) to raise its temperature when necessary. The fan is activated during two common clinical situations: (1) desflurane induction and maintenance and (2) sevoflurane induction.

The Aladin vaporizing system incorporates several important safety features. The electronic ratio control of the workstation is incorporated into the vaporizing system. This ensures no less than 25% oxygen at the common gas outlet regardless of the gas composition *and* the concentration of anesthetic agent. By contrast, anesthetic agent concentration does not affect conventional oxygen ratio controllers, so this feature is unique. The system is equipped with a safety relief valve that opens when the pressure within the cassette exceeds 2.5 bar (1899 mm Hg). When the Aladin cassette is removed from the unit, valves prevent the loss of fresh gas from the mount. Another valve prevents liquid anesthetic from entering the fresh gas line. This system also has an overfilling protection mechanism. Finally, because the Aladin cassette is immune from the problems associated with tipping that occur with conventional variable bypass vaporizers, it has no restrictions on tilting during handling or storage.[121]

Maquet Injection-Type Vaporizer. The Maquet vaporizer is an electronically controlled, injection-type vaporizer that is used exclusively with Maquet FLOW-i anesthesia workstations. Because these vaporizers are located upstream from the patient's breathing circuit, they are designated as out-of-circuit vaporizers, similar to the desflurane vaporizer and most variable bypass vaporizers. The Maquet injection vaporizers are also agent specific, with vaporizers available for isoflurane, sevoflurane, and desflurane. Agent-specific filling adapters are used for each anesthetic agent. Externally, the device has a lid, filling port, electronic level indicator, and alert indicators, but no concentration control dial. Vaporizer output adjustments are accomplished through an electronic interface on the workstation (personal communication, Maquet Critical Care, January 14, 2013).

The Maquet vaporizer principle of operation is illustrated in Figure 29-26. Gas from the anesthesia machine is used to pressurize an anesthetic liquid storage container. Pressurization of the reservoir provides the force to drive liquid anesthetic agent through the vaporizer injector and minimizes evaporation of the agent within the chamber. Liquid anesthetic agent is injected into a heated vaporizing chamber under microprocessor control in a pulsed and intermittent manner, and it rapidly evaporates. Anesthetic liquid is injected at small increments until the desired injection volume is obtained. The total amount of anesthetic injected at any given interval is based on the desired anesthetic concentration and the fresh gas flow through the vaporizer. A dedicated gas analysis line downstream from the vaporizer monitors the output. An optical sensor in the vaporizer monitors the integrity of the anesthetic injections (personal communication, Maquet Critical Care, January 14, 2013).

Fresh gas from the anesthesia workstation, under the control of operator and the fresh gas modules, flows through the vaporizing chamber and is enriched with gaseous anesthetic agent. Although some of the injected liquid anesthetic evaporates while in flight within the vaporizing chamber, the remaining liquid is deposited on an evaporative surface within the chamber. This evaporative surface is heated to ensure immediate evaporation. The heating of the surface is carefully regulated to compensate for the effect of evaporative cooling (personal communication, Maquet Critical Care, January 14, 2013).

During the daily workstation preuse check, the vaporizers are automatically tested with respect to functionality and leaks. This feature is unique relative to variable bypass vaporizers, which must be manually selected to participate in automated or manual leak testing. A safety valve stops the flow of liquid agent in the case of vaporizer malfunction. The vaporizer is not vulnerable to tipping because it has no wicks to saturate, and agent cannot spill into the vaporizing chamber. The vaporizer can be filled during use, although no vaporizer output occurs during filling. An alarm triggers when the vaporizer level is less than 10%, and a higher-priority alarm triggers when it reaches 5%. At this time, no published data are available

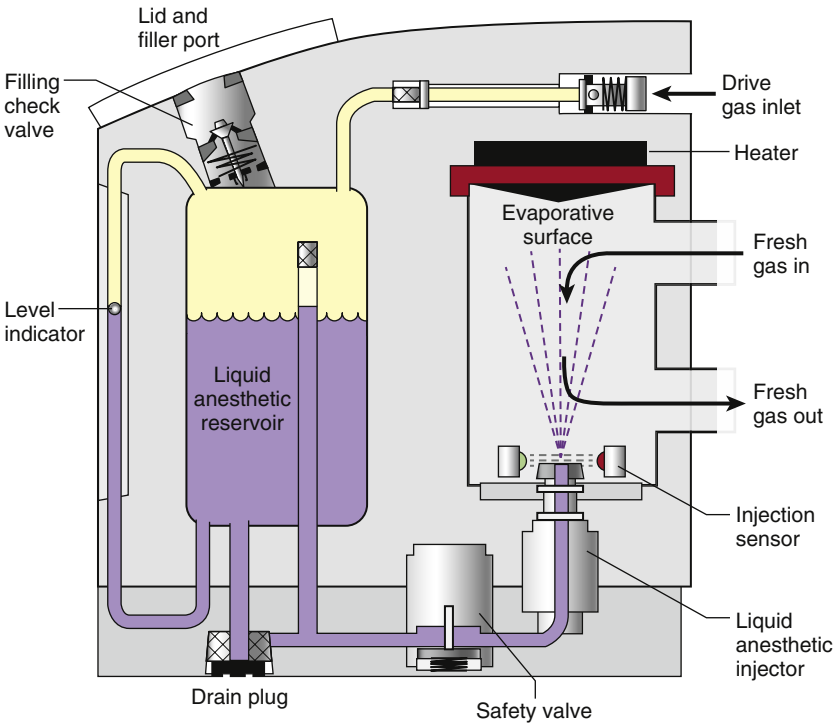

Figure 29-26. The Maquet anesthetic vaporizer. Drive gas from the anesthesia machine is used to pressurize a liquid anesthetic reservoir. Under microprocessor control, liquid agent is injected into a vaporizing chamber. Injection is carefully monitored. A heated surface within the vaporizing chamber facilitates evaporation of the anesthetic agent. Fresh gas flows through the chamber and is enriched with anesthetic gas. A safety valve stops the flow of liquid agent in the case of vaporizer malfunction. *(Personal communication, illustration adapted with permission from Maquet Critical Care, Solna, Sweden, January 14, 2013).*

on the vaporizer's performance at variable barometric pressure, temperature, flesh gas flow rates, or with variable fresh gas compositions (personal communication, Maquet Critical Care, January 14, 2013).

ANESTHETIC BREATHING CIRCUITS

Fresh gas departs from the gas supply system and enters the anesthetic breathing circuit through the fresh gas line. The functions of the breathing circuit are to deliver oxygen and other gases to the patient and to eliminate carbon dioxide. The breathing system must contain a low-resistance conduit for gas flow, a reservoir for gas that can meet the patient's inspiratory flow demand, and an expiratory port or valve to vent excess gas.[122] Applying these criteria as foundational for any anesthetic breathing system, one can then further categorize the circuits as those that use an absorber to eliminate carbon dioxide (the circle system) and those that do not (the Mapleson circuits).[123] Circle systems are the most common breathing circuits used for anesthetic delivery. However, certain Mapleson systems are used in anesthesia workstations, particularly in pediatrics, and they are often used by anesthesia providers for ventilation and oxygenation during transport of patients, procedural sedation, liberation from tracheal intubation (the T-piece), and preoxygenation during out-of-the-operating-room airway management. Therefore, both systems are discussed.

Leaks and obstruction represent the two most important hazards associated with the breathing circuit. Most of the time, these problems can be detected during the preuse checkout of the workstation. However, a firm understanding of the components and function of the breathing system is critical if one is to perform a proper preuse checkout of the workstation and troubleshoot acute problems. The operator should also be aware of the various standards and alarms associated with this critical part of the anesthesia workstation.

Circle Breathing Systems

For many years, the overall design of the classic circle breathing system changed very little (Figs. 29-27 to 29-29). From one anesthesia workstation to the next, the circle breathing circuits shared similar schematics and components. More recently, however, with the increasing technologic complexity of the anesthesia workstation, circle breathing systems have evolved and their diversity has increased. These changes have resulted in part from an effort to improve patients' safety, such as integration of fresh gas decoupling during positive-pressure ventilation.

The circle breathing system is so named because it allows circular, unidirectional gas flow, which is facilitated by unidirectional valves. Some of the main advantages of the circle system include (1) maintenance of relatively stable inspired gas concentrations, (2) conservation of respiratory moisture and heat, (3) elimination of carbon dioxide, (4) an economy of anesthetic gases resulting from rebreathing, and (5) prevention of operating room pollution. The capability to rebreathe and conserve anesthetic gases is a unique aspect of the circle breathing system as compared with an ICU ventilator breathing circuit, in which the entirety of each exhaled breath is vented into the room. To allow rebreathing of the exhaled gases, carbon dioxide must be removed. Another unique aspect of the circle system is that waste gases, which are composed of excess gas flows, anesthetic agent, and carbon dioxide, must able to be scavenged and eliminated. Circle systems also must allow for spontaneous ventilation, manual ventilation, and positive-pressure ventilation. Therefore, the circle system must function with both the anesthesia reservoir bag and a ventilator.

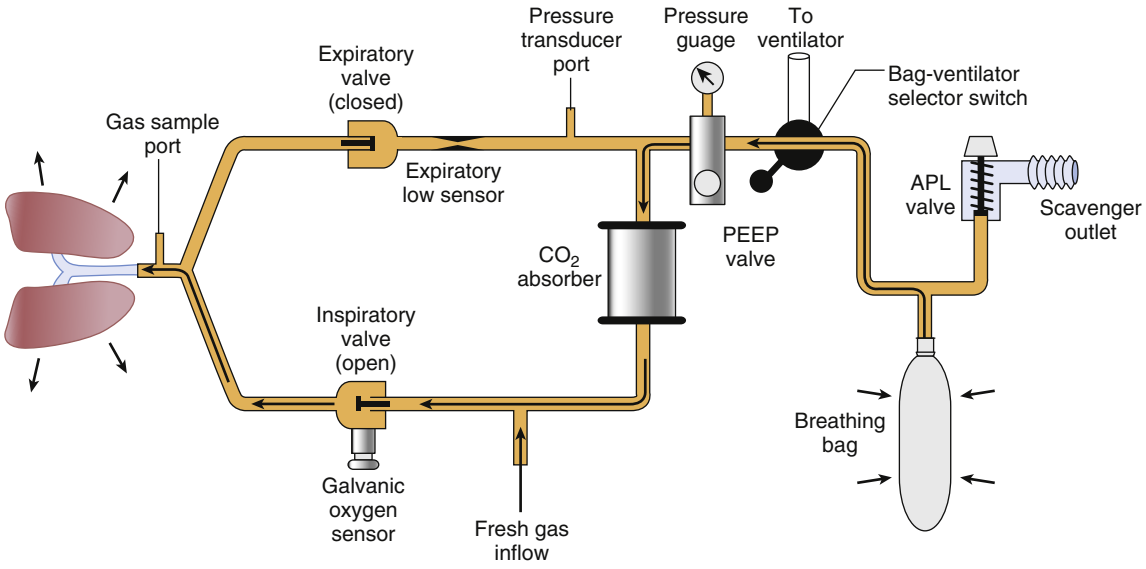

Figure 29-27. Classic circle breathing system. Spontaneous breathing-inspiratory phase (ventilator not shown). Gas is drawn by the patient from the breathing bag and through the carbon dioxide (CO_2) absorber. It is then mixed with the fresh gas inflow from the gas supply system, traverses the inspiratory valve, and flows to the patient. The expiratory valve prevents rebreathing by disallowing bypass of the CO_2 absorber. *PEEP,* Positive end-expiratory pressure. *(Courtesy Dr. Michael A. Olympio; modified with his permission.)*

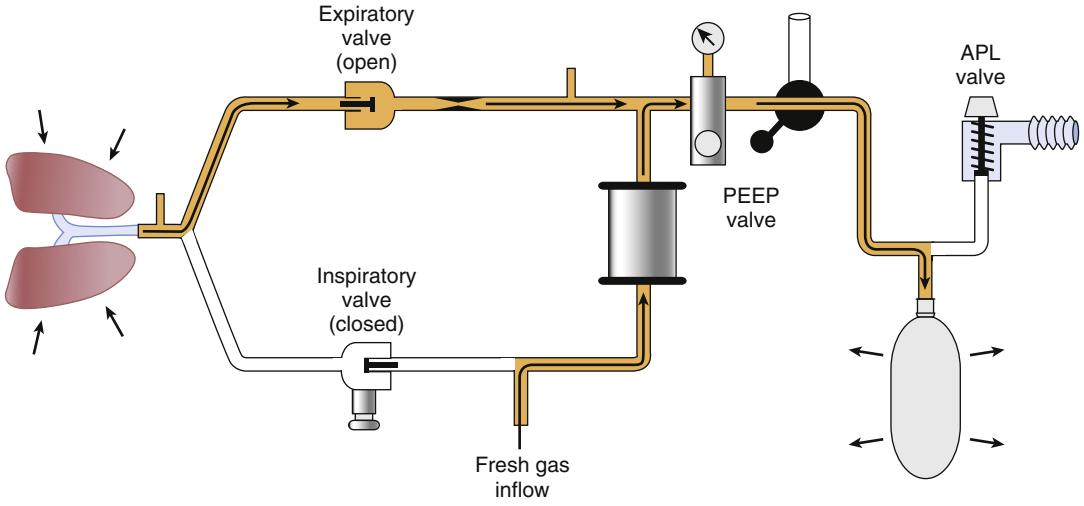

Figure 29-28. Spontaneous breathing: early expiratory phase. The inspiratory unidirectional valve ensures that all exhaled carbon dioxide (CO_2)–containing gas flows toward the breathing bag and adjustable pressure-limiting (APL) valve before being scrubbed of CO_2. Fresh gas continues to flow, but now in retrograde fashion, and combines with the exhaled breath. The APL valve remains closed in this example because circuit pressure is still lower than the practitioner-set APL valve pressure threshold (i.e., 10 cm H_2O). *PEEP,* Positive end-expiratory pressure. *(Courtesy Dr. Michael A. Olympio; modified with his permission.)*

The major disadvantage of the circle system stems from its complex design. Commonly, the circle system may have 10 or more different connections. These multiple connection sites set the stage for misconnections, disconnections, obstructions, and leaks. In a closed-claim analysis of adverse anesthetic outcomes arising from gas delivery equipment, 39% of malpractice claims resulted from breathing circuit misconnections or disconnection.[124] Malfunction of the circle system's unidirectional valves can cause life-threatening problems. Rebreathing can occur if the valves stick in the open position, and total occlusion of the circuit can occur if the valves are stuck shut. If the expiratory valve is stuck in the closed position, breath stacking and barotrauma can result. The circle breathing system is large compared with the Mapleson systems. Therefore, the overall compliance of the circuit tends to be higher, and this can decrease tidal volume delivery during controlled ventilation. Many newer anesthesia workstations assess circuit compliance to better deliver accurate tidal volumes, or they can compensate for disparities in set versus delivered tidal volume. Finally, because circle breathing systems use a carbon dioxide absorber, anesthetic degradation can occur (see the section on carbon dioxide absorbers).[125]

The circle system consists of several essential components, including (1) a fresh gas inflow source, (2) inspiratory and expiratory unidirectional valves, (3) inspiratory and expiratory corrugated tubes, (4) a Y-piece that connects to the patient, (5) an overflow or adjustable pressure limiting (pop-off) valve (the APL valve), (6) a reservoir or

breathing bag, and (7) a canister containing a carbon dioxide absorbent (see Fig. 29-27). Several additional common circuit components are added to enhance patients' safety, including a circuit pressure sensor, a circuit pressure gauge, an expiratory (and possibly an inspiratory) flow sensor, and an inspired oxygen concentration sensor. A separate positive end-expiratory pressure (PEEP) valve may be present. A ventilator serves as an alternate source of ventilation apart from the patient or the anesthesiology provider. The inspiratory and expiratory valves are placed in the system to ensure that gas flow through the circuit remains unidirectional. The fresh gas inflow enters the circle by a connection from the common gas outlet of the anesthesia machine. The major circle system components are described in the following subsections.

Unidirectional Valves. The one-way valves are essential elements of the circle breathing system (Fig. 29-30; see Fig. 29-57). They are usually constructed so that their function is not impaired by the humidity that sometimes accumulates in the breathing system. However, incompetence is one of the most common problems encountered with these usually reliable valves, and the expiratory valve seems to be most vulnerable because it is subject to greater moisture exposure. Stuck-open unidirectional valves result in rebreathing of carbon dioxide, and each valve demonstrates a characteristic incompetence pattern on the capnography tracing.[126] Assessing for proper unidirectional valve function should be part of the anesthesia workstation preuse check out procedure. Anesthesia machines are constructed so functioning of these valves is visible.[127]

Adjustable Pressure-Limiting Valve. The APL valve is an operator-adjustable relief valve that vents excess breathing circuit gas to the scavenging system and provides control of the breathing system pressure during spontaneous and manual modes of ventilation. Switching the workstation to a ventilator mode excludes or closes the valve.[127] Several other common names exist for these devices, including "pop-off" valve and pressure relief valve.[122] The two basic types of pressure-limiting valves are the variable-resistor (or variable-orifice) type and the pressure-regulating type. The variable-type functions as a needle valve, much like a flow control valve (Fig. 29-31). The operator adjusts the outlet orifice size, so the

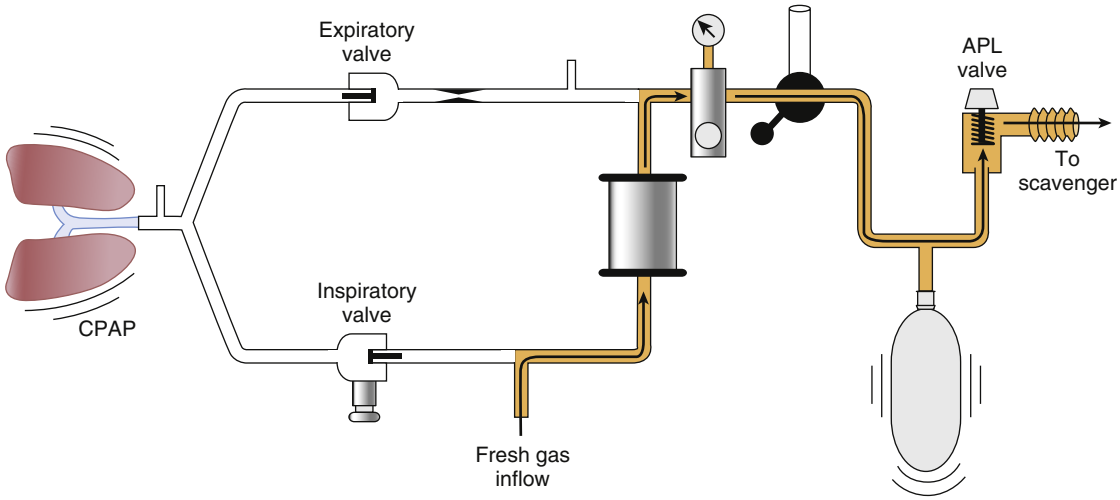

Figure 29-29. Spontaneous breathing: end-expiratory phase with continuous positive airway pressure (CPAP). Fresh gas continues to flow into the circuit generating pressure that maintains distention of the lungs (CPAP) and the breathing bag. Once the circuit pressure exceeds the adjustable pressure-limiting (APL) valve's set threshold (i.e., 10 cm H_2O), the valve opens, and excess gas flow is vented to the scavenger. *(Courtesy Dr. Michael A. Olympio; modified with his permission.)*

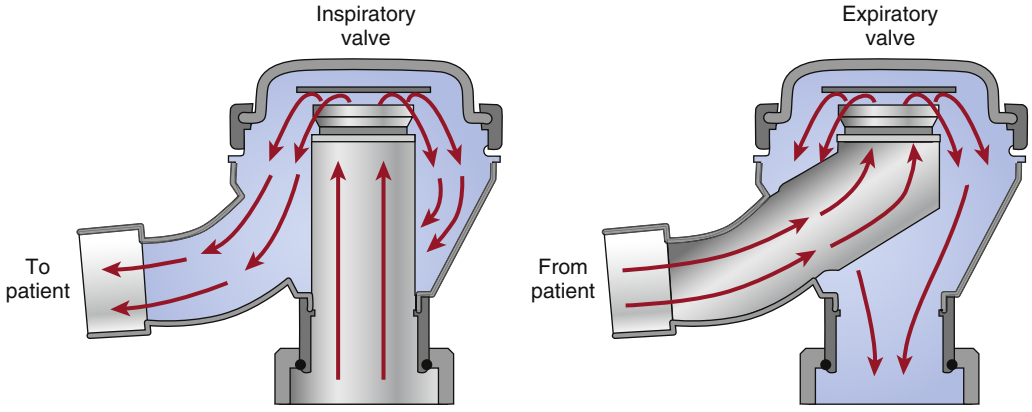

Figure 29-30. Circle breathing system unidirectional valves *(Modified from Yoder M: Absorbers and breathing systems. In* Understanding modern anesthesia systems, *Telford, Pa., 2009, Dräger Medical, pp 83-126.)*

resultant breathing system pressure at any given adjustment is directly related to the fresh gas flow rate. Modern machines now mostly use pressure-regulating–type APL valves (Fig. 29-32). This type of APL valve has an adjustable internal tension spring and an external scale indicating approximate or relative opening pressure. When the pressure in the system exceeds spring tension, a disk opens and gas is vented (see Fig. 29-32, *B*). In this manner, the operator can adjust the circuit pressure, which remains stable even as the fresh gas flow is increased. Continuous positive airway pressure (CPAP) can be more reliably controlled using this type of APL valve; however, circuit pressure should be carefully monitored. This type of valve usually has a fully open position for spontaneous breathing whereby the valve is open to the atmosphere (see Fig. 29-32, *C*). Gas is prevented from returning from the scavenging system by a downstream check valve. When the valve is placed in the manual mode, spring pressure is applied to the valve in an amount proportional to the desired maximal circuit pressure as described before.[41,122]

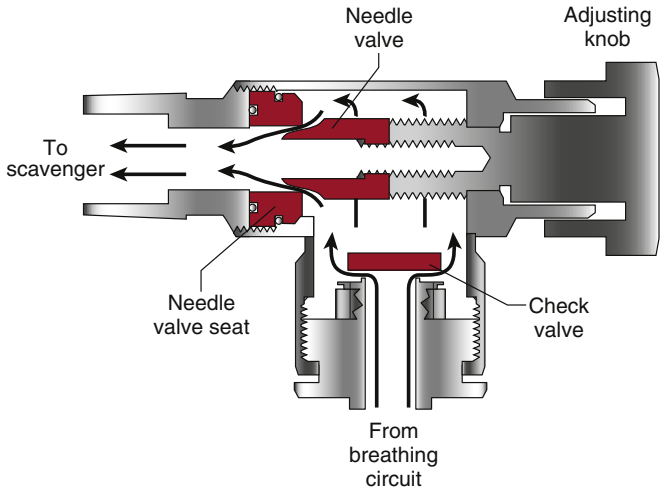

Figure 29-31. Adjustable pressure-limiting valve: variable orifice type. A weighted check valve prevents gas from flowing backward after being sent to the scavenger. A variable orifice needle valve controls rate of gas egress from the breathing circuit, thereby controlling the circuit pressure. At any given adjusted valve orifice, the pressure in the circuit will depend on the fresh gas flow rate. *(Modified from Yoder M: Absorbers and breathing systems. In* Understanding modern anesthesia systems, *Telford, Pa., 2009, Dräger Medical, pp 83-126.)*

Anesthesia Reservoir Bag or "Breathing Bag." The anesthesia reservoir bag, or "breathing bag," provides several important functions, including (1) serving as a reservoir for exhaled gas and excess fresh gas, (2) providing a means of delivering manual ventilation or assisting spontaneous breathing, (3) serving as a visual or tactile means of monitoring a patient's spontaneous breathing efforts, and (4) partially protecting the patient from excessive positive pressure in the breathing system such as in the case of inadvertent closure of the APL valve or an obstruction of the scavenge line (Fig. 29-33). The reservoir bag is the most compliant part of the breathing system. The pressure-volume characteristics of this bag are such that it inflates to a maximal pressure and then slightly decreases to a plateau as it continues to fill even to high volumes.[122,128,129] Anesthesia reservoir bags must adhere to pressure standards, which allow a minimal pressure of approximately 30 cm H_2O and a maximal pressure of approximately 60 cm H_2O when the bag is filled to four times its stated capacity.[130] Although most bags adhere to these standards, some latex-free bags have exceeded this maximal value.[129] Classically, the reservoir bag was excluded from the breathing circuit when the ventilator was in use. However, on some contemporary workstations, such as the Dräger Fabius and Dräger Apollo, the reservoir bag is integral to circuit function during mechanical ventilation, where it serves as an exhaled and fresh gas reservoir.[41,131]

Corrugated Breathing Circuit Tubing. The breathing circuit tubing, which accounts for most of the volume within the breathing, has certain vulnerabilities. First, these circuits are distensible; therefore, some of the volume to be delivered to the patient during positive-pressure ventilation is absorbed by the distention of the tubing. Many modern machines perform a compliance test to compensate for this distention, so it is important that these tests be performed with the circuit that is to be used. For instance, if an extension is to be used on the

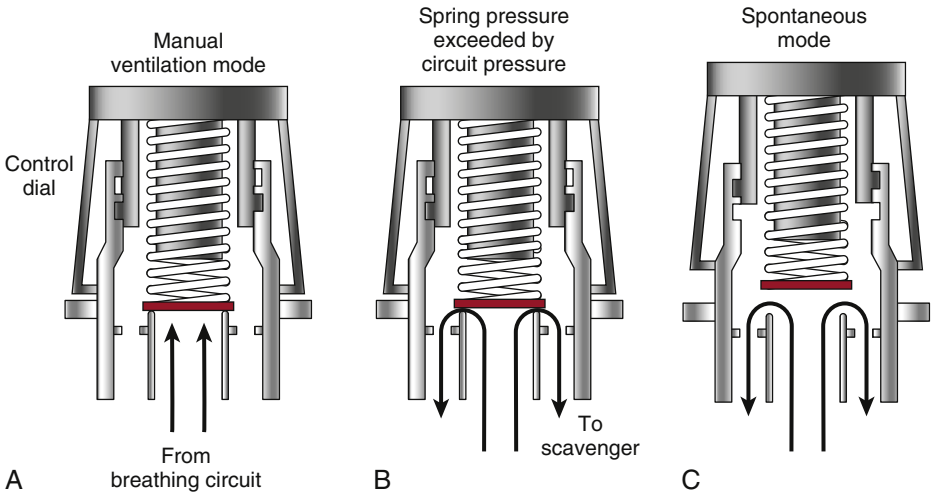

Figure 29-32. Adjustable pressure-limiting (APL) valve: pressure-regulating type. **A,** In the "manual" setting, the operator adjusts spring tension, thereby adjusting valve opening pressure. In this image the breathing circuit pressure has not yet exceeded spring tension. **B,** Breathing circuit pressure has exceeded the set pressure (spring tension), and gas is vented to the scavenger. With the pressure regulating type of APL valve circuit pressure is independent of the fresh gas flow rate. **C,** When the valve is placed in the spontaneous mode, the disk is lifted off the valve seat, and gas flows freely to the scavenger. A check valve downstream prevents waste gas from returning to the breathing circuit.

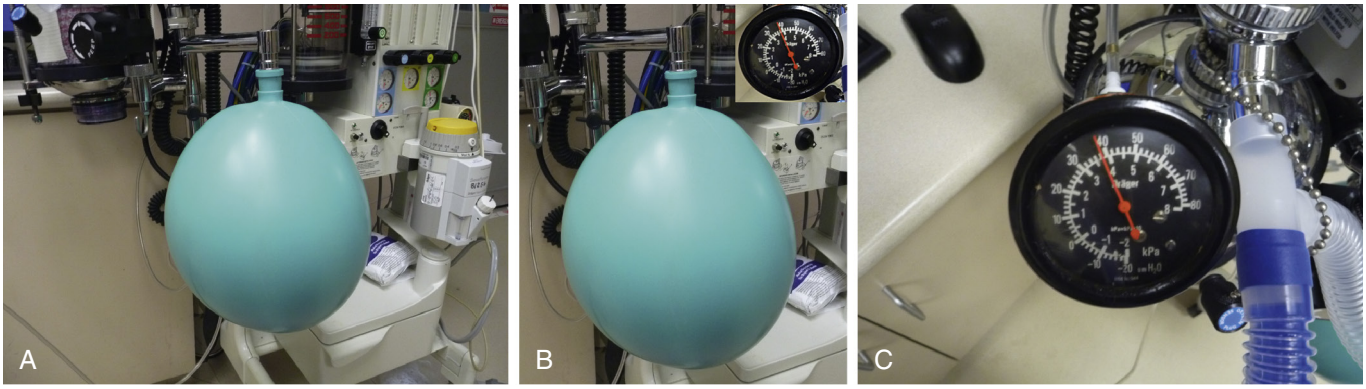

Figure 29-33. Breathing circuit reservoir bag or breathing bag. The standard for reservoir bags is that their maximum pressure should not exceed approximately 60 cm H_2O at four times their stated capacity.[130] However, many reservoir bags peak and plateau at lower pressures, and all should maintain plateau as they expand.[128] reservoir bags peak at lower pressures yet continue to expand. A peak pressure followed by a plateau is usually seen. In **A** and **B,** this breathing bag was allowed to inflate to several times its capacity. **C,** The breathing circuit pressure has plateaued at approximately 40 cm H_2O. Vigilance should prevent this from occurring because the continuing positive-pressure alarm should be sounding while the bag is inflating.

circuit to facilitate turning the operating room table 180 degrees**,** the compliance, leak, and flow tests should be performed with the extension in place. Another potential problem is that these circuits can leak or house an obstruction (see later).

Y-Piece. The Y-piece of the circuit is the distal part of the near the patient connection that merges the inspiratory and expiratory limbs of the circle breathing system. It has a distal inner 15-mm diameter to it can connect to an endotracheal tube or elbow connector, and a 22-mm outer diameter to connect to a face directly if needed. On modern anesthesia machines, the gas monitoring sample port is located at or near the Y-piece because inspiratory and expiratory gases can be sampled there. The anatomic dead space in the circle system begins at the Y-piece.

Inspired Oxygen Concentration Monitor. The ASTM standards state that the workstation must be provided with an oxygen monitor for the measurement of the oxygen concentration in the breathing circuit inspiratory limb or at the Y-piece. A low–oxygen concentration alarm must be associated with the device, and the alarm must activate within 30 seconds of an oxygen concentration drop below the set limit, which cannot be adjustable to less than 18% v/v%.[12] The oxygen sensor is truly the patient's last line of defense from receiving a hypoxemic gas mixture. Galvanic cell oxygen analyzers are often used for this purpose (see Fig. 29-55). A common location for this sensor is on the housing of the inspiratory unidirectional valve. Galvanic cell oxygen analyzers have a finite life span and are prone to drift. They therefore require daily calibration during the workstation preuse check (see the section on the Preuse check). Sidestream multigas analyzers are now used more often as the exclusive inspiratory oxygen monitor because machines are increasingly incorporating integrated gas monitoring capabilities. Paramagnetic oxygen analysis is typically employed within these monitors, and this analysis requires less frequent calibration. Multigas side-stream analysis is performed at the Y-piece.

Flow Sensors. Flow sensors are used on the anesthesia machine primarily to provide tidal volume measurement. In fact, ASTM standards state that the workstation must have a device that monitors the patient's exhaled tidal volume or minute ventilation, or both.[12] Some machines, if capable, also use the sensors to produce flow waveform or flow-volume loops, or both. Finally, some machines use tidal volume measurements as a feedback signal to maintain stable tidal volume delivery regardless of the total fresh flow rate. Although early flow sensors were usually mechanical respirometers, contemporary machines may employ differential pressure sensors, heated wire anemometers, ultrasonic flow sensors, and variable orifice flow sensors. The location of the flow sensor can vary, but the machine must have, at a minimum, a sensor for exhaled gas flow.

Breathing Circuit Pressure Sensors. The continuous measurement of airway pressure in the patient's breathing circuit is critical to the patient's safety, and it fulfills several requirements. First, anesthesia workstations must continuously display pressure in the breathing system. Second, operator-adjustable alarm conditions must exist for *high pressure*, as well as for *continuing positive pressure* for 15 seconds or longer. Excessive high pressure or prolonged positive airway pressure can compromise venous return, decrease cardiac output, interfere with ventilation, or cause barotrauma.[12] An alarm must also occur if the pressure in the breathing circuit becomes *less than –10 cm H_2O* for more than 1 second. Finally, when automatic ventilation is in use, the machine must alarm whenever the breathing pressure falls below a preset or adjustable pressure threshold for more than 20 seconds. Because the machine must also have a breathing system disconnection alarm, this low-pressure alarm may serve that purpose. However, low-volume or exhaled CO_2 monitoring may also be used.[12] The location of pressure sample site in the breathing system can be variable. It can be located in either the inspiratory or expiratory nondisposable circuitry, but it is usually close to one of the unidirectional valves. Anesthesia machines also have an analog breathing pressure gauge. Although it does not have any alarm

capabilities or an electronic interface, it continues to serve as a faithful adjunct.

Filters and Heat and Moisture Exchangers. The use of heat and moisture exchangers and filters within the anesthesia breathing circuit is common. The rationale for the use of heat and moisture exchangers is to replace the normal warming and humidifying function of the upper airway, which is bypassed by an artificial airway.[132] The basis for filter use is to prevent the transmission of microbes from the patient to the machine and hence potentially to other patients. Heat and moisture exchanging filters serve both purposes. Although a discussion of the benefits and potential hazards associated with these devices is beyond the scope of this chapter, no consensus agreement pertaining to the use of these devices exists. Further, current ASA recommendations endorse the use of filters only in the context of patients with tuberculosis, to protect the machine from contamination with airborne infectious disease.[133] If a filter is to be used for this purpose, it should have an efficiency rating higher than 95% for particle sizes of 0.3 um. The filter should be placed between the endotracheal tube and the Y-piece.[134]

Circle System Function. Classic circle system function is illustrated in Figures 29-27 to 29-29. The extent of rebreathing and the conservation of the other exhaled gases depend on the fresh gas flow rate. Higher fresh gas flow rates result in less rebreathing and greater waste gas. Contemporary circle systems are usually operated in a *semiclosed* manner, meaning that some waste flow is always vented through the APL valve or the waste gas valve associated with the ventilator. The use of low gas flows (≈1.0 L/minute) or minimal flows (≈0.5 L/minute) during anesthesia is an example. A *semiopen* system, as it pertains to the circle system, connotes higher fresh gas flows where minimal rebreathing would occur and more waste gas is vented. The potential advantages of conducting minimal fresh gas flow anesthesia include a decreased use of volatile anesthetic agents, improved temperature and humidity control, and reduced environmental pollution. The disadvantages include difficulty in rapidly adjusting anesthetic depth and the theoretical possibility of accumulation of endogenously released gases (e.g., carbon monoxide [CO], acetone, methane) or volatile anesthetic–absorbent related degradation products (e.g., compound A, CO).[135] A *closed* circuit is one in which the rate of oxygen inflow exactly matches metabolic demand, rebreathing is complete, and no waste gas is vented (APL valve remains closed). A volatile anesthetic agent is added to the breathing circuit in liquid form in precise amounts or is initially introduced through the vaporizer.[136] Closed-circuit anesthesia maximizes the advantages of low and minimal flow anesthesia. However, the technical demands of the technique relative to the benefits make it impractical for routine use with contemporary equipment, thus it is rarely employed.[137]

Potential Circle System Problems

Leaks and Disconnections. Breathing circuit leaks and disconnections continue to cause critical incidents in anesthesia.[138-140] Common sources of leaks include disposable tubing and components, as well as points of connection within the breathing circuit and at the carbon dioxide absorber canister.[141] Although leaks can develop during the course of anesthesia, such as a partial disconnection, most leaks can be detected during a thorough workstation preuse checkout. Leaks can be small, compensated only by increase in fresh gas flow to overcome the loss of volume, or they can be very large, prohibiting any ventilation at all. No matter the size, all leaks should be investigated. Several monitors can assist the anesthesia provider in detecting a leak or circuit disconnection during the course of anesthetic care (Table 29-6).

Breathing circuit pressure monitoring is an extremely important aid in diagnosing leaks and disconnections. As discussed earlier, breathing circuit pressure monitoring is a required feature, and alarms must be present for high-pressure, elevated sustained-pressure, and negative-pressure situations. The threshold pressure limit alarm is useful for detecting leaks and disconnections. Machines must be designed so that whenever the breathing system pressure remains lower than the threshold limit while in a controlled ventilation mode for more than 20 seconds, an audible and visual alarm is generated (Fig. 29-34, *A*).

TABLE 29-6 METHODS OF DETECTING LEAKS AND DISCONNECTIONS DURING THE COURSE OF ANESTHESIA

Method	Leak Indications
Breathing circuit pressure sensors	*Threshold pressure alarm** Pressure waveform evaluation Trend of peak pressures
Workstation tidal volume sensors	Low minute ventilation or low tidal volume alarm Failure to deliver set tidal volume Disparity between inhaled and exhaled tidal volumes Decreasing trend of tidal volume and minute ventilation
Exhaled gas analysis	Exhaled carbon dioxide automated monitoring Abnormal appearance and trend of capnography tracing
Physiologic sensors (e.g., SpO_2%, HR, BP)	*Late detection* of significant leaks and disconnections because the patient is already decompensating
A vigilant practitioner	Assesses breath sounds and chest wall excursion Pays close attention to alarms and responds promptly Observes workstation and physiologic monitors Notes that ventilator bellows is not refilling completely and tidal volumes are decreasing Notes that flow rate requirements are increasing to refill an ascending bellows Senses that breathing bag motion and feel are not normal Detects the odor of anesthetic gas Follows his or her instinct that something is not right

BP, Blood pressure; *HR,* heart rate; *SpO_2,* saturation of peripheral oxygen.
*ASTM standard.

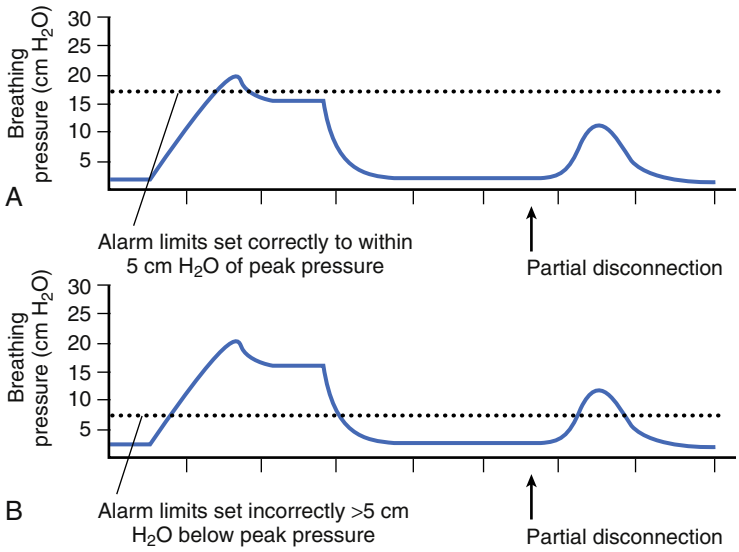

Figure 29-34. Threshold pressure alarm limit. **A,** The threshold pressure alarm limit (*dotted line*) has been set appropriately. An alarm is actuated when partial disconnection occurs (*arrow*) because the threshold pressure alarm limit is not exceeded by the breathing circuit pressure. **B,** Partial disconnection is unrecognized by the pressure monitor because the threshold pressure alarm limit has been set too low. *(Redrawn from North American Dräger:* Baromed breathing pressure monitor: operator's instruction manual, *Telford, Pa., 1986, North American Dräger.)*

Visual alarm examples include "Apnea Pressure," "Check Breathing Circuit," and "Low Pressure."[33,34,41] The specific pressure threshold alarm times on machines may vary slightly. The pressure threshold limit may be operator adjustable on some machines, and some may also have an "autoset" feature, which applies an algorithm to set an appropriate threshold limit based on the current airway pressures.[31,131] As can be seen in Figure 29-34, *B,* allowing the threshold limit to remain too low may allow a partial disconnection (leak) to go unrecognized. Conversely, allowing the threshold pressure limit to remain too high can result in an erroneous "apnea pressure" or "threshold low" alert.

Respiratory volume monitors are useful in detecting leaks or disconnections, and anesthesia workstations must be able to monitor exhaled tidal volume or minute ventilation. Alarms for low minute ventilation and low exhaled tidal volume alert the operator when these values drop to less than adjustable limits. The user should bracket the high and low threshold minute ventilation alarm slightly higher and lower than the patient's requirements. For example, if the exhaled minute volume of a patient is 10 L/minute, reasonable alarm limits would be 8 to 12 L/minute. An autoset feature may be available for minute ventilation monitoring as well.[131] Some workstations have an alarm if a significant disparity exists between inhaled and exhaled tidal volume, or when the measured tidal volume does not achieve the set tidal volume.[142] Finally, some workstations that have integrated gas monitoring may also use exhaled carbon dioxide as a means to alert the operator in the event of a loss of ventilation.

Misconnections. Misconnections of the breathing system are unfortunately not uncommon. Despite the efforts of standards committees to eliminate this problem by assigning different diameters to various hoses and hose terminals, they continue to occur. Anesthesia workstations, breathing systems, ventilators, and scavenging systems incorporate many of these diameter-specific connections. The ingenuity of some individuals in outwitting these "foolproof" systems has led to various hoses being cleverly adapted or forcefully fitted to inappropriate terminals and even to various other solid cylindrically shaped protrusions of the anesthesia machine.[143,144] Operators and technicians should be properly trained on their respective workstations, and workstation modification should be discouraged.

Occlusion. Occlusion (obstruction) of the breathing circuit may occur and can have severe consequences. Tracheal tubes can become kinked. Breathing circuit valves or other components can malfunction. Hoses throughout the breathing circuit are subject to occlusion by internal obstruction or external mechanical forces that can impinge on flow. Blockage of heat and moisture exchangers by secretions can cause significant obstruction, and blockage of a bacterial filter in the expiratory limb of the circle system has caused bilateral tension pneumothorax.[145,146] A misplaced disk in an expiratory valve also caused expiratory limb obstruction and tension pneumothorax.[147] Because retained carbon dioxide absorber canister wrapping has been associated with circuit obstruction, ASTM standards now require that absorbers be packaged in a way that immediately identifies the presence of a wrapper.[127,148,149] Defects associated with disposable circuit components or the disposable tubing itself have been associated with severe circuit obstruction and sometimes injury to the patient.[150-154] Misplaced Luer caps have made their way into the elbow connector of the circuit because of packaging or processing and have caused significant circuit obstruction.[155,156] Incorrect insertion of flow direction–sensitive components can result in a no-flow state. Examples of these components include some older PEEP valves and cascade humidifiers. Only the performance of manual circuit flow test, or a similar automated test, during the preuse checkout procedure reliably detects a circuit obstruction. *If you are struggling to ventilate a patient and are unsure regarding why, do not delay in switching to a self-inflating resuscitation bag.* Ventilate first, troubleshoot later.

Variations in Circle Breathing System Design. Numerous variations of the circle arrangement are possible, depending on the relative positions of the unidirectional

valves, the pop-off valve, the reservoir bag, the carbon dioxide absorber, and the site of fresh gas entry. However, to prevent rebreathing of carbon dioxide in a traditional circle system, three rules must be followed: (1) a unidirectional valve must be located between the patient and the reservoir bag on both the inspiratory and expiratory limbs of the circuit, (2) the fresh gas inflow cannot enter the circuit between the expiratory valve and the patient, and (3) the overflow (pop-off) valve cannot be located between the patient and the inspiratory valve. If these rules are followed, any arrangement of the other components will prevent rebreathing of carbon dioxide.[125] Design departures from the traditional circle breathing system are becoming more common as workstations evolve. Some of these designs are driven by the compensatory strategies intended to eliminate the impact of varying fresh gas flow rates or oxygen flush on inspiratory tidal volume and airway pressure during mechanical ventilations (fresh gas decoupling or compensation). Breathing system variations are addressed later, in the section on anesthesia ventilators.

Carbon Dioxide Absorbers

Circle breathing systems require a means of carbon dioxide removal from the exhaled gases to avoid carbon dioxide rebreathing and hypercapnia. Although increasing the fresh gas inflow to high levels can dilute out most carbon dioxide in the circle breathing circuit, this would be a very inefficient way to conduct an anesthetic regimen for reasons described earlier. Because gas flows through the anesthetic machine are less than minute ventilation, absorption of carbon dioxide prevents hypercarbia from occurring. If one could design an ideal carbon dioxide absorbent, its characteristics would include a lack of reactivity with common anesthetics, an absence of toxicity, low resistance to airflow, minimal dust production, small cost, ease of handling, and high efficiency carbon dioxide absorption. There should also exist a reliable method of assessing for absorbent depletion (i.e., a diminished ability to remove carbon dioxide). Finally, the container that houses the absorbent should be easy to remove and replace, should maintain breathing circuit integrity during rapid "in-flight" replacement, and should impose minimal risk of causing breathing system leaks or obstruction. Carbon dioxide absorbers are not unique to anesthesiology. They are also used in certain military and commercial diving equipment, submarines, space operations, mining and rescue operations, and hyperbaric facilities. In these environments, carbon dioxide absorbers are often referred to as *CO_2 scrubbers*.

Absorber Canister. Although anesthesia circuit absorber canister configurations vary considerably, they are all similar in that they must be visible to the operator and transparent to monitor for absorbent presence and color. Traditionally, the absorber canister has been composed of one or two clear plastic canisters arranged in series. Opening the canister assembly abolished the integrity of the breathing circuit, so ventilation had to be accomplished via other means if the absorbent had to be changed during the course of anesthesia and apnea could not be tolerated. Because of the multiple components and their compression assembly method, absorber canister assemblies of this type are not an uncommon source of leaks.[141] The canisters are filled either with loose bulk absorbent or with absorbent supplied by the factory in prefilled plastic disposable cartridges called *prepacks*. Free granules from bulk absorbent can create a clinically significant leak if they lodge between the clear plastic canister and the O-ring gasket of the absorber. Leaks have also been caused by defective prepacks that were larger than factory specifications.[157] Prepacks can also cause total obstruction of the circle system if the clear plastic shipping wrapper is not removed before use or if the prepack itself is defective.[148,154] Problems with rebreathing carbon dioxide have been caused by canister apparatus reassembly issues.[158-160] Many modern workstations now use single canister absorbers, with some being disposable and easily replaceable. Increasingly, workstation design allows the canister to be replaced during anesthesia without interfering with breathing system continuity, sometimes referred to as a *bypass* feature.[33] A potential risk imposed by this feature is that the machine may pass an automated or manual leak test *without* the absorber attached. This emphasizes the importance of actually inspecting the absorber before every anesthetic.

Chemistry of Absorbents. The process of removing carbon dioxide from the breathing circuit involves the absorption of the exhaled carbon dioxide by chemical absorbents contained within the absorber canister, whereby carbon dioxide is converted into water, heat, and other byproducts. Therefore, the removal of the acid gas carbon dioxide from the breathing circuit ultimately occurs via a series of chemical reactions; it is not merely a physical process like water soaking into a sponge. Most anesthesia machine absorbents use calcium hydroxide [$Ca(OH)_2$] to react with the expired carbon dioxide, producing insoluble calcium carbonate ($CaCO_3$). However, because carbon dioxide does not react quickly with $Ca(OH)_2$, water and small amounts of stronger bases have been used to speed up the carbon dioxide reaction. These calcium absorbents vary in terms of their contents of water; reaction catalysts such as sodium hydroxide (NaOH), potassium hydroxide (KOH), humectants (i.e., calcium chloride); and hardening agents such as silica. Many newer absorbents have only trace amounts of KOH, or it is absent altogether because this base has been associated with anesthetic degradation. Some have also limited or eliminated NaOH for the same reason. One absorbent brand replaces $Ca(OH)_2$ entirely with lithium hydroxide (LiOH), which does not require any additional catalysts to react with carbon dioxide. Key differences in absorbents include their absorptive capacity of carbon dioxide and their propensity to react with volatile anesthetics that produce potentially harmful degradation products (e.g., CO and compound A). The composition of several absorbents is shown in Table 29-7.[161-166]

The chemistry of carbon dioxide absorption by $Ca(OH)_2$-based absorbents is illustrated next using classic soda lime as an example. Carbon dioxide reacts relatively slowly with the $Ca(OH)_2$, so a few steps must occur first to catalyze the reaction. First, carbon dioxide reacts with liquid water present on and within the granules and

†Up to 60% of LiOH is chemically bound 1:1 with H_20 as Lithium Hydroxide Monohydrate (see text for details).

creates weak carbonic acid (H_2CO_3). This step emphasizes the importance water in the reaction, thus all calcium hydroxide–based absorbents contain approximately 12% to 19% H_2O by weight. Because the H_2CO_3 also does not react quickly with $Ca(OH)_2$, the strong base additives NaOH and KOH are used to form sodium carbonate (Na_2CO_3) and potassium carbonate (K_2CO_3). This occurs in the second step of the reaction. Na_2CO_3 and K_2CO_3 are capable of reacting quickly with $Ca(OH)_2$, which is seen in the third reaction. This results in the formation of insoluble $CaCO_3$ and the liberation of NaOH and KOH for reuse. The rate of conversion of carbon dioxide to H_2CO_3 in the first reaction is determined by how fast H_2CO_3 can be consumed by the catalyst requiring a second reaction. Therefore the third reaction is the rate-limiting step. Some carbon dioxide may react directly with $Ca(OH)_2$, but as mentioned, this reaction is slower. Byproducts of the entire process are water and heat.[167,168] As it became apparent that the strong base catalysts such as NaOH and KOH were associated with potentially adverse effects, their proportions were reduced or they were removed altogether.

1. $CO_2 + H_2O \rightleftharpoons H_2CO_3$
2. $H_2CO_3 + 2NaOH\ (KOH) \rightleftharpoons Na_2CO_3\ (K_2CO_3) + 2H_2O + Heat$
3. $Na_2CO_3\ (K_2CO_3) + Ca(OH)_2 \rightleftharpoons CaCO_3 + 2NaOH\ (KOH) + Heat$

In contrast to the calcium hydroxide–based absorbents, lithium hydroxide (LiOH)-based absorbents do not require additives to react with carbon dioxide. LiOH is capable of reacting quickly with carbon dioxide by itself. Although liquid water is not required as in the classic $Ca(OH)_2$ reaction (where it combines with CO_2 to create H_2CO_3), H_2O molecules are still required for the reaction to take place. Traditionally, these water molecules come from exhaled breathing gases to complete the reaction of carbon dioxide with LiOH to produce lithium carbonate. Additionally, LiOH absorbents may contain molecules of water, where they are chemically bound to LiOH (1:1) through the following exothermic reaction:[168a]

$$2LiOH + 2H_2O \rightleftharpoons 2LiOH * H_2O + Heat$$

LiOH that does not contain water is referred to as *LiOH anhydrous*. LiOH containing chemically bound water is called *lithium hydroxide monohydrate*. Because the water addition reaction gives off heat, LiOH absorbents that already contain chemically bound water (lithium hydroxide monohydrate) react at a lower temperature than LiOH anhydrous absorbents.

Granular anhydrous LiOH is formed by removing the water from a granule of lithium hydroxide monohydrate. This provides greater surface area for reaction with carbon dioxide when the absorbent is of granular form. One manufacturer has a technique that creates a large surface area by using lithium hydroxide anhydrous powder instead of large granules and binds this fine powder within a nongranular polymer matrix. The fine powder is then partially hydrated, resulting in both a large surface area for carbon dioxide to quickly react while also reducing the reaction temperature (personal communication, Micropore, Inc., Elkton, MD, 2014). When LiOH is bound with water (lithium hydroxide monohydrate), it removes carbon dioxide from the breathing circuit through the following endothermic reaction, producing insoluble lithium carbonate:

$$2LiOH * H_2O + CO_2 \rightleftharpoons Li_2CO_2 + 3H_2O - Heat$$

Interactions of Inhaled Anesthetics With Absorbents

Formation of Potentially Harmful Degradation Products. The interaction of volatile anesthetic agents with the strong bases present in calcium hydroxide–based carbon dioxide absorbents, such as KOH and NaOH, has been long known to be associated with the formation of degradation products. For historical perspective, trichloroethylene, a volatile anesthetic introduced to clinical use in 1940, was found to be associated with neurologic toxicity, particularly cranial nerve neuropathies and encephalitis.[169,170] Experimental investigation determined that dichloroacetylene, a toxin, was being formed by a base-catalyzed reaction due to prior formulations of soda lime, particularly if the soda lime had a large base content and was dry. Today, the main degradation products of concern are compound A, associated with the use of sevoflurane, and CO, mainly associated with the use of desflurane, enflurane, and isoflurane.[171] Other degradation products include formaldehyde and methanol, but these are not discussed here.[165]

Compound A Production. Sevoflurane can undergo a base-catalyzed degradation within the breathing circuit into fluoromethyl-2,2-difluoro-1-(trifluoromethyl) vinyl ether, known as *compound A*. Compound A has been shown to be nephrotoxic in rats at concentrations that are capable of occurring in the breathing circuit during clinical conditions.[169,172] Moreover, in a limited number of volunteer studies, sevoflurane was associated with transient albuminuria and glucosuria.[173,174] To date, however, mounting data have shown no relationship between sevoflurane use and postoperative renal dysfunction in humans, including patients with preoperative renal insufficiency.[169,175-180] Several physical factors can contribute to an increase in the concentration of compound A in the breathing circuit, including the following:

- Low-flow or closed-circuit anesthetic techniques
- Higher concentrations of sevoflurane in the anesthetic circuit
- The type of absorbent
- Higher absorbent temperatures
- Fresh absorbent[171,172,175,181]

Sevoflurane product information states that, to minimize the risk of exposure to compound A, sevoflurane exposure should not exceed 2 MAC-hours at flow rates of 1 to less than 2 LPM, although this recommendation predates several studies demonstrating safety at lower flow rates.

The type and ratio of strong bases within the carbon dioxide absorbent seem to be related to the degree of degradation of sevoflurane and compound A formation. KOH seems to be a stronger precipitant of breakdown than is NaOH.[164,166] For example, the absorbent Baralyme, which has been voluntarily withdrawn from the market, and classic soda lime, which both contain KOH and NaOH, have a greater propensity to cause sevoflurane degradation to compound A than do newer absorbents that contain only trace amounts of KOH.[166] Calcium hydroxide–based absorbents that contain neither KOH nor NaOH produce negligible amounts of compound A in some studies, and none in others.[163,166,182] LiOH-based absorbent has negligible or no compound A production.[162,182,182a,182b] Given the safe track record of sevoflurane and the ongoing improvements in carbon dioxide absorbents, the risk to patients imposed by compound A during routine clinical practice must be minimal.[183]

Carbon Monoxide Production. Strong-base absorbents that are extremely dry (desiccated) can also degrade contemporary inhaled anesthetics to clinically significant concentrations of CO and can cause patient injury.[164] Under certain conditions, this process can produce very high carboxyhemoglobin concentrations that reach 35% or greater.[184] A typical scenario involving patient exposure to a high concentration of CO would involve the first case of the day on a Monday, where high continuous gas flows circulating through the breathing system during the weekend cause desiccation of the absorbent.[185,186] Machines in remote locations are also at a more frequent risk of absorbent desiccation.[186] In the absence of a patient connected to the circuit, prolonged fresh gas flow rates of 5 L/min or greater through the absorbent are sufficient to cause critical drying of the absorbent material. The situation is even worse when the breathing bag is left off the breathing circuit with conventional circle systems. An absence of a slight pressure building in the reservoir bag facilitates retrograde flow through the circle system.[184] Because the inspiratory valve leaflet produces some resistance to flow, fresh gas flow takes the retrograde path of least resistance through the absorbent and out the 22-mm breathing bag mount (see the classic circle breathing system in Fig. 29-27).

Several factors increase the production of CO and resultant increased carboxyhemoglobin levels, including the following:

- The inhaled anesthetic used (for a given MAC multiple, the magnitude of CO production from greatest to least is desflurane ≥ enflurane > isoflurane >> halothane = sevoflurane),
- The dryness of the absorbent
- The type of absorbent
- The temperature (increased temperature increases CO production)
- The anesthetic concentration (more CO is produced with higher anesthetic concentrations)[187]
- Low fresh gas flow rates
- Reduced experimental animal (patient) size per 100 g of absorbent.[188,189]

As with compound A production, the presence of strong bases like KOH and NaOH in the absorbent correlates to the ability of desiccated absorbent to degrade certain anesthetics and liberate CO. Therefore the now withdrawn agent Baralyme and, to a lesser extent, conventional soda lime and similar absorbents were more likely to produce CO when desiccated than are newer-generation absorbents, which have minimized or eliminated the presence of these bases.[190] Elimination of NaOH and KOH from the calcium hydroxide–based absorbents diminishes or eliminates degradation of desflurane to CO and sevoflurane to compound A, but it does seem to compromise carbon dioxide absorption.[182,191] LiOH absorbent

produces essentially no CO and maintains the same or higher carbon dioxide absorption.[162, 182b,191a]

Absorbent Heat Production. One extremely rare but potentially life-threatening complication related to carbon dioxide absorbent is the development extreme exothermic reactions that lead to fires and explosions within the breathing system.[192-194] Specifically, this seems to occur as a result of interactions between desiccated strong-base absorbents (particularly Baralyme) and the inhaled anesthetic sevoflurane. Under experimental conditions using desiccated Baralyme, absorber temperatures reached 200° C (392° F) and higher, and fire was noted in some of the breathing circuits.[195] The buildup of very high temperatures, the formation of combustible degradation byproducts (formaldehyde, methanol, and formic acid), and the oxygen- or nitrous oxide–enriched environment provide all the substrates necessary for a fire to occur.[196] Avoidance of the combination of sevoflurane with strong base–heavy absorbents like the now discontinued Baralyme, especially if they have become desiccated, is the best way to prevent this unusual, potentially life-threatening complication. Anhydrous lithium hydroxide absorbents reacting with moisture from expired gas also can generate high temperatures, but formulations containing lithium hydroxide monohydrate do not.

A consensus statement established by the Anesthesia Patient Safety Foundation provides guidance to reduce the risk adverse interactions between volatile anesthetics and conventional carbon dioxide absorbents that may degrade volatile anesthetics when absorbent desiccation occurs.[164] The recommendations include the following:

- Turning off all gas flow when the machine is not in use
- Changing the absorbent regularly
- Changing the absorbent whenever the color change indicates exhaustion
- Changing all absorbent, not just one canister in a two-canister system
- Changing the absorbent when uncertain about the state of hydration, such as if the fresh gas flow has been left on for an extensive of indeterminate period of time
- If used, changing compact canisters more frequently

Given the improvements in absorbent chemistry, selecting an absorbent that minimizes risk adverse reactions is a prudent risk reduction strategy. Finally, educating anesthesia personnel regarding these hazards and their preventive measures will also reduce the likelihood of an adverse event.

Indicators. Conventional absorbents contain an indicator dye, ethyl violet, that allows anesthesia personnel to visually assess the functional integrity of the absorbent. Ethyl violet is a substituted triphenylmethane dye with a critical pH of 10.3.[168] The dye changes from colorless to violet when the pH of the absorbent decreases as a surrogate indicator of exhaustion. When the absorbent is fresh, the pH exceeds the critical pH of the indicator dye, and it exists in its colorless form. However, as the absorbent becomes exhausted, the pH decreases below 10.3 and ethyl violet changes to its violet form because of alcohol dehydration. This change in color indicates that the absorptive capacity of the material has been consumed. Unfortunately, in some circumstances ethyl violet may not always be a reliable indicator of the functional status of the absorbent. For example, prolonged exposure of ethyl violet to fluorescent light can produce photodeactivation of this dye. When this occurs, the absorbent appears white even though it may have a reduced pH and its absorptive capacity has been exhausted.[197] Similarly, color reversion (purple back to white) can occur with some absorbents due to the strongly alkaline nature of NaOH. Many newer generation absorbent indicators are more resistant to color reversion, and several now endorse permanent color change. At least one absorbent contains no indicator and relies upon the measured increase in inspired carbon dioxide and/or a time schedule to trigger replacement.

Like absorbent exhaustion, desiccation of calcium hydroxide–based absorbents is also an occult phenomenon. Therefore some newer generation $Ca(OH)_2$ absorbents may also include indicators that reveal whether the material has become desiccated. Users should refer to the product manufacturer's literature to determine whether their absorbent material uses this type of indicator.

Carbon Dioxide Removal Capacity and Absorber Resistance. The ability of the workstation's absorber to remove carbon dioxide is related to three main factors: (1) the amount of surface area of the absorbent that the exhaled gas is exposed to, (2) the intrinsic capacity of the absorbent to remove carbon dioxide, and (3) the amount of functionally intact absorbent remaining in the absorber. The size and shape of the actual absorptive granules are intended to maximize absorptive surface and flow throughout the canister while trying to minimize the resistance to airflow.[198] The smaller the granule size, the greater the surface area that is available for absorption. However, as particle size decreases, airflow resistance increases. The size and shape of the granules is of a proprietary nature. The granule size is often referred to by mesh size. Mesh size refers to the number of openings per linear inch in a sieve through which the granular particles can pass. For example, a 4-mesh screen means that there are four quarter-inch openings per linear inch.[167] The granular size of some common absorbents is between 4 and 8 mesh, a size at which absorptive surface area and resistance to flow are optimized.

As the absorbent granules stack up in the absorber canisters, small passageways inevitably form. These small passages channel gases preferentially through low-resistance areas. Because of this phenomenon, known as *channeling,* the functional absorptive capacity of the absorbent may be substantially decreased.[199] At least one manufacturer makes a nongranular, molded absorbent that uses a polymer to bind the absorbent particles together. This absorbent has molded airflow channels, eliminating the phenomenon of channeling typical of granular systems (personal communication, Micropore, Inc., Elkton, MD, June 3, 2014).

If completely reacted, a pound of calcium hydroxide has the capacity to absorb 0.59 lb of carbon dioxide.

Lithium hydroxide has the ability to absorb 0.91 lb of carbon dioxide per pound.[199a] Lithium hydroxide absorbents typically neutralize or "scrub" more carbon dioxide by weight [199a,199b] because of their higher capacity to react with carbon dioxide.

Mapleson Breathing Systems

In 1954, Mapleson described and analyzed five different breathing circuits, and they are now classically referred to as the Mapleson systems.[200] These systems are similar to the circle breathing system in that they accept a fresh gas flow, supply the patient with a sufficient volume of gas from a reservoir to satisfy the inspiratory flow and volume requirements, and eliminate carbon dioxide. They differ from the circle system because they have bidirectional flow and do not use an absorber. Therefore, these systems depend on an appropriate rate of fresh gas inflow to eliminate carbon dioxide.

Mapleson described five circuits, designated A through E (Fig. 29-35).[200] Subsequently, in 1975, Willis and coauthors described the F system, which was added to the original five.[201] The Mapleson systems consist of several common components, including a connection point to a facemask or endotracheal tube, reservoir tubing, fresh gas inflow tubing, and an expiratory pop-off valve or port. All the Mapleson circuits except for the E version use a bag as an additional reservoir.

Three distinct functional groups can be seen: A, BC, and DEF groups. The Mapleson A, also known as the Magill circuit, has a spring-loaded pop-off valve located near the facemask, and fresh gas flow enters the opposite end of the circuit near the reservoir bag. In the B and C systems, the spring-loaded pop-off valve is located near the facemask, but the fresh gas inlet tubing is located near the patient. The reservoir tubing and breathing bag serve as a blind limb where fresh gas, dead space gas, and alveolar gas can collect. Finally, in the Mapleson D, E, and F, or "T-piece" group, fresh gas enters near the patient, and excess gas is vented off at the opposite end of the circuit.

Even though the components and their arrangement are simple, functional analysis of the Mapleson systems can be complex.[202,203] The amount of carbon dioxide rebreathing associated with each system is multifactorial, and variables that dictate the ultimate carbon dioxide concentration include the following: (1) the fresh gas inflow rate, (2) minute ventilation, (3) the mode of ventilation (spontaneous or controlled), (4) tidal volume, (5) the respiratory rate, (6) the inspiratory-to-expiratory ratio, (7) the duration of the expiratory pause, (8) the peak inspiratory flow rate, (9) the volume of the reservoir tube, (10) the volume of the breathing bag, (11) ventilation by mask, (12) ventilation through an endotracheal tube, and (13) the carbon dioxide sampling site.

The performance of the Mapleson systems is best understood by studying the expiratory phase of the respiratory cycle.[204] Illustrations of the various arrangements of Mapleson systems components may be found in Figure 29-35. During spontaneous ventilation, the Mapleson A has the best efficiency of the six systems because it requires a fresh gas inflow rate of only 1 times minute ventilation to prevent rebreathing of carbon dioxide.[205] However, it has the worst efficiency during controlled ventilation because a minute ventilation as high as 20 L/minute is needed to prevent rebreathing. Systems DEF are slightly more efficient than systems BC. To prevent rebreathing carbon dioxide, the DEF systems require a fresh gas inflow rate of approximately 2.5 times minute ventilation, whereas the fresh gas inflow rates required for BC systems are somewhat higher.[203]

The following summarizes the relative efficiency of different Mapleson systems with respect to prevention of rebreathing during spontaneous ventilation: A > DFE > CB. During controlled ventilation, DFE > BC > A.[200,203] The Mapleson A, B, and C systems are rarely used today, but the D, E, and F systems are commonly used. In the United States, the most popular representative from the DEF group is the Bain circuit.

Mapleson systems have low resistance to gas flow, they are small and contain few parts, and changes in the

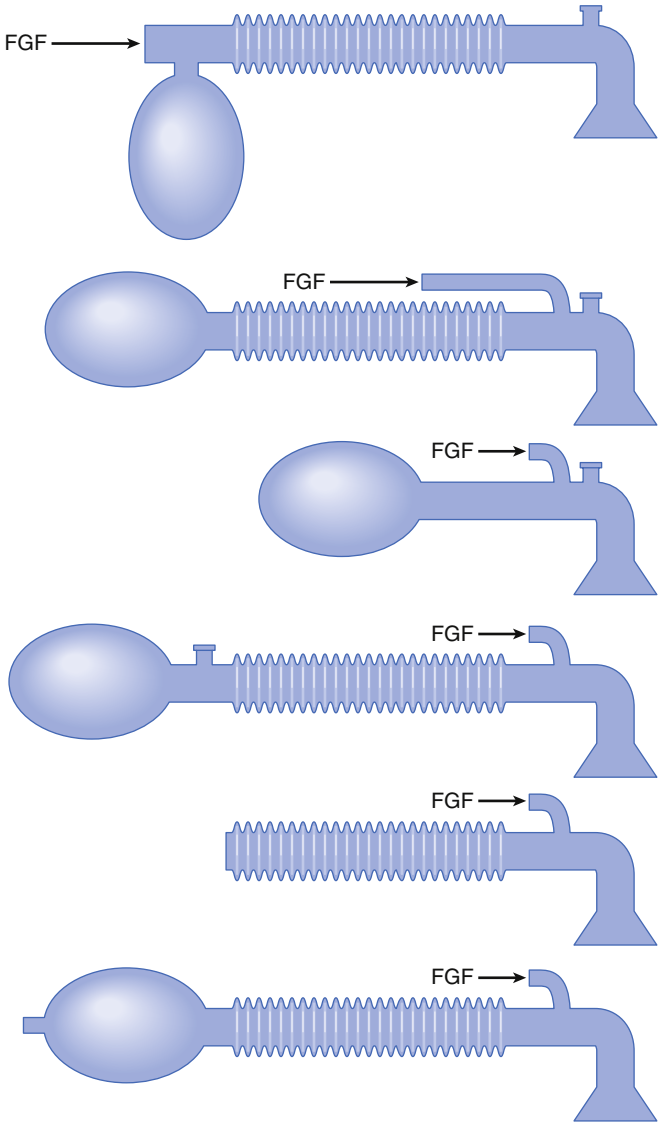

Figure 29-35. Mapleson breathing systems. *FGF,* Fresh gas flow. *(Redrawn from Willis BA, Pender JW, Mapleson WW: Rebreathing in a T-piece: volunteer and theoretical studies of the Jackson-Rees Modification of Ayer's T-piece during spontaneous respiration,* Br J Anesth *47:1239, 1975.)*

fresh gas flow composition result in rapid similar changes in the breathing circuit. In addition, the volatile anesthetic agents within a Mapleson breathing circuit have no chance of degradation because of the absence of a carbon dioxide absorber. However, given their need for higher gas flows, to dilute carbon dioxide their minimum required fresh gas flows are much higher than the circle system. Because of the higher gas flows, heat and humidity conservation is less efficient. Finally, scavenging can be challenging with these circuits, except for the Mapleson D, which has the pressure-limiting valve located away from the patient.[205]

Bain Circuit

The Bain circuit is a coaxial circuit and a modification of the Mapleson D system (Fig. 29-36). Fresh gas flows through a narrow inner tube within the outer corrugated tubing.[206] The central fresh gas tubing enters the outer corrugated hose near the reservoir bag, but the fresh gas actually empties into the circuit at the patient's end. Exhaled gases enter the corrugated tubing and are vented through the expiratory valve near the reservoir bag. The Bain circuit may be used for both spontaneous and controlled ventilation. The fresh gas inflow rate necessary to prevent rebreathing is 2.5 times minute ventilation.

The Bain circuit has many advantages over other systems. It is lightweight, convenient, easily sterilized, and potentially reusable. Being a Mapleson system, it has a very low resistance to breathing. Scavenging of gases from the expiratory valve is facilitated because the valve is located away from the patient. Exhaled gases in the outer reservoir tubing add warmth to the inspired fresh gases by countercurrent heat exchange. The main hazards related to use of the Bain circuit are an unrecognized disconnection and kinking of the inner fresh gas hose. These problems can cause hypercapnia as a result of inadequate gas flow or increased respiratory resistance. As with other circuits, an obstructed antimicrobial filter positioned between the Bain circuit and the endotracheal tube can result in increased resistance in the circuit. This may produce hypoventilation and hypoxemia that may even mimic the signs and symptoms of severe bronchospasm.[207]

The outer corrugated tube should be transparent to allow ongoing inspection of the inner tube. The integrity of the inner tube can be assessed as described by Pethick.[208] With his technique, high-flow oxygen is fed into the circuit while the patient's end is occluded until the reservoir bag is filled. The patient's end is opened, and oxygen is flushed into the circuit. If the inner tube is intact, the Venturi effect occurs at the patient's end. This causes a decrease in pressure within the circuit, and as a result, the reservoir bag deflates. Conversely, a leak in the inner tube allows fresh gas to escape into the expiratory limb, and the reservoir bag remains inflated. This test is recommended as part of the preanesthesia check if a Bain circuit is used.

ANESTHESIA VENTILATORS

Only a few decades ago, anesthesia ventilators were mere adjuncts to the anesthesia machine. Historical draw-over systems relied only on spontaneous breathing by the patient. Later, breathing bags were added to anesthetic delivery devices to allow manual ventilation. As the use of muscle relaxants and opiates became more common and the scope of surgery expanded, the need for automated mechanical ventilation increased. Today, ventilators have attained a prominent central role within the anesthesia workstation. Whereas early anesthesia ventilators provided only controlled mandatory ventilation that did not allow any patient-ventilator synchrony, many modern workstations incorporate ventilators with ICU-like capabilities that allow triggering by the patient's inspiratory effort, patient breath cycling, and multiple modes of ventilation. As the demands for precise, controlled ventilation and supported spontaneous ventilation increase, anesthesia workstation ventilator capability attempts to keep pace. However, incorporating an ICU-like ventilator on the anesthesia workstations is a challenging engineering endeavor because anesthesia ventilator requirements are unique. In particular, the anesthesia ventilator must act as a reservoir to receive and redeliver the patient's exhaled gas. For this reason, anesthesia machine ventilators incorporate either a bellows or piston-like design (or a volume reflector in the case of the Maquet FLOW-I

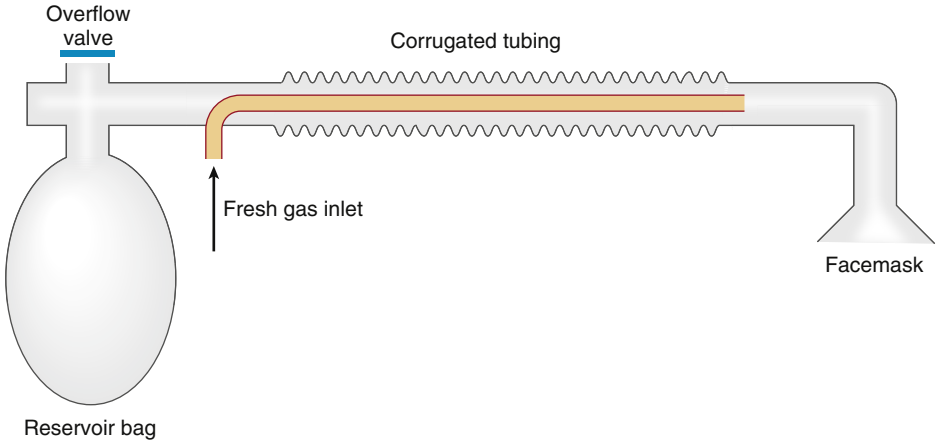

Figure 29-36. The Bain circuit. *(Redrawn from Bain JA, Spoerel WE: A streamlined anaesthetic system,* Can Anaesth Soc J *19:426, 1972.)*

Anesthesia System. See Maquet FLOW-i section). Further, the anesthesia ventilator system must function in the semiclosed environment of the circle breathing system and must be capable of venting excess circuit gas (waste gas). ICU ventilators are simply open circuit, venting all exhaled gas into the atmosphere. The demands imposed on the anesthesia ventilator systems mandate differences in circuit design and control. This discussion focuses on the classification, operating principles, and hazards associated with contemporary anesthesia ventilators.

Classification

Modern anesthesia ventilators can be best classified according to the type of reservoir that receives and delivers the breathing gas (bellows, piston, or volume reflector) and the drive mechanism of the reservoir (pneumatic or mechanical). The latter classification is almost unnecessary because bellows-type ventilators are virtually always pneumatically driven, and piston-type ventilators are usually mechanically driven. Bellows-type ventilators can be subclassified as ascending or descending. The direction of bellows movement during the *expiratory phase* determines the bellows classification. An ascending (standing) bellows *ascends* during the expiratory phase, whereas a descending (hanging) bellows *descends* during the expiratory phase. The implications of this difference are discussed later. Both types of bellows ventilators and a piston ventilator are illustrated in Figures 29-37 and 29-38.

Additional classifications involve the modes of ventilation that are available. Older anesthesia machine ventilators operated only in a time-triggered and time-cycled manner, or as "controller ventilators." Modern machines

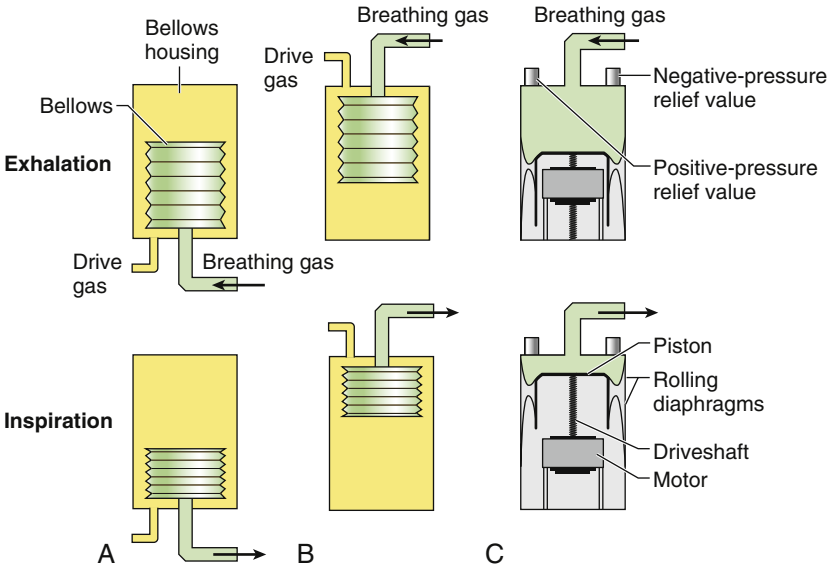

Figure 29-37. Three types of anesthesia ventilators during exhalation (**top row**) and inhalation (**bottom row**). Breathing gas is *green.* Ventilator drive gas is *yellow.* **A,** Ascending bellows **B,** Descending bellows. **C,** Piston ventilator. See text for additional details. *(Piston ventilator modified from Yoder M: Ventilators. In* Understanding modern anesthesia systems, *Telford, Pa., 2009, Dräger Medical.)*

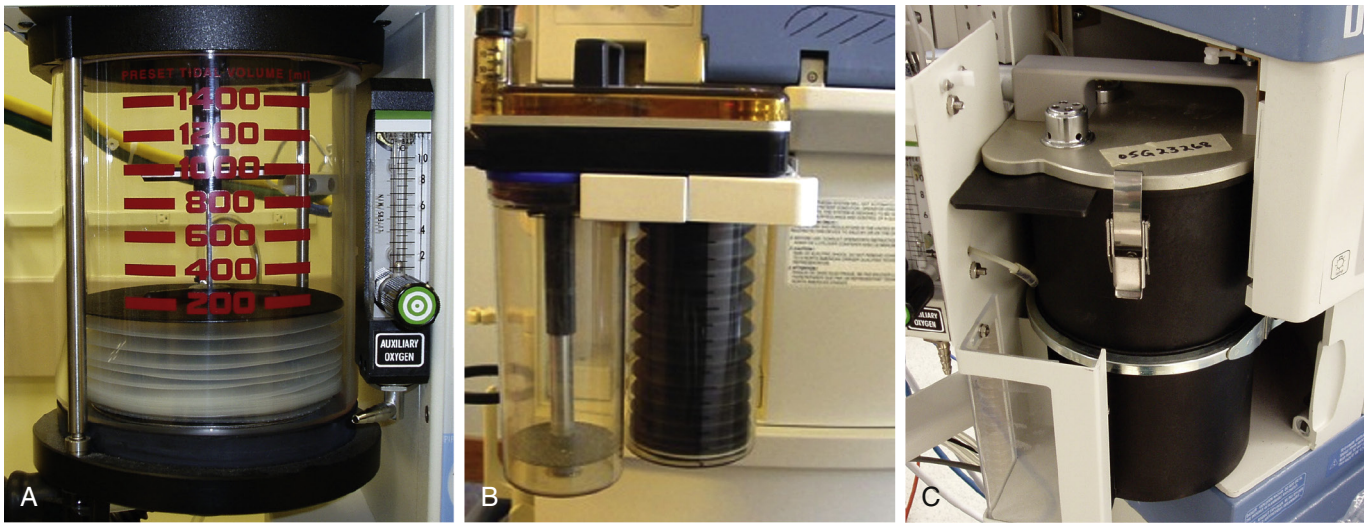

Figure 29-38. Anesthesia workstation ventilators. To allow rebreathing and the conservation of anesthetic gases, the anesthesia workstation ventilator must serve a reservoir for the patient's exhaled breathing gas, just as the breathing bag does in manual and spontaneous modes of ventilation. This is a unique requirement of ventilators in anesthesia workstations. Intensive care unit ventilators, conversely, can simply vent exhaled gases into the environment. **A,** Ascending bellows. **B,** Descending (hanging) bellows. **C,** Piston ventilator housing.

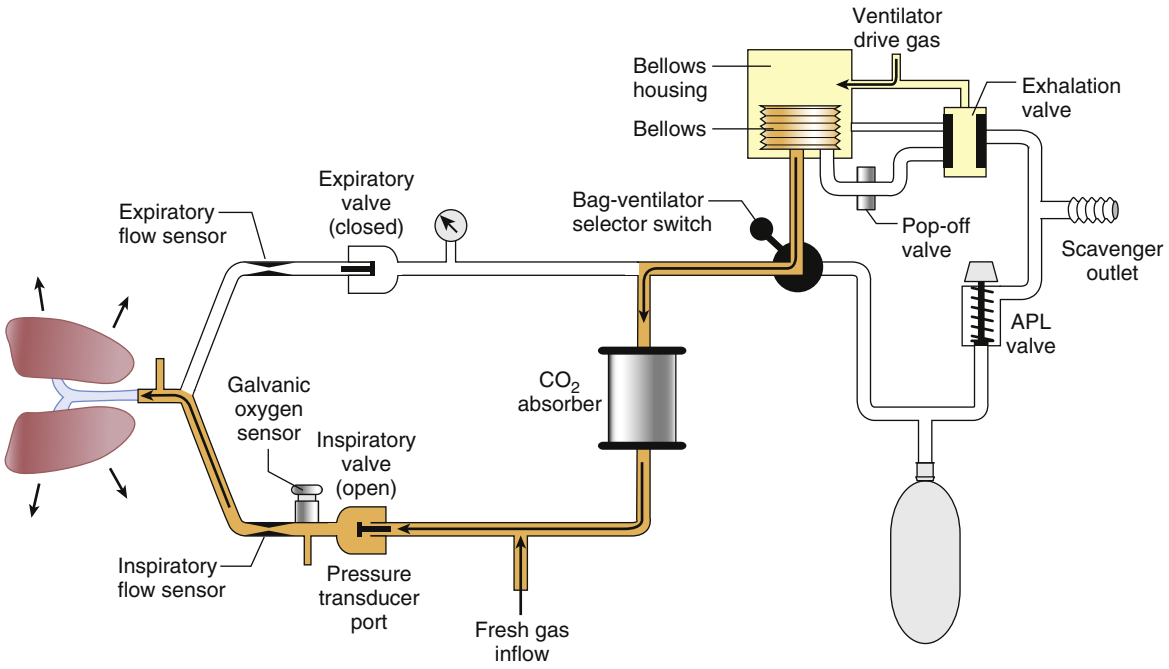

Figure 29-39. Inspiratory phases of ventilation with an ascending bellows ventilator represented by GE Aisys anesthesia workstation.. The ventilator drive gas circuit is located outside the bellows, and the patient's breathing circuit is inside the bellows. During the inspiratory phase the electronically controlled ventilator driving gas enters the bellows chamber and causes the pressure to increase, thereby compressing the bellows, which delivers gas to the patient's lungs. The drive gas also closes the exhalation valve and prevents the breathing gas from escaping into the scavenging system. Compensation for the impact of fresh gas flow on tidal volume accuracy is accomplished by monitoring the inhaled tidal volumes and adjusting ventilator drive gas volumes accordingly. *APL,* Adjustable pressure-limiting; *CO_2,* carbon dioxide. *(Image courtesy Dr. Michael A. Olympio; modified with his permission. Adapted from Datex-Ohmeda:* Aisys anesthesia machine: technical reference, *Madison, Wis., 2005, Datex-Ohmeda.)*

that offer synchronized intermittent mandatory ventilation (SIMV), assist control (A/C), and pressure support ventilation (PSV) must offer patient's triggering and patient's breath cycling and can be referred to as "noncontroller" ventilators. Many anesthesia ventilators can function in a volume-controlled or pressure-controlled modes. Finally, even though some ventilators may be pneumatically driven, all modern ventilators are under electronic control. The following sections review ventilator classification from a functional perspective, using specific workstations as examples.

Pneumatically Driven Bellows Ventilator

The operating principle of the bellows ventilator is that it functions as bellows in a box. The bellows, which is enclosed in an airtight housing, serves as reservoir for the patient's breathing gas. The driving force used to squeeze the gas out of bellows and back to the patient, as an anesthesia provider would squeeze a breathing bag, is pressurized gas that flows into the bellows housing under electropneumatic control. As the bellows is compressed, it delivers the breathing gas to the patient. The patient's exhalation and fresh gas flowing into the breathing circuit refill the bellows. Once the bellows is refilled, excess circuit gas is vented to the scavenging system during the expiratory pause. The mechanisms that vent breathing circuit waste gas during mechanical ventilation with bellows ventilators differ among manufacturers and models. The bellows ventilator is traditionally designated as a *double circuit*, meaning that the ventilator drive gas and the breathing gas exist in two separate circuits. The bellows serves as the interface between the breathing gas and the drive gas, much like the reservoir bag serves as the interface between the breathing gas and the anesthesia care provider's hands.[209] Figures 29-39 to 29-41 illustrate the inspiratory, early expiratory, and late expiratory phases of mechanical ventilation with an ascending bellows ventilator on the GE Aisys workstation. Many modern bellows ventilators, like the one shown in the example, can provide pressure- and volume-controlled ventilation, patient's triggering to support modes such as SIMV, and patient's cycling for pressure support ventilation.

The source of the drive gas for the bellows is either oxygen or air, which is obtained from the gas supply section of the workstation. Some workstations allow for the selection of either oxygen or air as the ventilator drive gas, and some can entrain room air through a Venturi effect into the oxygen drive gas flow, thereby decreasing the oxygen gas requirement. The type of gas used does have implications. First, if oxygen is used as the drive gas, the consumption of oxygen by the machine will equal that selected at the oxygen flow control valve *in addition to* an amount approximately equal to the minute ventilation being delivered by the ventilator. When oxygen is in finite supply (e.g., loss of hospital line supply, austere conditions), the use of the ventilator may rapidly deplete the oxygen supply. For example, a full E-cylinder contains approximately 625 L of oxygen. At an average oxygen

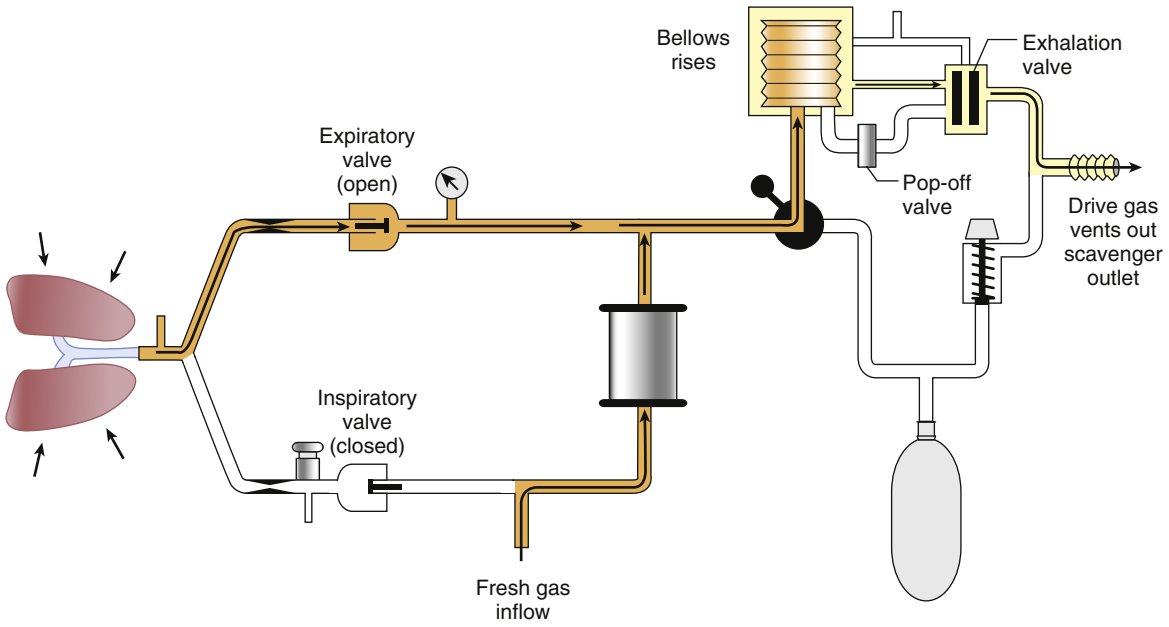

Figure 29-40. During the early expiratory phase, the patient is able to exhale into the bellows because the ventilator exhalation valve is now open, thus allowing the drive gas in the bellows housing to vent through the scavenger outlet. The pop-off or ventilator relief valve prevents bellows gas from escaping at this point so the bellows can fill. *(Courtesy Dr. Michael A. Olympio; modified with his permission. Figure 29-41. During the late expiratory phase, positive end-expiratory pressure (PEEP) is provided by pressurization of the bellows housing and pressure modulation of the expiratory valve. Whenever the pressure in the bellows exceeds the surrounding housing pressure by 2.5 cm H_2O, the pop-off or ventilator relief valve vents excess breathing gas to the scavenger. Bellows ventilator PEEP control and excess gas venting methods differ among manufacturers. *(Courtesy Dr. Michael A. Olympio; modified with his permission. Adapted from Datex-Ohmeda:* Aisys anesthesia machine: technical reference, *Madison, Wis., 2005, Datex-Ohmeda.)*

fresh gas flow rate of 1.5 L/minute, the tank would last almost 7 hours. However, if oxygen is *also* required as the ventilator drive gas, and the delivered minute ventilation is approximately 5.75 L/min, the tank would only last approximately 86 min.

As described earlier, bellows-type ventilators can be classified according to the direction that they move during patient exhalation. Ascending bellows rises with exhalation, and descending bellows falls with exhalation (see Fig. 29-37). Older pneumatic ventilators and some newer anesthesia workstations use weighted descending bellows, but most contemporary bellows ventilators employ an ascending bellows design. Of the two configurations, the ascending bellows is considered safer.

An ascending bellows will not fill if total disconnection occurs, or it may only partially fill if a circuit leak exceeds the fresh gas flow rate. However, the bellows of a descending bellows ventilator continues its upward and downward movement despite patient disconnection, so a descending bellows does not provide a visual cue for a circuit disconnect. The driving gas pushes the bellows upward during the inspiratory phase. During the expiratory phase, room air can entrained into the breathing system at the site of the disconnection because gravity acts on the weighted bellows. The disconnection pressure monitor and the volume monitor may be fooled even if disconnection is complete.[37] An essential safety feature of any anesthesia workstation that uses a descending bellows is an integrated carbon dioxide apnea alarm that cannot be disabled while the ventilator is in use. Some contemporary anesthesia workstation designs have returned to the descending bellows to integrate fresh gas decoupling.

Bellows Assembly Problems. Leaks can occur in the bellows assembly. Improper seating of the plastic bellows housing can result in inadequate ventilation because a portion of the driving gas is vented to the atmosphere. A hole in the bellows can lead to alveolar hyperinflation and possibly barotrauma in some ventilators because high-pressure driving gas can enter the patient's circuit. The oxygen concentration of the patient's gas may increase when the driving gas is 100% oxygen, or it may decrease if the driving gas is composed of air or an air-oxygen mixture.[210]

The ventilator relief valve can potentially cause problems. Hypoventilation can occur if the valve becomes incompetent because anesthetic gas is delivered to the scavenging system during the inspiratory phase instead of to the patient. Ventilator relief valve incompetency can result from a disconnected pilot line, a ruptured valve, or a damaged flapper valve.[211,212] A ventilator relief valve stuck in the closed or partially closed position can cause either barotrauma or undesired PEEP.[213] Excessive suction from the scavenging system can draw the ventilator relief valve to its seat and close the valve during both the inspiratory and expiratory phases.[37] In this case, breathing circuit pressure escalates because the excess anesthetic gas cannot be vented. During the expiratory phase, some machines (e.g., Datex-Ohmeda S/5 ADU, Many contemporary GE machines, Mindray AS 3000 [Mindray, Mahwah, NJ]) send to the scavenge interface both excess patient's gas and the exhausted ventilator drive gas. In other words, when the ventilator relief valve opens and waste anesthetic gases are vented from the breathing circuit, the drive gas from the bellows housing joins with these gases to enter the scavenging system. Under certain conditions, the large volume of exhaust gases could overwhelm the scavenging system and cause pollution of the operating room with waste anesthetic gases (see the section on scavenging systems). Other mechanical problems that can occur include leaks within the system, faulty pressure regulators, and faulty valves.

Mechanically Driven Piston Ventilator

A resurgence in the use of mechanically driven anesthesia ventilators has occurred. These "piston"-type ventilators use a computer-controlled stepper motor instead of compressed drive gas to drive the cylinder and actuate gas movement in the breathing system (see Fig. 29-37, *C*). They are classified, in anesthesia ventilator parlance, as piston-driven *single-circuit* ventilators because a separate ventilator drive gas circuit is not necessary The piston operates much like the plunger of a syringe to deliver the desired tidal volume or airway pressure to the patient. Computerized controls can provide advanced types of ventilation support in addition to the conventional control-mode ventilation such as SIMV, pressure-controlled ventilation (PCV), and pressure support–assisted ventilation.

Because the patient's mechanical breath is delivered without the use of compressed gas to actuate a bellows, these systems consume dramatically less compressed gas during ventilator operation than do traditional pneumatic ventilators. This improvement in efficiency may have clinical significance when the anesthesia workstation is used in a setting where no pipeline gas supply is available (e.g., remote locations or office-based anesthesia practices). Another advantage of the piston ventilator is the potential for very accurate tidal volume delivery. Because of the low compliance of the piston chamber, tidal volume delivery is closely related to piston movement. This is in contrast to bellows-type ventilators, in which the drive gas can be subject to varying degrees of compression. However, with either piston or bellows ventilators, feedback mechanisms that help maintain stable tidal volume delivery are becoming increasingly more common. These include circuit compliance compensation and the use of inspired tidal volume measurement as a feedback signal. Figures 29-42 to 29-44 illustrate the inspiratory and expiratory phases of mechanical ventilation with a piston ventilator on the Dräger Fabius workstation. Note the location of the ventilator within the breathing circuit on the Dräger Fabius system, the fresh gas decoupling valve (described later), and the fact that the breathing bag participates in the mechanical ventilation mode.

Piston ventilators tend to be hidden relative to their bellows ventilator counterparts because they are usually fully or partially concealed from view. Because of this concealment, visual feedback of the patient's exhaling back into the piston reservoir, as can easily be observed with the ascending bellows, is lost. In addition, piston ventilators tend to be extremely quiet, so the partially reassuring sound of the mechanical ventilator in operation is much more subtle. Some systems incorporate a breathing sound emulator that creates ventilator sounds to substitute for the traditional feedback noise (i.e., Dräger Apollo).

A potential hazard associated with piston ventilators is that, like descending bellows ventilators, they will refill even if a circuit disconnection occurs. Similarly, if a circuit leak is present, piston ventilators may entrain room air through the leak, thereby diluting oxygen and anesthetic agent. The associated risks are hypoxemia and awareness. The Dräger Fabius series piston ventilator will entrain room air through an auxiliary air valve, seen in Figure 29-37, *C,* to fill the piston chamber if the fresh gas flow fails or is inadequate (instead of causing negative pressure in the breathing circuit). However, if

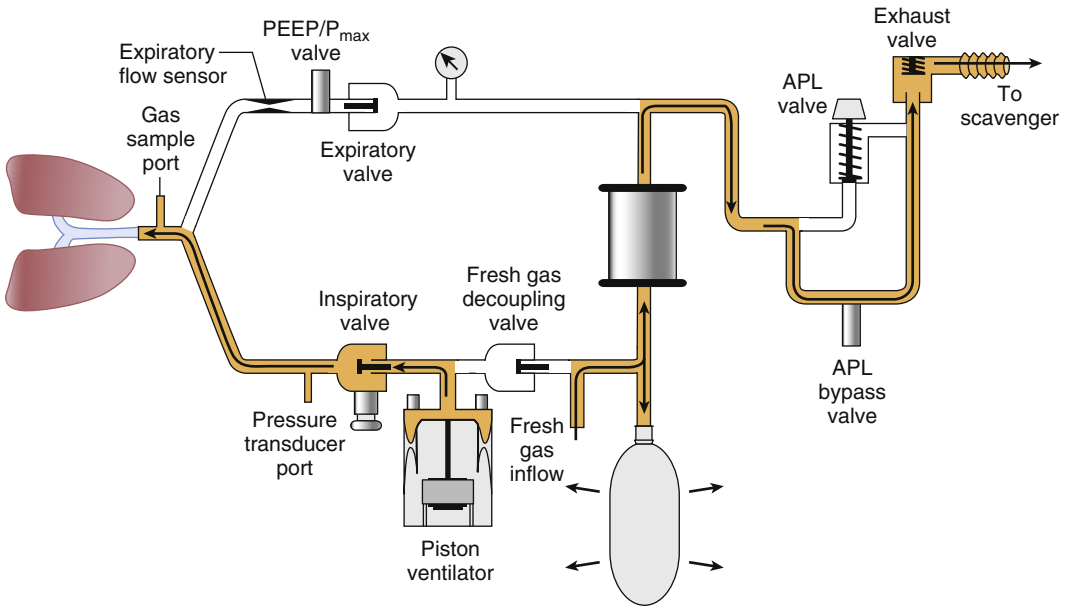

Figure 29-42. Inspiratory phase of ventilation with a piston ventilator represented by Dräger Fabius anesthesia workstation. During inspiration, the positive end-expiratory pressure (PEEP)/maximum pressure (P_{max}) valve is held closed. The pressure in the breathing circuit that is generated by the ventilator closes the fresh gas decoupling valve. This directs fresh gas flow toward the breathing bag during inspiration so it does not interfere with tidal volume accuracy. Excess gas fresh gas flows past the open adjustable pressure-limiting (APL) bypass valve, through the exhaust check valve, and to the scavenger. Note how the breathing bag is integral to circuit function during mechanical ventilation. In the manual and spontaneous modes of ventilation, the piston ventilator is held in the upward position, and the APL bypass valve closes, thus making the APL valve operable. *(Courtesy Dr. Michael A. Olympio; modified with his permission. Adapted from Dräger Medical:* Dräger technical service manual: Fabius GS anesthesia system, *Telford, Pa., 2002 Rev: E, Dräger Medical.)*

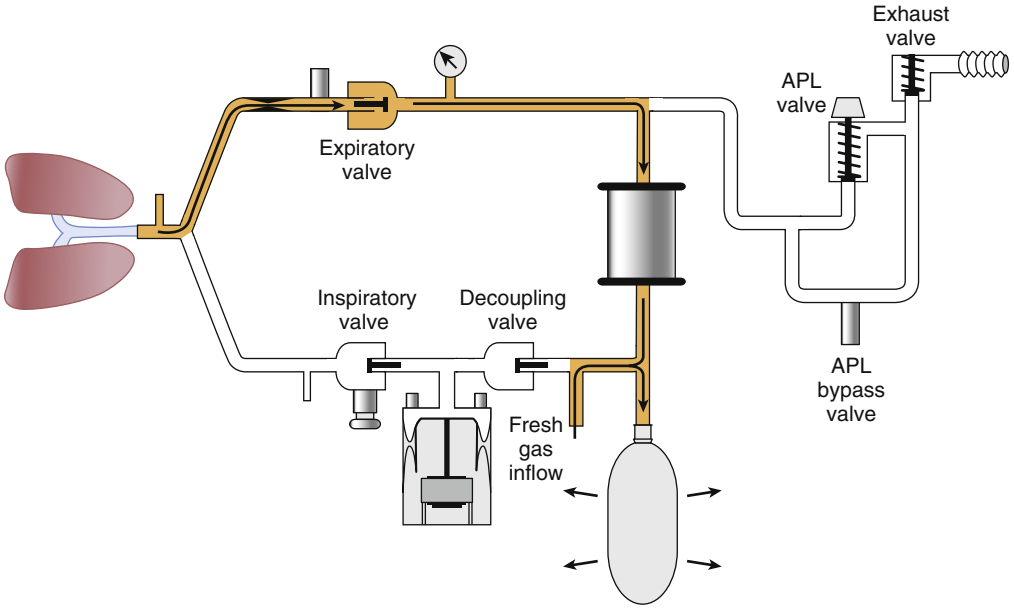

Figure 29-43. During the first step of exhalation the patient exhales into the breathing bag, and fresh gas continues to flow in retrograde fashion, as shown. *APL,* Adjustable pressure-limiting. *(Courtesy Dr. Michael A. Olympio; modified with his permission. Adapted from Dräger Medical:* Dräger technical service manual: Fabius GS anesthesia system, *Telford, Pa., 2002 Rev: E, Dräger Medical.)*

this occurs, an alarm will alert the operator. A positive-pressure relief valve on the ventilator prevents excessively high breathing circuit pressure (60 to 80 cm H_2O).[214]

Maquet FLOW-i Anesthesia System With Volume Reflector

Instead of employing a bellows or piston ventilator, the Maquet FLOW-i anesthesia workstation uses a device called the volume reflector (Figs. 29-45 and 29-46). The volume reflector is a coiled, 3.6-m plastic channel with an approximate 1.2-L capacity, which serves as reservoir for exhaled gases. The volume reflector is functional and "in-circuit" during all modes of ventilation. It is interposed between the patient and the reflector gas module during positive-pressure ventilation or between the patient and the breathing bag during spontaneous or assisted ventilation.

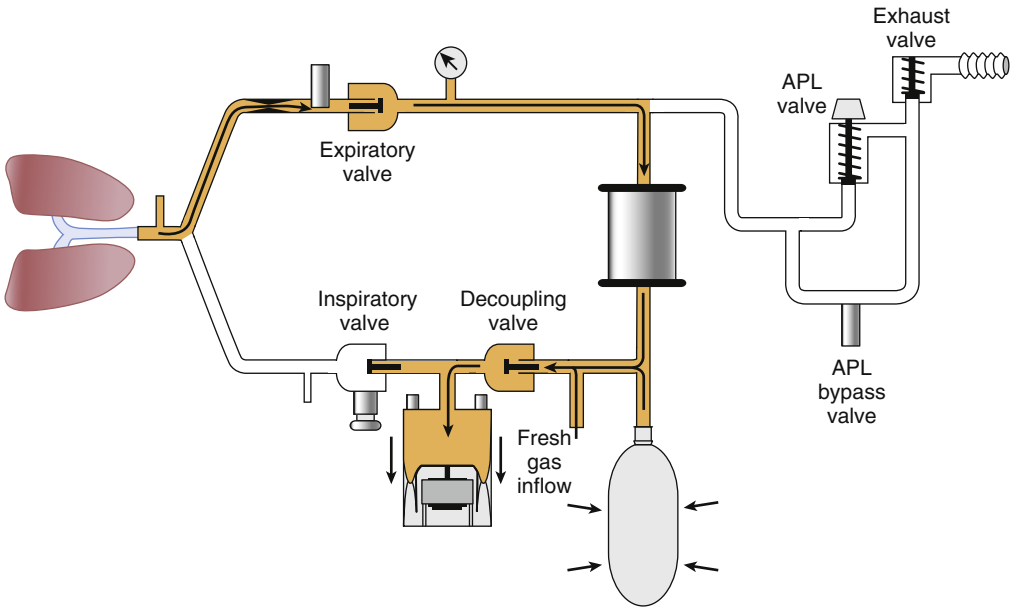

Figure 29-44. During the second step of exhalation the ventilator returns to its staring position, drawing in gas stored within the breathing bag and fresh gas from the gas supply system. Positive end-expiratory pressure (PEEP) is maintained by the PEEP/maximum pressure valve, which also prevents the ventilator from pulling in gas from the lungs. Once the piston reaches the bottom of its stroke, fresh gas flow reverses course and flows in retrograde fashion toward the breathing bag and the absorber (as in Figure 29-42). Excess gas vents through the exhaust valve to the scavenger (also depicted in right side of Figure 29-42). *APL,* Adjustable pressure-limiting. *(Courtesy Dr. Michael A. Olympio; modified with his permission. Adapted from Dräger Medical:* Dräger technical service manual: Fabius GS anesthesia system, *Telford, Pa., 2002 Rev: E, Dräger Medical.)*

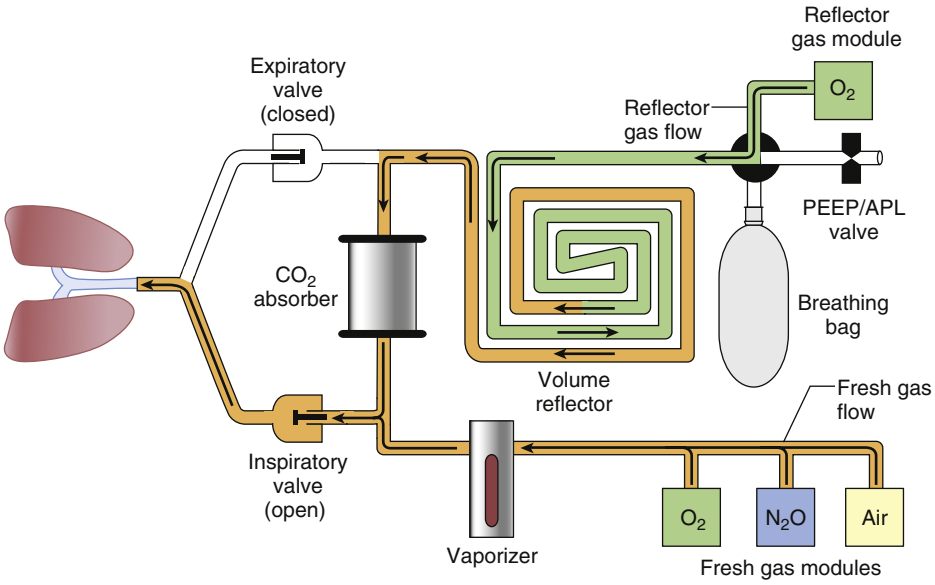

Figure 29-45. Simplified schematic of the Maquet FLOW-i anesthesia workstation breathing circuit and gas supply system. During controlled positive-pressure ventilation, the reflector gas module provides the driving force for ventilation by pushing gas out of the volume reflector to the patient. Volume reflector gas combines with the fresh gas flow downstream from the carbon dioxide (CO_2) absorber. *APL,* Adjustable pressure-limiting; *N_2O,* nitrous oxide; *O_2,* oxygen; *PEEP,* positive end-expiratory pressure. Please see text for additional details. *(Personal communication, Maquet Critical Care, January 14, 2013. The reflector gas module serves as the controlled ventilation driving force. At the end of exhalation, the volume reflector is filled at its proximal end (nearer the patient) with exhaled gas and is filled distally with a mixture of exhaled gases and reflector gas. The reflector gas module is a solenoid-controlled oxygen flow source, which pushes the exhaled gas back out of the volume reflector during inspiration, much like a piston, through the carbon dioxide absorber to the patient. Fresh gas combines with the volume reflector outflow to maintain the desired oxygen and anesthetic concentration. The fresh gas modules and the reflector gas module work together in a coordinated manner to control gas flow and pressure in the breathing circuit so that operator determined ventilation parameters are maintained. All the gas modules use feedback loop–controlled, solenoid-actuated, pneumatic valves similar in function those found in a servo-controlled ICU ventilator (personal communication, Maquet Critical Care, January 14, 2013).

When the workstation is in the spontaneous mode of ventilation, the breathing bag is enabled, and the reflector gas module is disabled. The patient breathes in and out of the volume reflector, and circuit pressure controlled by the operator adjustable APL valve. Excess gases

in controlled and spontaneous modes of ventilation are vented to the scavenger through the dual-function PEEP-APL valve.

The FLOW-i system can compensate for breathing system leaks by increasing reflector gas module flow. The operator is informed if this occurs. Because the reflector gas module provides only 100% oxygen, dilution of anesthetic gas occurs in this circumstance. The machine is nearly entirely electronically interfaced; therefore, an emergency manual ventilation backup mode is provided for cases of system failure. This emergency backup mode provides mechanical oxygen flow adjustment and mechanical APL valve linkage (personal communication, Maquet Critical Care, January 14, 2013).

Fresh Gas Flow Compensation and Fresh Gas Decoupling

On most anesthesia workstations, gas flow from the fresh gas line into the breathing circuit is continuous and independent of ventilator activity. During the inspiratory phase of mechanical ventilation, the ventilator relief valve (also known as the ventilator pop-off valve) is typically closed, and the breathing system's APL valve is most commonly out of circuit. Therefore, during positive-pressure ventilation on most traditional machines, the patient's lungs received the volume from the bellows in addition to that from the flowmeters during the inspiratory phase. The amount of excess volume (and pressure) that the patient received was proportional to the direction and magnitude of the change in the fresh gas flow rate. As the practitioner turned up the fresh gas flow, the tidal volume increased. The opposite would occur if the flow rate were decreased from the baseline. It was therefore common knowledge that the operator needed to adjust the set tidal volume on the ventilator if the total fresh gas flow rate was changed to maintain stable tidal volumes and airway pressure. Many newer workstations have engineering features that provide compensation of fresh gas flow to maintain stable tidal volume delivery. The manner in which this is accomplished also accounts for much of the variation in breathing system design. Using GE Aisys as an example (see Fig. 29-39), inspiratory tidal volume measurement serves as a feedback signal for the automatic adjustment of ventilator drive gas volume to compensate for changes in fresh gas flow, small leaks, and compression upstream of the breathing circuit.[144] On the Dräger Fabius workstation, a principle called *fresh gas decoupling* is used to prevent changes in the fresh gas flow rate from altering positive-pressure tidal volumes and breathing circuit pressures. During the inspiratory phase of ventilation, a decoupling valve located upstream from the piston ventilator diverts the fresh gas stream toward the breathing bag and scavenge outlet during each positive-pressure breath (see Fig. 29-42).

On traditional and many contemporary workstations without a fresh gas decoupling feature, inappropriate activation of the oxygen flush valve during the inspiratory phase of mechanical ventilation can add a substantial amount of volume to the circuit and can result in barotrauma or volutrauma (or both) because excess pressure and volume may not be able to be vented from the breathing circuit.[26] Although the circuit high-pressure alarm may provide warning, unless an adjustable inspiratory pressure limiter is set to a relatively low value, high pressures can be realized. On workstations equipped with adjustable inspiratory pressure limiters, maximal

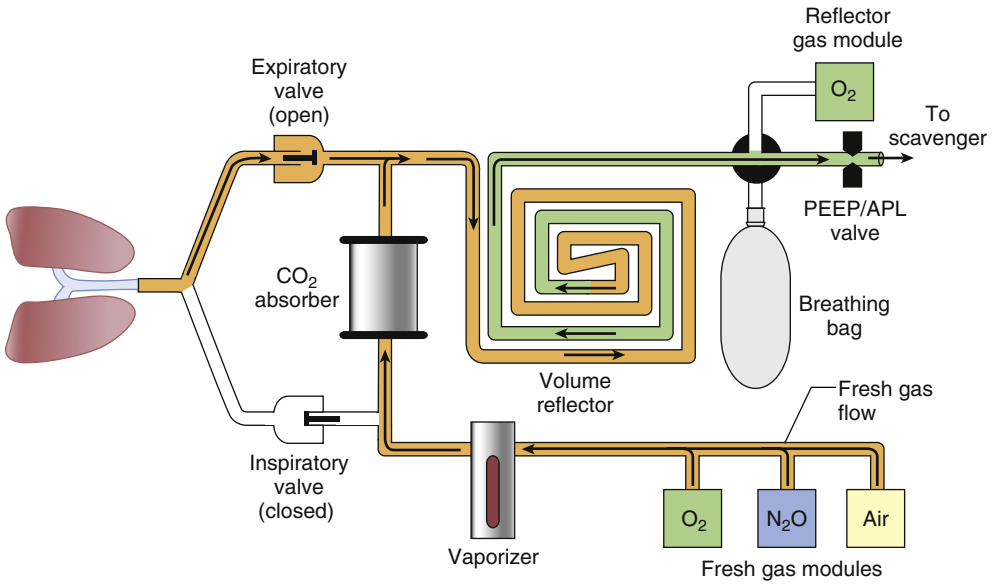

Figure 29-46. Maquet FLOW-i breathing circuit and gas supply during exhalation in a controlled ventilation mode. The patient exhales into the volume reflector, which serves as an exhalation reservoir. The patient only partially fills the volume reflector. Fresh gas flows in retrograde fashion and combines with the exhaled gas. Excess gas is vented to the scavenger through the positive end-expiratory pressure (PEEP)/adjustable pressure-limiting (APL) valve, which also controls breathing circuit pressure (PEEP). When the machine is placed in the manual mode of ventilation, the breathing bag is enabled and the reflector gas module is disabled. In the manual mode, the patient breathes in and out of the volume reflector and can be assisted with the breathing bag. The PEEP/APL valve vents excess gas to the scavenger and serves controls breathing circuit pressure (continuous positive airway pressure). CO_2, Carbon dioxide, N_2O, nitrous oxide; O_2, oxygen. *(Personal communication, Maquet Critical Care, January 14, 2013. Adapted from Maquet Critical Care:* User's manual: FLOW-i 1.2 anesthesia system, *Solna, Sweden, 2011, Rev: 11, Maquet Critical Care.)*

inspiratory pressure may be set by the user to a desired peak airway pressure. An adjustable pressure relief valve opens when the predetermined user-selected pressure is reached. This theoretically prevents the generation of excessive airway pressure. However, this feature depends on the user's having preset the appropriate pop-off pressure. If the setting is too low, insufficient pressure for ventilation may be generated and can result in inadequate minute ventilation; if set too high, the excessive airway pressure may still occur and result in barotrauma. Some machines may also include a factory-preset inspiratory pressure safety valve that opens at a preset airway pressure, such as 60 to 80 cm H_2O, to minimize the risk of barotrauma. Therefore, modern workstations without fresh gas decoupling usually reach a maximum pressure limit and terminate ventilation, release pressure, or sustain at the pressure limit.[215] In machines with a fresh gas decoupling feature, the oxygen flush inflow is diverted away from the patient during positive-pressure ventilation, thereby maintaining stable volumes and pressures (Fig. 29-47).

SCAVENGING SYSTEMS

Scavenging is the collection and subsequent removal of waste anesthetic gases from both the anesthesia machine and the anesthetizing location.[216] Scavenging is required because the fresh gas flow rates used during most anesthetic regimens deliver more volatile anesthetic agent and nitrous oxide than necessary, as well as more oxygen than is being consumed. When air is used, all the nitrogen is excess. Therefore, scavenging minimizes operating room pollution by removing these excess gases. In 1977, the National Institute for Occupational Safety and Health (NIOSH) prepared a document entitled *Criteria for a Recommended Standard: Occupational Exposure to Waste Anesthetic Gases and Vapors*.[217] Although it was maintained that a minimal safe level of exposure could not be defined, the NIOSH proceeded to issue the recommendations shown in Table 29-8. These same criteria remain in place today. ASTM International standard ASTM F1343-02 entitled *Standard Specification for Anesthetic Equipment: Scavenging Systems for Anesthetic Gases* established requirements for transfer and receiving systems of active anesthetic gas scavenging systems intended to reduce the exposure of

TWA, Time-weighted average.

*Time-weighted average sampling, also known as time-integrated sampling, is a sampling method that evaluates the average concentration of anesthetic gas over a prolonged period, such as 1 to 8 hours.

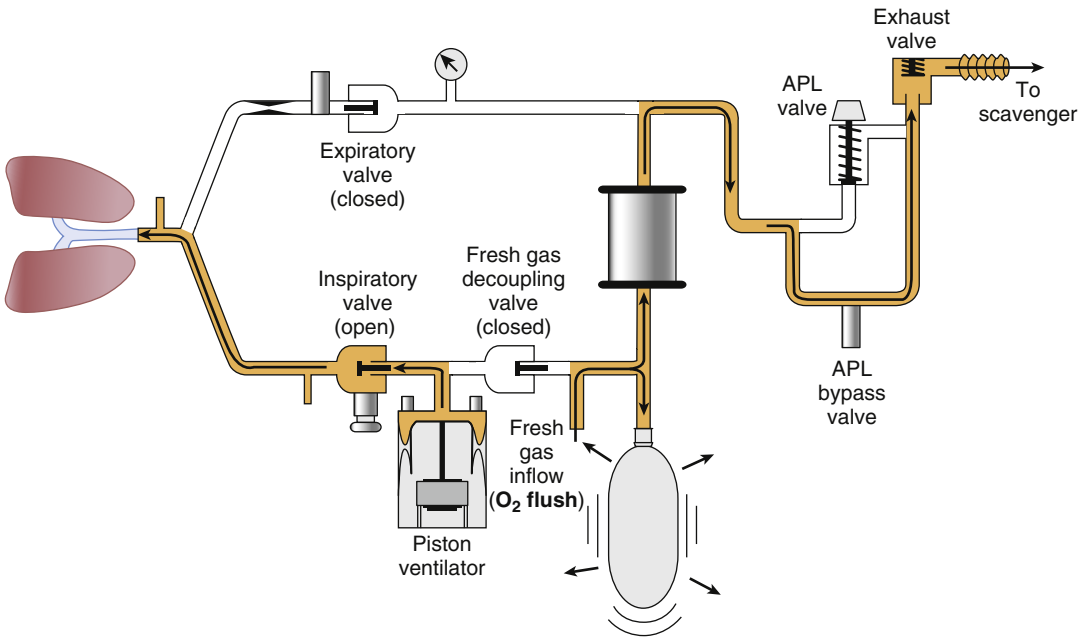

Figure 29-47. Fresh gas decoupling during an oxygen (O_2) flush shown on the Dräger Fabius workstation. During inspiration the positive end-expiratory pressure/maximum pressure valve is held closed. The pressure in the breathing circuit that is generated by the ventilator closes the fresh gas decoupling valve. This directs the high-volume oxygen flush flow toward the breathing bag during inspiration so it does not contribute to inhaled tidal volume and breathing circuit pressure. The O_2 flush gas also flows past the open adjustable pressure-limiting (APL) bypass valve, through the exhaust check valve, and to the scavenger. *(Modified image courtesy of Dr. Michael A. Olympio. Adapted from Dräger Medical:* Dräger technical service manual: Fabius GS anesthesia system, *Telford, Pa., 2002 Rev: E, Dräger Medical.)*

health care personnel to anesthetic gases and vapors.[218] In 1999, the ASA Task Force on Trace Anesthetic Gases developed a booklet entitled *Waste Anesthetic Gases: Information for Management in Anesthetizing Areas and the Postanesthesia Care Unit*. This publication describes the role of regulatory agencies, reviews scavenging and monitoring equipment, and provides recommendations.[219]

The two major causes of waste gas contamination in the operating room are the anesthetic technique used and equipment issues.[219,220] Regarding the anesthetic technique, the following are some of the causes of operating room contamination: (1) failure to turn off the gas flow control valves or the vaporizer when the circuit is disconnected from the patient; (2) use of poorly fitting masks; (3) flushing of the circuit into the room; (4) filling of anesthetic vaporizers, particularly if spillage occurs; (5) use of uncuffed endotracheal tubes; and (6) use of breathing circuits other than the circle system. Equipment failure or lack of understanding of proper equipment use can also contribute to operating room contamination. Leaks can occur in the high-pressure hoses, the nitrous oxide tank mounting, the high- or low-pressure circuits of the anesthesia machine, or the circle system, particularly at the carbon dioxide absorber assembly. The anesthesia care provider must be certain that the room suction and scavenging system is operational and adjusted properly to ensure adequate scavenging. Side-stream breathing gas analyzer waste flow (50 to 250 mL/minute) must be directed to the scavenging system or returned to the breathing system to prevent pollution of the operating room. [219,220]

Components

Scavenging systems classically have five components (Fig. 29-48): (1) the gas-collecting assembly, (2) the transfer tubing, (3) the scavenging interface, (4) the gas disposal assembly tubing, and (5) an active or passive gas disposal assembly.[216] An "active system" uses a central evacuation system to eliminate waste gases. With a "passive system," the pressure imposed by the venting of the breathing circuit produces flow. Although active systems are more common today, both are addressed here.

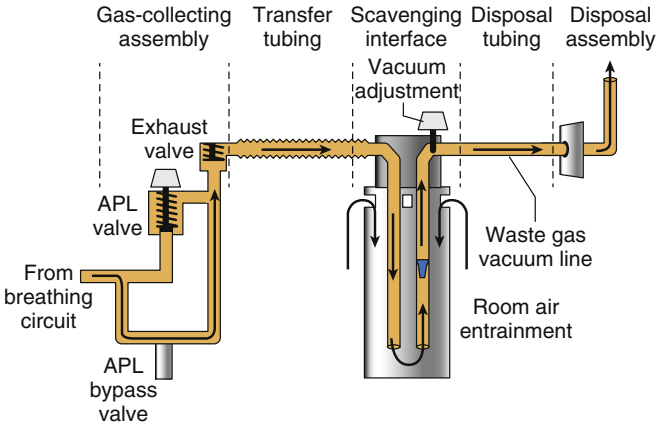

Figure 29-48. Components of a scavenging system using the example of a Dräger Fabius system (Dräger Medical, Telford, Pa.) connected to an open, active scavenging system. The transfer tubing has a connector size distinct from the breathing circuit to prevent misconnections. Obstructions in the gas-collecting assembly or transfer tubing can cause high pressure in the breathing circuit. Leaks, inadequate suction, or failure of the scavenging interface can cause environmental contamination. Closed systems can cause other problems. *APL,* Adjustable pressure-limiting. Please see text for details. *(From Brockwell RC: Delivery systems for inhaled anesthesia. In Barash PG, editor:* Clinical anesthesia, *ed 5, Philadelphia, 2006, Lippincott Williams & Wilkins, p 589.)*

Gas-Collecting Assembly. The gas-collecting assemblies are the points of waste gas exit from the breathing circuit that connect to the transfer tubing.[221] Waste anesthetic gases are vented from the anesthesia system either through the APL valve or through some sort of ventilator relief valve. Excess patient's gas either exits the breathing system through one of these valves or is shed into the room (e.g., poor facemask fit, endotracheal tube leak, machine leak). Conventional machines have separate outlet ports for these valves; however, many newer workstations only have one. Some anesthesia workstations may also exhaust the ventilator drive gas into the scavenging system (i.e., Datex-Ohmeda S/5 ADU, Mindray AS 3000). This is significant because under conditions of high fresh gas flow and high minute ventilation, the gases flowing into the scavenging interface may overwhelm the evacuation system. If this occurs, waste anesthetic gases may overflow the system through the positive-pressure relief valve (closed systems) or through the atmospheric vents (open systems) and pollute the operating room. In contrast, many other pneumatically driven ventilators exhaust their drive gas (100% oxygen or oxygen/air mixture) into the operating room through a small vent on the back of the ventilator control housing.

Transfer Tubing. The transfer means carries excess gas from the gas-collecting assembly to the scavenging interface. As specified by ASTM standard 1343-02, if the tubing is interchangeable, it must have 30-mm connectors on either end, which are distinct from the 22-mm connectors on the breathing system tubing.[218] Some manufacturers color-code the transfer tubing with yellow bands to distinguish it from 22-mm breathing system tubing. The tubing must be sufficiently rigid to prevent kinking to minimize the chance of occlusion, or it must contain some means of pressure relief in case of occlusion. Occlusion of the transfer means can be very problematic because it is upstream from the pressure-limiting features of the scavenging interface. If the transfer means is occluded by kinking or misconnection, breathing circuit pressure will increase and barotrauma can occur.[144,222-224] On machines that have separate transfer tubes for the APL valve and for the ventilator relief valve, the two tubes merge before or at the scavenging interface.

Scavenging Interface. The scavenging interface is the most important component of the system because it protects the breathing circuit or ventilator from excessive positive or negative pressure.[216] The interface should limit the pressure immediately downstream from the gas-collecting assembly to between –0.5 and +3.5 cm H_2O under normal working conditions.[218] Positive-pressure relief is mandatory irrespective of the type of disposal system used, so the system can vent excess gas in case

of occlusion (or inadequate suction with active systems) downstream from the interface. If the disposal system is an active system (see later), negative-pressure relief will be necessary to protect the breathing circuit or ventilator from excessive subatmospheric pressure. Subatmospheric pressure in the scavenging system could induce gas flow from the patient's breathing system. A reservoir is highly desirable with active systems because it stores waste gases until the evacuation system can remove them. Interfaces can be open or closed, depending on the method used to provide positive- and negative-pressure relief.[216]

An "active" anesthetic gas scavenging system relies on a hospital central evacuation system to remove gas from the anesthetic scavenging system. "Passive" systems simply vent the waste gas in to into a *nonrecirculating* heating, ventilation, and air conditioning (HVAC) system or through a hose to the building's exterior through a wall, ceiling, or floor (or out of a tent in the case of an austere setting). Passive systems rely only on the slight positive pressure of the gases leaving the gas-collecting assembly to provide the flow. Passive systems are less common in contemporary operating rooms. The other major classification of scavenging interfaces is "open" or "closed."

Open Interfaces. The open scavenge interface requires no positive- or negative-pressure relief valves because the canister is open to the atmosphere. Relief ports on the top of the canister provide positive- and negative-pressure relief. Open interfaces are active systems designed to operate only with a central vacuum or hospital waste gas elimination system. Open interfaces require a reservoir canister because waste gases are intermittently discharged in surges whereas flow from the evacuation system is continuous.[216] Many contemporary anesthesia machines are equipped with open interfaces, such as those in Figure 29-49. An open scavenging interface is also shown in Figure 29-48. An open canister provides reservoir capacity. Waste gas enters the system at the top of the canister and travels to the bottom through an inner tube, where a vacuum line removes waste gases. When adjusted properly, the vacuum rate should exceed the rate of waste gas flow into the chamber, and some room air should also be drawn into the canister through the relief port. The vacuum flow rate is usually adjusted on the scavenging interface using a flow control valve and flowmeter. Adjusting the scavenger vacuum flow rate is an important part of the workstation daily preuse checkout procedure. If vacuum flow is inadequate, waste gas can spill out into the room through the relief ports.

Closed Interfaces. Closed scavenging interfaces are isolated from the environment by pressure relief valves, so the relationship of waste gas flow, vacuum flow, and the size of the system's reservoir bag determines the effectiveness of the gas elimination. All closed interfaces must have a positive-pressure relief valve to vent excess system pressure if obstruction occurs downstream from the interface. A negative-pressure relief valve is mandatory to protect the breathing system from subatmospheric pressure if an active disposal system is used.[216] Two types of closed interfaces are used in clinical practice. One is used with passive scavenging systems and has positive-pressure relief only; the other is used with active scavenging systems and has both positive- and negative-pressure relief. Each type is discussed in the following paragraphs.

Positive-Pressure Relief Only. This interface has a single positive-pressure relief valve and is designed to operate only with passive disposal systems (Fig. 29-50, *A*). Waste gas enters the interface at the waste gas inlets. Transfer of the waste gas from the interface to the disposal system relies on the slight positive pressure of the gases leaving the patient's breathing system because a negative-pressure evacuation system is not used. Waste gases are then passively vented to a nonrecirculating HVAC system or to the outdoors. The positive-pressure relief valve opens at a preset value such as 5 cm H_2O if an obstruction between the interface and the disposal system occurs.[225] With this type of system, a reservoir bag is not required.

Positive- and Negative-Pressure Relief. This interface has a positive-pressure relief valve and at least one negative-pressure relief valve, in addition to a reservoir bag. It is designed to be used with active disposal systems. Figure 29-50, *B,* is a schematic of Dräger Medical's closed

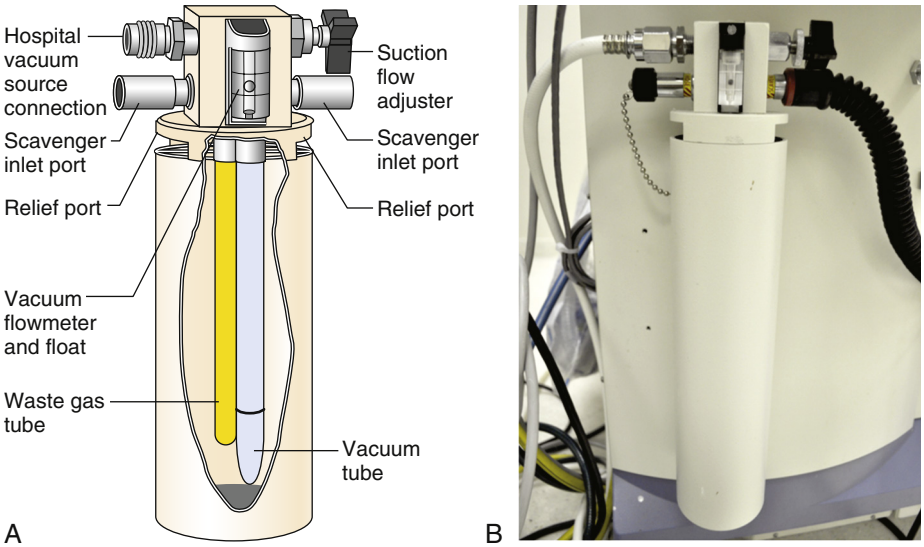

Figure 29-49. A and **B,** Open scavenge interface.

scavenge interface for active suction systems. A variable volume of waste gas intermittently enters the interface through the waste gas inlets. The reservoir bag intermittently accumulates excess gas until the evacuation system eliminates it. The operator must adjust the vacuum control valve so that the reservoir bag remains properly inflated (see Fig. 29-50, *B,* label *A*), and not overdistended (label *B*) or completely deflated (label *C*). Gas is vented to the atmosphere through the positive-pressure relief valve if the system pressure exceeds +5 cm H_2O. Room air is entrained through the negative-pressure relief valve if the system pressure is more negative than –0.5 cm H_2O. On some systems, a backup negative-pressure relief valve opens at –1.8 cm H_2O if the primary negative-pressure relief valve becomes occluded by dust or other causes. The effectiveness of a closed system in preventing spillage depends on the rate of waste gas inflow, the evacuation flow rate, and the size of the reservoir. Leakage of waste gases into the atmosphere occurs only when the reservoir bag becomes fully inflated and the pressure increases sufficiently to open the positive-pressure relief valve.

Gas Disposal Assembly Conduit or Extract Flow. The gas disposal assembly conduit conducts waste gas from the scavenging interface to the receiving end of the gas disposal system (see Fig. 29-48). It should be collapse-proof and should run overhead, if possible, to minimize the chance of accidental occlusion. The connection to the scavenging interface can be a permanent or proprietary connector, but the connection to an active gas disposal system should be a DISS-type connector.[218]

Gas Disposal System. The gas disposal assembly ultimately eliminates excess waste gas (see Fig. 29-48). The two types of environmental disposal mechanisms, active and passive, have been described.

Hazards

Scavenging systems minimize operating room pollution, yet they add complexity to the anesthesia system. A scavenging system functionally extends the anesthesia circuit all the way from the anesthesia machine to the ultimate disposal site. This extension increases the potential for problems. Obstruction of scavenging pathways can cause excessive positive pressure in the breathing circuit, and barotrauma can occur. Excessive vacuum applied to a scavenging system can cause undesirable negative pressures within the breathing system. In contrast, inadequate vacuum to the interface can cause venting of waste gas into the operating room. In one case report, inadequate suction caused a ventilator alarm condition resulting from backpressure caused within scavenge system.[226,227] In 2004, another unusual problem that resulted from waste gas scavenging was reported in the *ASA Newsletter* by Allen and Lees.[228] They reported fires in engineering equipment rooms that house the vacuum pumps used for evacuation of waste anesthetic gases. It seems that in some hospitals, waste gases are not directly vented outside but may be vented into machine rooms that have

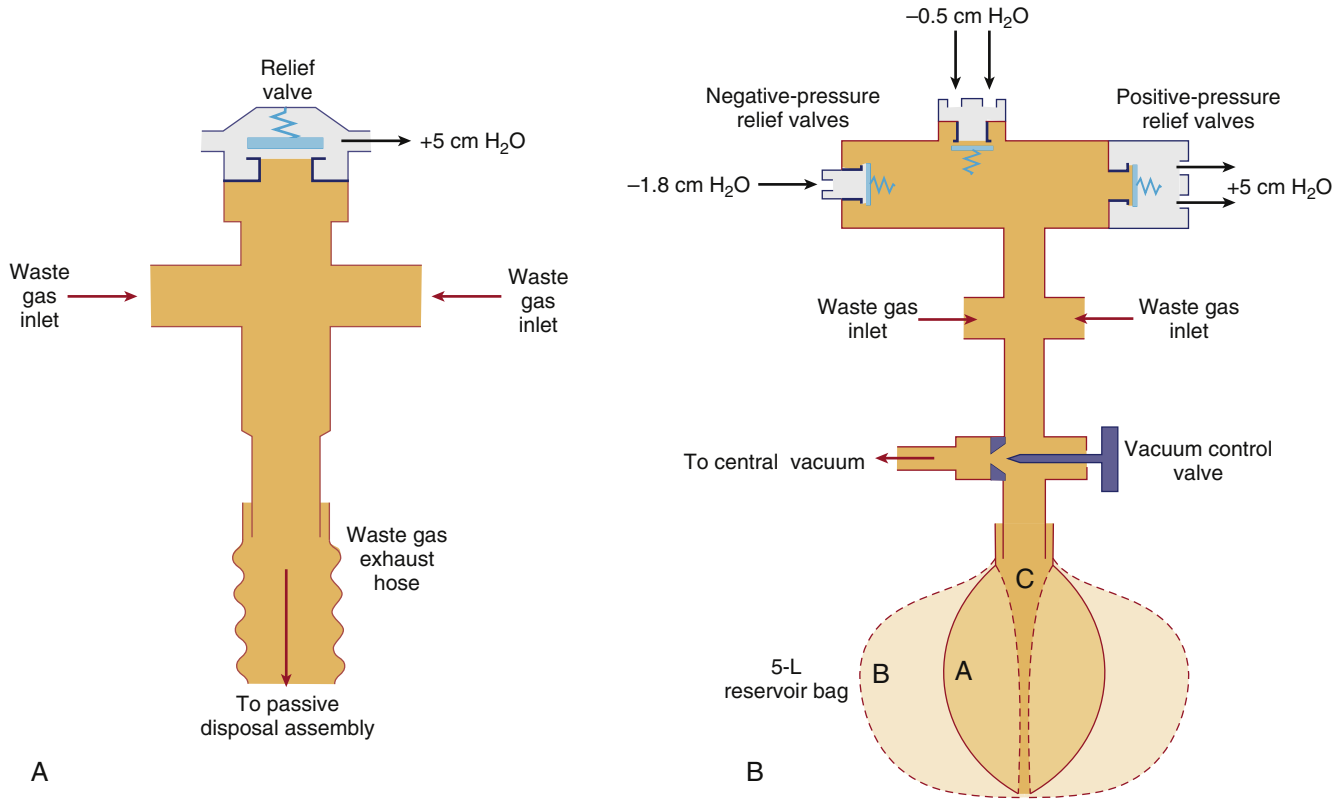

Figure 29-50. Closed scavenging interfaces. **A,** Interface used with a passive disposal system. **B,** Interface used with an active system. See text for details. vents opening to the outside. Because some anesthesia machines scavenge ventilator drive gas (which is 100% oxygen in most cases) in addition to gas from the breathing system, the environments in these machine rooms may become highly enriched with oxygen gas. The result has been the production of fires in these spaces outside the operating room. These sites may contain equipment or materials such as petroleum distillates (pumps, oil, or grease) that in the presence of an oxygen-enriched atmosphere could be excessively combustible and a severe fire hazard.[228]

CHECKING YOUR ANESTHESIA WORKSTATION

HISTORICAL PERSPECTIVE

A complete anesthesia apparatus checkout procedure must be performed each day before the anesthesia workstation is first used, and an abbreviated version should be performed before each subsequent case. The preanesthesia machine checkout (PAC) is a *checklist*-oriented procedure. The obvious industry parallel is in aviation, in which strict adherence to prevent checklists (e.g., Before Start, Takeoff, Approach) is known to enhance compliance with important procedural steps and save lives. Similarly, the routine performance of a PAC procedure is associated with a decreased risk of perioperative morbidity and mortality.[229]

Data predating the 1986 publication of the FDA's first *Anesthesia Apparatus Checkout Recommendations* demonstrated a low level of proficiency by anesthesiologists in detecting life-threatening machine-related problems.[230] At that time, available preuse checkout procedures for anesthesia machines were provided and promoted by individual machine manufacturers. These procedures were not entirely user-friendly or well suited for clinical application. Prompted by a series of anesthesia machine related accidents, in 1984 the FDA met with representatives of the ASA, anesthesia equipment experts, and anesthesia machine manufacturers to discuss methods of reducing the risks to patients during anesthesia.[231,232] As result, the first anesthesia workstation preuse checkout was released in August of 1986. Limited information suggests that this detailed guideline did not appear to be extensively used, nor did it greatly improve the ability of anesthesiologists to detect anesthesia machine faults.[232-234] Recognizing the poor compliance with the 1986 guideline, the FDA revised the PAC in the early 1990s. Other factors, including the development of monitoring standards by the ASA, the retirement of many older machines, and the introduction of newer-generation anesthesia machines following the ASTM specifications also provided impetus for the update.[233] The revised checklist was issued in 1993.[10,235] Although the newer checklist was fairly comprehensive and universal, a stated intent of the authors, similar to the 1986 version, was to encourage users to "modify [the guideline] to accommodate differences in equipment design and variations in local clinical practice" and to subject modifications to local peer review.[10,235]

Although the data are limited, evidence that the 1993 PAC recommendations led to improved detection of machine faults was also not forthcoming. Researchers demonstrated that anesthesiologists demonstrated poor fault detection on sabotaged machines despite having the guideline in hand.[236,237] Larson and associates observed 87 participants at a "nationally attended anesthesia meeting" while they were asked to perform a checkout on an anesthesia machine with preset faults. In other studies within controlled settings, researchers noted limited machine fault detection and low checklist item compliance.[3-5]

As tempting as it is to implicate the checklists for this poor performance, human factors and machine knowledge issues are more likely to blame. In particular, a lack of cultural discipline in the routine use of a PAC (*a checklist*) seems to be a key problem. Surveys have demonstrated poor compliance with machine checks, as well as low self-admitted competence with the procedure.[7,8,238] Further, human error and failures to check and inspect equipment have been related to a significant percentage of anesthetic mishaps.[6,239] It seems that no matter how well conceived and strongly promoted PAC recommendations have been, adoption and routine use of the PAC have not been consistent. Increasing machine diversity could potentially compound the issue because the application of a simple, generic PAC is now unlikely.

2008 RECOMMENDATIONS FOR PREANESTHESIA CHECKOUT PROCEDURES

To improve PAC compliance and performance, it is recommended that individual anesthesia departments align the ASA's *Recommendations for Pre-Anesthesia Checkout Procedures (2008)* with their respective manufacturers' suggested checkout procedures to develop their own effective, workstation-specific PAC checklists (Box 29-1).[240] The recommendations were developed with the knowledge that the existing PAC was neither well understood nor reliably used by anesthesia providers and that anesthesia delivery systems have evolved to the point where one checkout procedure was no longer universally applicable. The recommendations are therefore designed as a template to develop "checkout procedures that are appropriate for each individual anesthesia machine design and practice setting."[240]

The 2008 recommendations warn against an overreliance on automated machine checkouts and assert that anesthesiology providers may be unaware of what is actually assessed by these features and may omit important preuse checkout items if they place all faith in an automated checkout. When developing a local PAC, a detailed understanding of what is actually checked by the machine should be determined. However, this is not always easy to ascertain by simply reviewing user's manuals.

The authors of the 2008 guideline recognized that using anesthesia technicians or biomedical technicians, or both, to perform some aspects of the checkout procedures may improve compliance with a department's PAC and could add redundancy to critical steps.[240] Although the 2008 guideline suggests which steps may be checked by "a qualified anesthesia technician, biomedical technician, or manufacturer-certified technician," this should be an institutional decision. Local skill levels, work flow patterns, and training requirements may vary greatly. According to the

BOX 29-1 *Summary Recommendations of the 2008 Preanesthesia Checkout Procedures*

Items to Be Completed Daily

Item #	Task	Responsible Parties?
1	Verify that auxiliary oxygen cylinder and self-inflating manual ventilation device are available and functioning	Provider *and* technician
2	Verify that patient suction is adequate to clear the airway	Provider *and* technician
3	Turn on the anesthesia delivery system and confirm that AC power is available	Provider *or* technician
4	Verify the availability of required monitors, including alarms	Provider *or* technician
5	Verify that pressure is adequate on the spare oxygen cylinder mounted on the anesthesia machine	Provider *and* technician
6	Verify that the piped gas pressures are ≥50 psig	Provider *and* technician
7	Verify that vaporizers are adequately filled and, if applicable, that the filler ports are tightly closed	Provider *only*
8	Verify that the gas supply lines have no leaks between the flowmeters and the common gas outlet	Provider *or* technician
9	Test the scavenging system function	Provider *or* technician
10	Calibrate, or verify the calibration of, the oxygen monitor, and check the low-oxygen alarm	Provider *or* technician
11	Verify that carbon dioxide absorbent is not exhausted	Provider *or* technician
12	Perform breathing system pressure and leak testing	Provider *and* technician
13	Verify that gas flows properly through the breathing circuit during both inspiration and exhalation	Provider *and* technician
14	Document the completion of checkout procedures	Provider *and* technician
15	Confirm the ventilator settings, and evaluate readiness to deliver anesthesia care (Anesthesia Time Out)	Provider *only*

Items to Be Completed Before Each Procedure

Item #	Task	Responsible Parties?
1	Verify that patient suction is adequate to clear the airway	Provider *and* technician
2	Verify the availability of required monitors, including alarms	Provider *or* technician
3	Verify that vaporizers are adequately filled and, if applicable, that the filler ports are tightly closed	Provider only
4	Verify that carbon dioxide absorbent is not exhausted	Provider *or* technician
5	Perform breathing system pressure and leak testing	Provider *and* technician
6	Verify that gas flows properly through the breathing circuit during both inspiration and exhalation	Provider *and* technician
7	Document the completion of checkout procedures	Provider *and* technician
8	Confirm the ventilator settings, and evaluate readiness to deliver anesthesia care (Anesthesia Time Out)	Provider only

Modified from Sub-Committee of American Society of Anesthesiologists Committee on Equipment and Facilities: Recommendations for pre-anesthesia checkout procedures (2008). <http://www.asahq.org/For-Members/Clinical-Information/2008-ASA-Recommendations-for-PreAnesthesia-Checkout.aspx>. (Accessed 01.03.11.)

guideline, the use of technician checks is not intended to be mandatory. Regardless of who participates in the PAC, the anesthesia care provider is ultimately responsible for the proper and safe functioning of the equipment.

The recommendations are intended to describe a basic approach to developing sound institution-specific PAC procedures designed "for the equipment and resources available." The method used to check each item depends on the specific equipment. The recommendations simply suggest the minimum machine-related items that should be assessed before use. A local PAC checklist should represent a workable merger of this guideline with the manufacturer's checkout recommendations.

In addition to developing effective PACs, it is also important that anesthesia providers remain knowledgeable about their equipment and embrace a "checklist culture." The 2008 guideline can be found at https://www.asahq.org/For-Members/Clinical-Information/2008-ASA-Recommendations-for-PreAnesthesia-Checkout.aspx.[240] Anesthesia workstation-specific PACs from individual departments can also be found at the site, which can be used for PAC development.

MINIMUM PREANESTHESIA CHECKLIST

Item 1: Verify Auxiliary Oxygen Cylinder and Self-Inflating Manual Ventilation Device Are Available and Functioning

Frequency: Daily
Responsible parties: Provider and technician

> "Failure to be able to ventilate is a major cause of morbidity and mortality related to anesthesia care. Because equipment failure with resulting inability to ventilate

the patient can occur at any time, a self-inflating manual ventilation device (e.g., an Ambu bag) should be present at every anesthetizing location for every case and should be checked for proper function. In addition, a source of oxygen separate from the anesthesia machine and pipeline supply, specifically an oxygen cylinder with regulator and a means to open the cylinder valve, should be immediately available and checked. After checking the cylinder pressure, it is recommended that the main cylinder valve be closed to avoid inadvertent emptying of the cylinder through a leaky or open regulator."[240]

This step was the most important item on the checklist on the 1993 PAC and remains so in the 2008 recommendations. No matter what happens to the machine, you should always be prepared to keep the patient alive without it. The auxiliary ventilation device should be self-inflating, which *excludes* Mapleson circuits that are often found in and out of the operating room. These devices should be located at "every anesthetizing location," and the guideline further recommends that they be checked for proper function. The recommendation also states that the auxiliary oxygen source should be separate from the machine and its pipeline supply, "specifically an oxygen cylinder." Ensuring that properly filled portable cylinders with attached flowmeters are available at specific locations requires an institutional logistic commitment and careful attention to detail by support staff.

Item 2: Verify Patient Suction Is Adequate to Clear the Airway

Frequency: Before each use
Responsible parties: Provider and technician

"Safe anesthetic care requires the immediate availability of suction to clear the airway if needed."[240]

Item 3: Turn on Anesthesia Delivery System and Confirm That AC Power Is Available

Frequency: Daily
Responsible party: Provider or technician

"Anesthesia delivery systems typically function with backup battery power if AC power fails. Unless the presence of AC power is confirmed, the first obvious sign of power failure can be a complete system shutdown when the batteries can no longer power the system. Many anesthesia delivery systems have visual indicators of the power source showing the presence of both AC and battery power. These indicators should be checked and connection of the power cord to a functional AC power source should be confirmed. Desflurane vaporizers require electrical power and recommendations for checking power to these vaporizers should also be followed."[240]

Item 4: Verify Availability of Required Monitors and Check Alarms

Frequency: Before each use
Responsible party: Provider or technician

"Standards for patient monitoring during anesthesia are clearly defined. The ability to conform to these standards should be confirmed for every anesthetic. The first step is to visually verify that the appropriate monitoring supplies (BP cuffs, oximetry probes, etc.) are available. All monitors should be turned on and proper completion of power-up self tests confirmed. Given the importance of pulse oximetry and capnography to patient safety, verifying proper function of these devices before anesthetizing the patient is essential. Capnometer function can be verified by exhaling through the breathing circuit or gas sensor to generate a capnogram, or verifying that the patient's breathing efforts generate a capnogram before the patient is anesthetized. Visual and audible alarm signals should be generated when this is discontinued. Pulse oximeter function, including an audible alarm, can be verified by placing the sensor on a finger and observing for a proper recording. The pulse oximeter alarm can be tested by introducing motion artifact or removing the sensor. Audible alarms have also been reconfirmed as essential to patient safety by ASA, AANA, APSF and JCAHO [The Joint Commission]. Proper monitor functioning includes visual and audible alarm signals that function as designed."[240]

Verifying the availability and proper functioning of standard and other required monitors is a relatively straightforward task. However, the process of checking alarm thresholds, and possibly resetting them, can be tedious. Monitor alarm settings may possibly vary within individual facilities as a result of provider manipulation of alarms for case requirements, a lack of standard default settings, and failure to reset alarm limits routinely. Departmental alarm default settings can be established and programmed into anesthesia workstation monitors. Alarm limit settings also include anesthesia machine alarms such as volume, pressure, and inspired oxygen concentration limits (Fig. 29-51). The practitioner should ensure that critical alarm limits are set to values that permit these alarms to do what they were intended to do.

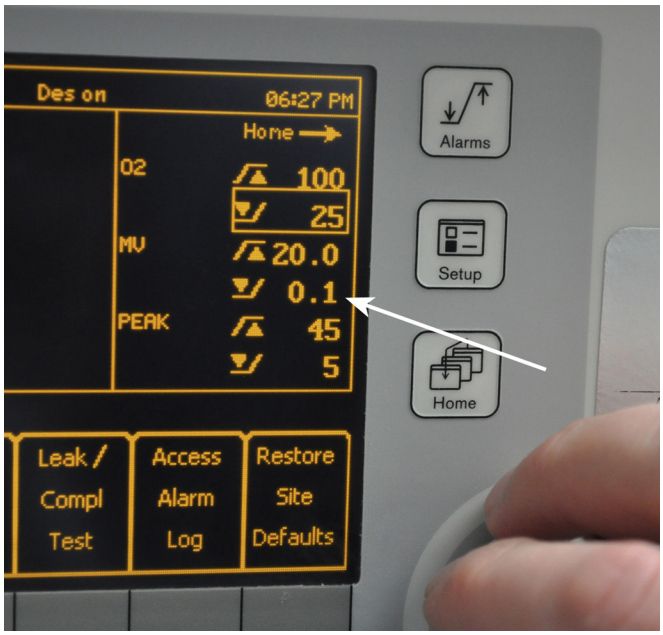

Figure 29-51. Setting machine alarm limits: Note the inappropriately low setting that was encountered on this machine's low minute ventilation alarm limit. Alarm limit values are easy to adjust, although this process can be time consuming during routine preuse checkout. Safe default values can be established locally and set by trained technicians, to help keep limits consistent.

Here, anesthesia technicians can improve the quality of the preuse checkout by checking the function of standard monitors and confirming that critical alarm thresholds are set to established default values.

Item 5: Verify That Pressure Is Adequate on the Spare Oxygen Cylinder Mounted on the Anesthesia Machine

Frequency: Daily
Responsible parties: Provider and technician

> "Anesthesia delivery systems rely on a supply of oxygen for various machine functions. At a minimum, the oxygen supply is used to provide oxygen to the patient. Pneumatically-powered ventilators also rely on a gas supply. Oxygen cylinder(s) should be mounted on the anesthesia delivery system and determined to have an acceptable minimum pressure. The acceptable pressure depends on the intended use, the design of the anesthesia delivery system and the availability of piped oxygen."[240]

Verification of oxygen cylinder pressure is accomplished by opening the oxygen cylinder or cylinders on the back of the machine and evaluating the tank gauge pressure, which is located on the front of the machine. Some newer machines may also have a tank gauge located on the back of the machine. The 1986 PAC guideline recommended to "replace any cylinder less than about 600 psig."[241] The 1993 PAC guideline recommended that the oxygen cylinder be "at least half full (about 1000 psi)" during checkout. The current recommendations do not provide a specific value, but some manufacturer's manuals still suggest the 1000 psi minimum.[242]

Additional bulleted comments in this item of the 2008 guideline include the following:

> "Typically, an oxygen cylinder will be used if the central oxygen supply fails."[240]

The auxiliary oxygen cylinder or cylinder will be used if the pipeline supply of oxygen fails or becomes contaminated. As discussed earlier, if the tank is to be used in the setting of a suspected oxygen pipeline contamination, the pipeline supply must be disconnected from the machine for tank gas to flow into the gas supply system.

> "If the cylinder is intended to be the primary source of oxygen (e.g., remote site anesthesia), then a cylinder supply sufficient to last for the entire anesthetic is required."[240]

It is always wise to estimate finite oxygen source needs (e.g., portable tank supply) by applying a wide margin on the side of safety.

> "If a pneumatically-powered ventilator that uses oxygen as its driving gas will be used, a full "E" oxygen cylinder may provide only 30 minutes of oxygen. In that case, the maximum duration of oxygen supply can be obtained from an oxygen cylinder if it is used only to provide fresh gas to the patient in conjunction with manual or spontaneous ventilation. Mechanical ventilators will consume the oxygen supply if pneumatically powered ventilators that require oxygen to power the ventilator are used. Electrically-powered ventilators do not consume oxygen so that the duration of a cylinder supply will depend only on total fresh gas flow."[240]

Generally speaking, mechanical ventilators using a bellows are typically gas driven (with either oxygen or air), the Maquet volume reflector is oxygen driven, and piston driven ventilators are electrically driven. This underscores the importance of machine familiarity.

> "The oxygen cylinder valve should be closed after it has been verified that adequate pressure is present, unless the cylinder is to be the primary source of oxygen (i.e., piped oxygen is not available). If the valve remains open and the pipeline supply should fail, the oxygen cylinder can become depleted while the anesthesia provider is unaware of the oxygen supply problem."[240]

The operator should remember to close the tank valve after checking the pressure so the tank does not slowly loose pressure (see the earlier discussion of the gas supply system).

> "Other gas supply cylinders (e.g., Heliox, CO_2, Air, N_2O) need to be checked only if that gas is required to provide anesthetic care." [240]

Item 6: Verify That Piped Gas Pressures Are 50 psig or Higher

Frequency: Daily
Responsible parties: Provider and technician

> "A minimum gas supply pressure is required for proper function of the anesthesia delivery system. Gas supplied from a central source can fail for a variety of reasons. Therefore the pressure in the piped gas supply should be checked at least once daily." [240]

Normal pipeline pressures in the United States for common gases (oxygen, air, nitrous oxide) are 50 to 55 psig.[243] Although the guideline suggests verifying gauge pressures, an inspection of the supply hoses and connections is also recommended by some manufacturers. Checking that "hoses are connected" was a checklist item on the 1993 PAC. Despite gas-specific connectors, misconnections of gas hoses have been reported.[244-246] Similarly, medical gas supply lines behind the walls of the operating room are not immune from misconnection or contamination.[247-251] A preuse check that includes a quick daily inspection of connections, supply hoses, gas pressures, and the presence of more than 90% oxygen in the inspiratory limb greatly minimizes risk. An important safety item on all machines is an audible and visual alarm that warns the operator of diminishing oxygen supply pressure. The only way to evaluate this pneumatic safety device is to disconnect the wall oxygen supply and shut off the oxygen supply tank or tanks. During development of the 1993 PAC, it was noted that provider failure to reconnect the main oxygen supply line during the PAC was not a rare occurrence. Concern also existed that daily removal and reconnection of oxygen supply line connector could contribute to wear or breakdown. Given these concerns, disconnection of the oxygen pipeline supply is not a specified recommendation within the 1993 and 2008 guideline (personal communication, Dr. J. Jeff Andrews, February 9, 2011).

Item 7: Verify That Vaporizers Are Adequately Filled and, If Applicable, That the Filler Ports Are Tightly Closed

Responsible parties: Provider (technician if redundancy desired)

> "If anesthetic vapor delivery is planned, an adequate supply is essential to reduce the risk of light anesthesia or recall. This is especially true if an anesthetic agent monitor with a low agent alarm is not being used. Partially open filler ports are a common cause of leaks that may not be detected if the vaporizer control dial is not open when a leak test is performed. This leak source can be minimized by tightly closing filler ports. Newer vaporizer designs have filling systems that automatically close the filler port when filling is completed. High and low anesthetic agent alarms are useful to help prevent over- or under-dosage of anesthetic vapor. Use of these alarms is encouraged and they should be set to the appropriate limits and enabled."[240]

Although not part of the 2008 PAC guideline, some manufacturers recommend a check of their machine's vaporizer interlock system, which, if present, prevents more than one vaporizer from being activated simultaneously. If this step is added to a local checklist, make sure that when one vaporizer hand wheel is turned to a setting greater than "0," the other vaporizer remains locked in its "0" position. Test the system for all mounted vaporizers; then ensure all vaporizers are placed back to their "0" position. This is also a good time to make certain that the vaporizers are firmly mounted.

Item 8: Verify That No Leaks Are Present in the Gas Supply Lines Between the Flowmeters and the Common Gas Outlet

Frequency: Daily and whenever a vaporizer is changed
Responsible party: Provider or technician

> "The gas supply in this part of the anesthesia delivery system passes through the anesthetic vaporizer(s) on most anesthesia delivery systems. To perform a thorough leak test, each vaporizer must be turned on individually to check for leaks at the vaporizer mount(s) or inside the vaporizer. Furthermore, some machines have a check valve between the flowmeters and the common gas outlet, requiring a negative-pressure test to check for leaks adequately. Automated checkout procedures typically include a leak test but may not evaluate leaks at the vaporizer especially if the vaporizer is not turned on during the leak test. When relying on automated testing to evaluate the system for leaks, the automated leak test would need to be repeated for each vaporizer in place. This test should also be completed whenever a vaporizer is changed. The risk of a leak at the vaporizer depends on the vaporizer design. Vaporizer designs where the filler port closes automatically after filling can reduce the risk of leaks. Technicians can provide useful assistance with this aspect of the machine checkout since it can be time consuming."[240]

This step checks the integrity of the so-called low-pressure section (LPS) of the workstation's gas supply system, which extends from the flow control valves to the fresh gas outlet. It evaluates the portion of the machine that is downstream from all safety devices except the oxygen analyzer. Leaks in this section of the machine are associated with hypoxemia or patient awareness under anesthesia.[23,25] The components located within this area are *precisely* the ones most subject to breakage and leaks, such as the anesthetic vaporizer, the vaporizer mounting, or the flowmeter tubes (Fig. 29-52). Loose filler caps on vaporizers are a common source of leaks, and these leaks can cause patient awareness under anesthesia.[230,238]

Because of significant machine design differences, several tests have been described to check for leaks within the LPS.[215] These tests use either positive pressure (assessing either leak flow or system pressure stability) or negative pressure to facilitate leak detection in this vulnerable part of the anesthesia machine. Selecting the proper test had been historically confusing because a few machines have an outlet check between the common gas outlet and the vaporizers, whereas most do not. An example of an anesthesia machine with an outlet check valve is

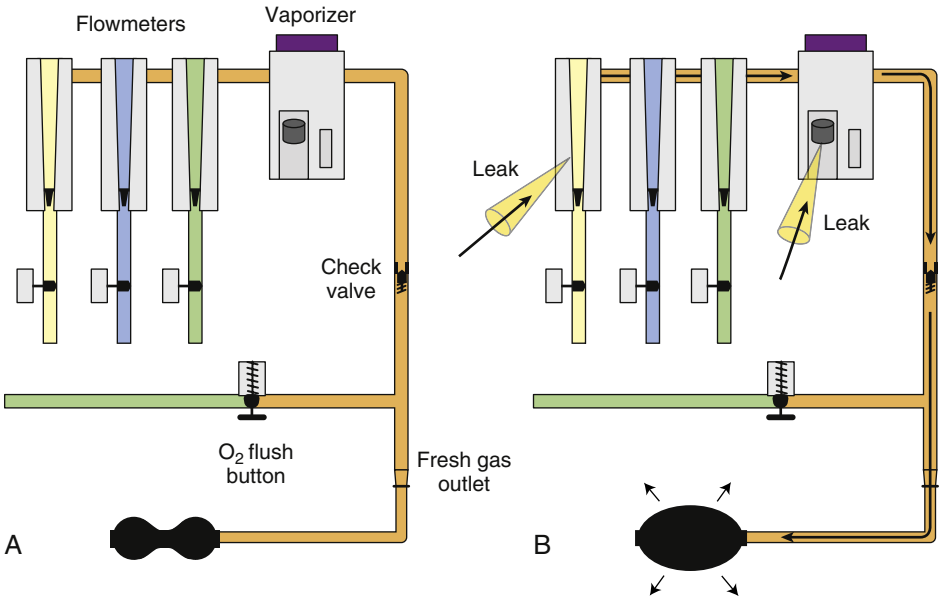

Figure 29-52. The negative-pressure "universal" low-pressure system leak test. **A,** A specially configured suction bulb is connected to the common (fresh) gas outlet and collapsed. Subatmospheric pressure is created in the low pressure circuit, thus opening the outlet check valve (if present) and exposing the vaporizers, tubing, and associated piping and connections to the vacuum. **B,** Leaks in the system draw in ambient air and inflate the suction bulb. O_2, Oxygen.

seen in Figures 29-1 and 29-52. The check valve is meant to minimize the effects of intermittent backpressure on vaporizer output. For machines without an outlet check valve, positive-pressure tests of the LPS are generally sufficient. These include simple pressurization of the patient's breathing circuit in the manner of performing a breathing circuit leak test as described later, or more complex positive-pressure testing of the low pressure system using specialized bulbs, manometers, or flowmeters.[5,32] Several mishaps have resulted from application of the wrong leak test to the wrong machine.[231-234] It is therefore mandatory that the appropriate low-pressure leak test be performed each day.

Again, the presence of an outlet check valve on some machines precludes manual positive-pressure testing of the LPS because the valve is held closed by downstream positive pressure (see Figs. 29-1 and 29-52). To eliminate confusion with this, the 1993 PAC's *Leak Check of the Machine Low Pressure System* prescribed the so-called *Universal Leak Test*. The universal leak test is a *negative-pressure* test that checks for leaks in the LPS regardless of whether or not an outlet check valve is present. The negative-pressure leak test is simple to perform and is highly sensitive, detecting leaks as small as 30 mL/minute. This simple test requires that the machine be turned off and that the flow control valves be fully closed to prevent any flow of gas into the low-pressure circuit. A specially configured suction bulb, which can either be constructed or obtained from the manufacturer, is then attached to the common gas outlet by tubing and a 15-mm adapter (Fig. 29-53; see also Fig. 29-52). The bulb is then squeezed repeatedly until it is fully collapsed. If the bulb does not stay collapsed for a specified period of time, then air is being sucked by the bulb into the machine through a leak that will allow gas to escape when the machine is pressurized. The same maneuver is carried out with each vaporizer opened in turn to check for associated leaks. The specified period of bulb collapse varies by reference, from 10 seconds in popular texts to 30 seconds in some workstation's user's manuals.[30,215,252-254] Although small leaks may require more than 10 seconds for bulb reinflation, it is likely that the collapsed bulb will be noted to be steadily expanding before that time.[32] The most important aspect about the universal negative-pressure leak test is that it eliminates any potential for error in which an operator might mistakenly apply a positive-pressure leak test to a machine with an outlet check valve. Suction bulbs for negative-pressure leak testing can be purchased or constructed as shown in Figure 29-54.

Many of the newer-generation anesthesia machines do not have an accessible common gas outlet; therefore, negative-pressure low-pressure system testing cannot be performed. On these machines, either manual positive-pressure testing of the LPS (and vaporizers) is performed during the preuse checkout, or LPS testing is accomplished as part of an automated checkout feature. Table 29-9 describes the LPS checkout requirement for several common anesthesia workstations. These machines test the integrity of the low-pressure system by means of an automated checkout. For machines that require manual LPS leak testing, the universal negative-pressure leak test can be applied unless the common gas outlet not readily accessible or the manufacturer specifies a positive-pressure test maneuver. A locally devolved PAC should indicate which method is required based on user's manual instructions. Regardless of what type of test is performed, the practitioner must understand that variable bypass anesthetic vaporizers and the Tec 6–style desflurane vaporizer will not be leak tested unless the concentration control dial is turned "on" during the leak test. If this step is not taken, large leaks that could potentially result in a patient's awareness, such as from a loose filler cap or cracked fill indicator, could go undetected. An exception to this rule applies to workstations that perform automated vaporizer leak testing on their unique vaporizers such as Maquet anesthesia machines and GE Healthcare workstations that use the ADU vaporizer.

Item 9: Test Scavenging System Function

Frequency: Daily

Responsible party: Provider or technician

> "A properly functioning scavenging system prevents room contamination by anesthetic gases. Proper function depends upon correct connections between the scavenging system and the anesthesia delivery system. These connections should be checked daily by a provider or technician. Depending upon the scavenging system design, proper function may also require that

Figure 29-53. The negative-pressure "universal" low-pressure system leak test. **A,** With the machine off and the flow control valves fully closed, a specially configured suction bulb is connected to the common (fresh) gas outlet. **B,** The bulb is pumped until it is fully collapsed. It is then observed to verify that it stays collapsed for more than 10 seconds, thus indicating that the low-pressure side of the machine is gas tight. Then, each vaporizer is opened in turn, and the maneuver is repeated to establish that no leak is associated with that vaporizer. **C,** The ventilator was intentionally tilted on its mount to cause a low-pressure system leak resulting in immediate inflation of the suction

the vacuum level is adequate which should also be confirmed daily. Some scavenging systems have mechanical positive and negative pressure relief valves. Positive and negative pressure relief is important to protect the patient circuit from pressure fluctuations related to the scavenging system. Proper checkout of the scavenging system should ensure that positive and negative pressure relief is functioning properly. Due to the complexity of checking for effective positive and negative pressure relief, and the variations in scavenging system design, a properly trained technician can facilitate this aspect of the checkout process."[240]

A test of the scavenging system begins by checking the proper assembly and integrity of each component and connection within system including the gas transfer tubes leading from the APL valve and the ventilator relief valve to the scavenging interface. In the case of many modern machines, a single transfer tube may lead from a compact breathing system to the scavenge interface. The integrity of the vacuum tubing leading from the wall outlet to the scavenging interface should also be checked. The different categories of scavenging systems, active versus passive and open versus closed, are discussed in a previous section.

A manufacturer's recommended test of the closed, passive scavenger system as seen in Figure 29-50, *A*, involves creating gas flow (pressure) within the breathing system by occluding the patient "Y-piece" (or short-circuiting the inspiratory and expiratory limbs of the breathing circuit with breathing hose), occluding the exhaust hose outlet on the scavenging interface, and ensuring that the flow of gas exits the system through the positive-pressure safety relief valve so excess pressure does not build up in the breathing circuit (e.g., <10 cm H_2O).

Checking a closed, active scavenger system as seen in Figure 29-50, *B*, involves two steps. A check of positive-pressure relief is conducted as described earlier for the passive, closed scavenger. Some manufacturers recommend that the suction needle valve be turned off for this step. A check of negative-pressure relief is conducted

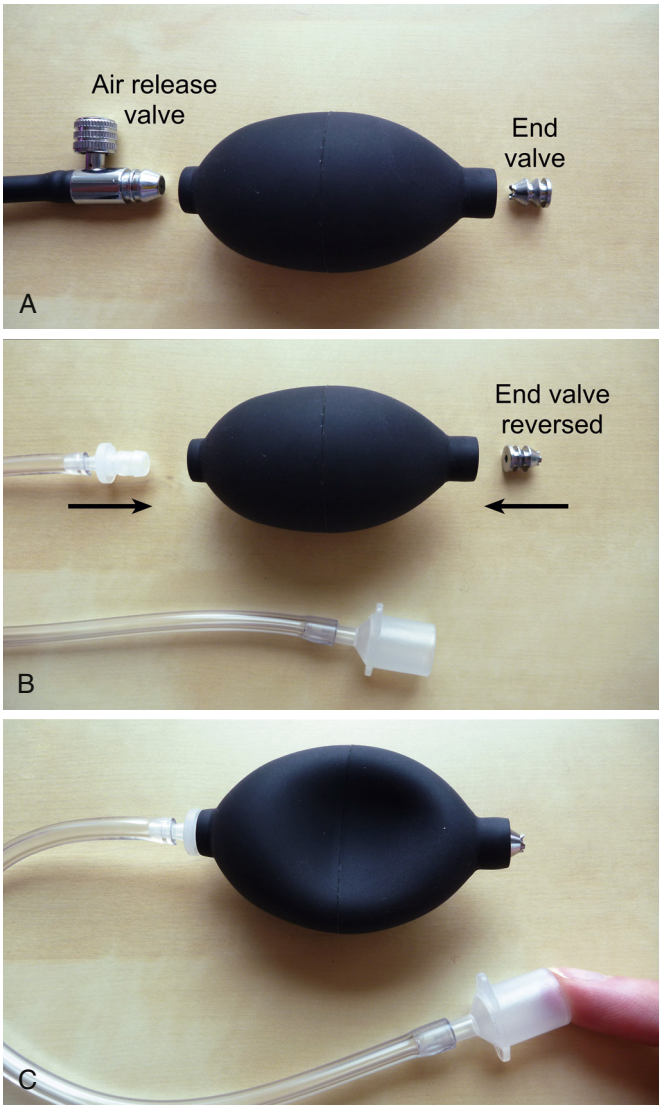

Figure 29-54. Constructing a negative-pressure system leak test suction bulb from a sphygmomanometer bulb. **A,** Remove the air release valve and discard. Remove the end valve. **B,** Reverse the end valve and reinsert it. Obtain a tight-fitting connector, some extra tubing, and a suitable endotracheal tube adapter. Insert the connector into the bulb. **C,** Squeeze the bulb, and occlude the adapter. The apparatus should remain collapsed for more than 60 seconds.

TABLE 29-9 LOW PRESSURE SYSTEM LEAK TEST TECHNIQUES OF VARIOUS ANESTHESIA WORKSTATIONS

Machine	Test Method
Dräger Narkomed 2B	Manual/positive pressure*†

Data from user's manuals from Datex-Ohmeda (Madison, Wis.), Dräger Medical (Telford, Pa.), GE Healthcare (Little Chalfont, United Kingdom), Maquet Critical Care (Solna, Sweden), Mindray (Mahwah, NJ), Penlon (Abingdon, United Kingdom), and Spacelabs Healthcare (Snoqualmie, Wash.).

ACGO, Auxiliary common gas outlet.

*Narkomed positive-pressure test using sphygmomanometer squeeze bulb, adapter, and inspiratory-expiratory port interconnection hose (Food and Drug Administration universal negative-pressure leak test can also be applied).

†Must manually open vaporizers to check them for leaks.

‡Alternatively, an "ISO 5358" or "BSI" flow test can be used, but an apparatus is required.

Figure 29-55. Testing the low–oxygen concentration alarm and calibrating the oxygen sensor. **A,** Removal of the oxygen sensor housing exposes the sensor to ambient air. **B,** When the oxygen concentration decreases to less than the alarm threshold value, which in this case is set at 25%, the visual and auditory low inspired oxygen concentration alarms should activate. **C,** After replacing the oxygen sensor, the oxygen flush button should be used to bring the fraction of inspired oxygen concentration (FiO_2) to at least 90%.

by setting scavenge interface suction to a routine setting, turning off all flow control valves on the anesthesia machine, and occluding inflow into the patient's breathing circuit at the patient's Y-piece (or short circuiting the inspiratory and expiratory limbs of the breathing circuit with breathing hose) and at the breathing bag mount. At this point, the breathing pressure gauge should indicate a negligible negative pressure (e.g., no lower than –1.0 cm H_2O). Generally speaking, the scavenging suction on active systems should be adjusted so the reservoir bag is never overinflated or underinflated, but it should remain slightly inflated during routine use. Because the volume of gas being passed into the scavenging system varies, it may be necessary to adjust the needle valve. Given the diversity of breathing systems, this check serves as another instance in which users must consider manufacturer-specified protocols when developing a local PAC.

Checking the function of an open, active system as seen in Figure 29-49 is relatively simple compared with checking a closed, active system. After ensuring that all gas transfer tubes and the suction lines are properly connected, the scavenger suction needle valve is adjusted to place the flowmeter bobbin between the indicator lines. A positive-pressure test and a negative-pressure test are then conducted as described earlier.

The 1993 PAC prescribed a simple procedure for checking the scavenging system that eliminated several steps described in manufacturer's user's manuals. It can be applied to both closed and open scavenging systems. For every machine, the evaluation of the scavenging system is a manual evolution. No automated checks are conducted.

Item 10: Calibrate, or Verify Calibration of, the Oxygen Monitor and Check the Low Oxygen Alarm

Frequency: Daily
Responsible Party: Provider or technician

> "Continuous monitoring of the inspired oxygen concentration is the last line of defense against delivering hypoxic gas concentrations to the patient. The oxygen monitor is essential for detecting adulteration of the oxygen supply. Most oxygen monitors require calibration once daily, although some are self-calibrating. For self-calibrating oxygen monitors, they should be verified to read 21% when sampling room air. This is a step that is easily completed by a trained technician. When more than one oxygen monitor is present, the primary sensor, which will be relied upon for oxygen monitoring should be checked. The low oxygen concentration alarm should also be checked at this time by setting the alarm above the measured oxygen concentration and confirming that an audible alarm signal is generated."[240]

The oxygen concentration analyzer is one of the most important monitors on the anesthesia workstation. It is the only monitor positioned to detect oxygen delivery problems downstream from the flow control valves.[215] All other oxygen related safety devices are located upstream from the flow control valves,[254] and it is the only monitor that evaluates the integrity of the low-pressure section of the gas supply system in an ongoing fashion. Other machine safety devices, such as fail-safe valves, oxygen pressure sensors, and proportioning systems are all upstream from the flow control valves. The only device that detects problems downstream from the flow control valves is the oxygen analyzer. Traditionally, most machines have used a galvanic cell oxygen sensor located near the patient's breathing circuit inspiratory valve (Fig. 29-55). These devices have a finite life span, which is inversely proportional to the amount of oxygen exposure.[255] They are also vulnerable to drift. Therefore, daily verification of calibration (and recalibration, if necessary) is recommended.

Galvanic oxygen sensors require that the sensor be removed from its mount during the recalibration procedure (see Fig. 29-55, *A*). At this time, the low-oxygen alarm should also be tested. The alarm should become activated if the low limit is set to more than 21% (see Fig. 29-55, *B*). A prudent default setting would be somewhere between 25% and 30%, unless oxygen concentrations lower than this value are used routinely. In any case, it is wise to keep it set to 21% or more. The steps involved in recalibrating the sensor to room air always involve removing the sensor from the breathing circuit. After calibration verification or recalibration, the breathing system is flushed with 100% oxygen. This should result in an oxygen concentration reading of more than 90% (see Fig. 29-55, *C*).

Some newer-generation anesthesia machines exclusively rely on side-stream gas analyzer to measure the inspired oxygen concentration. This is because the multigas analyzer on these workstations is an irremovable and permanent component. Thus, it fulfills the requirement

imposed on the manufacturer to provide inspired oxygen concentration monitoring. These monitors do not require daily calibration; however, the line should be disconnected from the circuit and sample room air to verify that it measures 21%.

Item 11: Verify Carbon Dioxide Absorbent Is Not Exhausted

Frequency: Before each use
Responsible Party: Provider or technician

> "Proper function of a circle anesthesia system relies on the absorbent to remove CO_2 from rebreathed gas. Exhausted absorbent as indicated by the characteristic color change should be replaced. It is possible for absorbent material to lose the ability to absorb CO_2 yet the characteristic color change may be absent or difficult to see. Some newer absorbents do change color when desiccated. Capnography should be utilized for every anesthetic and, when using a circle anesthesia system, rebreathing CO_2 as indicated by an inspired CO_2 concentration > 0 can also indicate exhausted absorbent."[240]

It is important for providers to know that absorbent color change is not as reliable as is the presence of *inspired* carbon dioxide on capnography in identifying exhausted absorbent. Absorbent "regeneration," indicator deactivation, inner canister channeling, and coloration of the absorbent canister wall are examples or circumstances that can mislead regarding the actual absorptive capacity.[197,216] Therefore, a normal-appearing absorbent may be significantly degraded in its ability to remove carbon dioxide, although some newer-generation absorbents are touted to maintain a permanent color change with exhaustion. It is no longer advised for providers to exercise (breathe in and breathe out of) the breathing circuit manually to assess the functionality of the absorbent during preuse checkout. Visual inspection and clinical suspicion of exhaustion or desiccation must suffice.

In addition to the exhaustion of carbon dioxide absorptive capacity, absorber desiccation is a potential hazard. Whereas colorimetric indicators identify the exhaustion of most absorbents, only few reportedly undergo color change with desiccation. Currently, no consistently reliable steps can be included in a PAC procedure to identify absorbent desiccation. However, certain situations increase the risk of absorbent desiccation, as described in the section on carbon dioxide absorbers.

Item 12: Breathing System Pressure and Leak Testing

Frequency: Before each use
Responsible parties: Provider and technician

> "The breathing system pressure and leak test should be performed with the circuit configuration to be used during anesthetic delivery. If any components of the circuit are changed after this test is completed, the test should be performed again. Although the anesthesia provider should perform this test before each use, anesthesia technicians who replace and assemble circuits can also perform this check and add redundancy to this important checkout procedure. Proper testing will demonstrate that pressure can be developed in the breathing system during both manual and mechanical ventilation and that pressure can be relieved during manual ventilation by opening the APL valve. Automated testing is often implemented in the newer anesthesia delivery systems to evaluate the system for leaks and also to determine the compliance of the breathing system. The compliance value determined during this testing will be used to automatically adjust the volume delivered by the ventilator to maintain a constant volume delivery to the patient. It is important that the circuit configuration that is to be used be in place during the test."[240]

It is not rare for either the disposable breathing circuit components or the fixed anesthesia machine components to leak. Therefore, a leak check of the breathing system is of paramount importance. Traditionally, this test has been performed manually after an inspection of the breathing circuit, removal of the gas sampling line, and capping of the gas sampling line port. With the machine set in the "bag" or the manual mode of ventilation, the gas flows are set to zero (or the minimal settings), the APL valve is closed, the patient's Y-piece is occluded, and breathing system is pressurized with the O_2 flush button to approximately 30 cm H_2O (Fig. 29-56). The circuit passes the leak test if it holds this pressure for at least 10 seconds. Some manufacturers may specify a low oxygen flow rate during the test.[256] A decrease in pressure during the test should prompt a check of all plug-in, push-fit, and screw connectors, the seal of the absorber canister, and a careful inspection of the disposable tubing. One of the most common locations of a circuit leak is at the absorber canister, and it is particularly important for the anesthesia provider to apply this check rigorously immediately after the absorbent has been changed.

On many modern anesthesia machines, breathing circuit leak testing is an automated feature, although manual steps are still required for test preparation. Circuit compliance is often also automatically assessed on some machines during this phase to guide ventilator tidal volume delivery. Therefore, the test should be performed with the circuit that is going to be used.

The APL valve can also assessed at this time by opening it widely after the pressure test and ensuring that the breathing circuit pressure decreases rapidly to zero. A prompt pressure drop should occur regardless of APL valve design. The ability of the pressure-limiting type APL valve to maintain stable circuit pressure can be easily assessed, if required, by setting the APL valve to 30 cm H_2O, occluding the patient's Y-piece in a manual mode of ventilation, increasing gas flow to approximately 5 L/minute, and ensuring the circuit pressure, once stable, remains within a range close to that set on the APL valve. This step may be specified in some user's manuals, whereas it is altogether absent in others.[257]

Item 13: Verify That Gas Flows Properly Through the Breathing Circuit During Both Inspiration and Exhalation

Frequency: Before each use
Responsible parties: Provider and technician

> "Pressure and leak testing does not identify all obstructions in the breathing circuit or confirm proper function

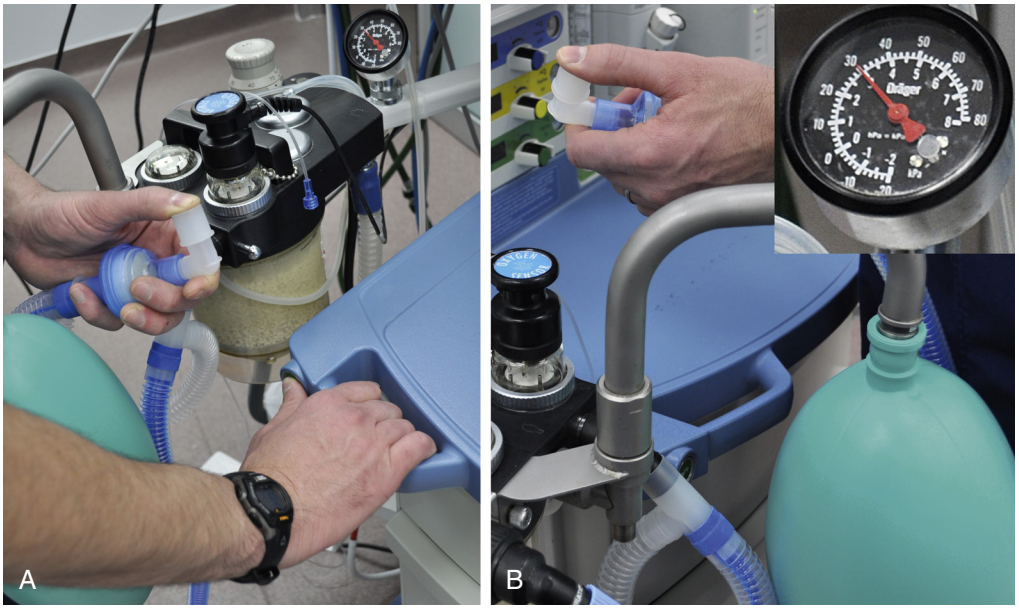

Figure 29-56. Manual breathing system pressure and leak testing. Breathing system pressure and leak testing should be performed with the circuit configuration that will be used during anesthetic delivery. **A,** The patient Y-piece or elbow is occluded, and the oxygen flush button is used to pressurize the breathing circuit to approximately 30 cm H_2O. **B,** The circuit should hold pressure at this level for at least 10 seconds. It is important to ensure that the gas flows are set to zero (or their minimal values), the gas sample line is removed, and its circuit port is occluded.

> of the inspiratory and expiratory unidirectional valves. A test lung or second reservoir bag can be used to confirm that flow through the circuit is unimpeded. Complete testing includes both manual and mechanical ventilation. The presence of the unidirectional valves can be assessed visually during the PAC. Proper function of these valves cannot be visually assessed since subtle valve incompetence may not be detected. Checkout procedures to identify valve incompetence which may not be visually obvious can be implemented but are typically too complex for daily testing. A trained technician can perform regular valve competence tests. Capnography should be used during every anesthetic and the presence of CO_2 in the inspired gases can help to detect an incompetent valve."[240]

The original 1986 FDA checklist recommended that the person checking the anesthesia machine inhale and exhale into the patient connector while observing the unidirectional valves for free gas flow in the correct direction and no flow in the opposite direction. Although it is controversial for the anesthesia provider to breathe in and out of the machine and through the next patient's breathing circuit, it is still important that the circuit be exercised to ensure that unidirectional flow is present and unimpeded. This test of circuit flow easily accomplished by placing a "test lung" or an extra breathing bag at the patient's elbow. In the "bag" or a manual mode of ventilation, the operator ventilates the artificial "lung" with the breathing bag, then actively "exhales" (squeezes) the test lung back to the breathing bag in a to-and-fro motion (Fig. 29-57). This is the so-called *flow test*. The inspiratory valve should open and the expiratory valve should close during inspiration, and vice versa for exhalation. A major malfunction of a unidirectional can be visually assessed, although subtle valve leaks (reverse flow) may be apparent only by capnography during anesthesia or through formal machine evaluation. Obstruction to flow during the flow test manifests as a "tight" breathing bag on "inspiration," whereas expiratory limb obstructions cause impeded "exhalation." Some form of flow test should be conducted because leak testing does not reliably identify circuit obstruction or unidirectional valve malfunction. Undetected circuit obstructions are particularly ominous and can manifest dramatically and sometimes immediately following induction.[147,148,150]

It cannot be stated definitively that all automated machine checks routinely assess for unimpeded circuit flow. Although most user's manuals for machines that perform automated aspects of the preuse checkout describe a leak test function, few specifically describe a flow test or an assessment of unidirectional valve function. In fact, some modern machines, which incorporate automated checkout steps, including a leak test, recommend a manual assessment of the inspiratory and expiratory valves.[257]

Item 14: Document Completion of Checkout Procedures

Responsible parties: Provider and technician

> "Each individual responsible for checkout procedures should document completion of these procedures. Documentation gives credit for completing the job and can be helpful if an adverse event should occur. Some automated checkout systems maintain an audit trail of completed checkout procedures that are dated and timed."[240]

Documentation of completion of the anesthetic checkout procedure by *providers* should occur within the anesthetic record. Currently, no guidance is available regarding where anesthesia or biomedical technician documentation of checkout procedures should occur. However, it would be prudent to maintain a detailed departmental log as a quality assurance tool.

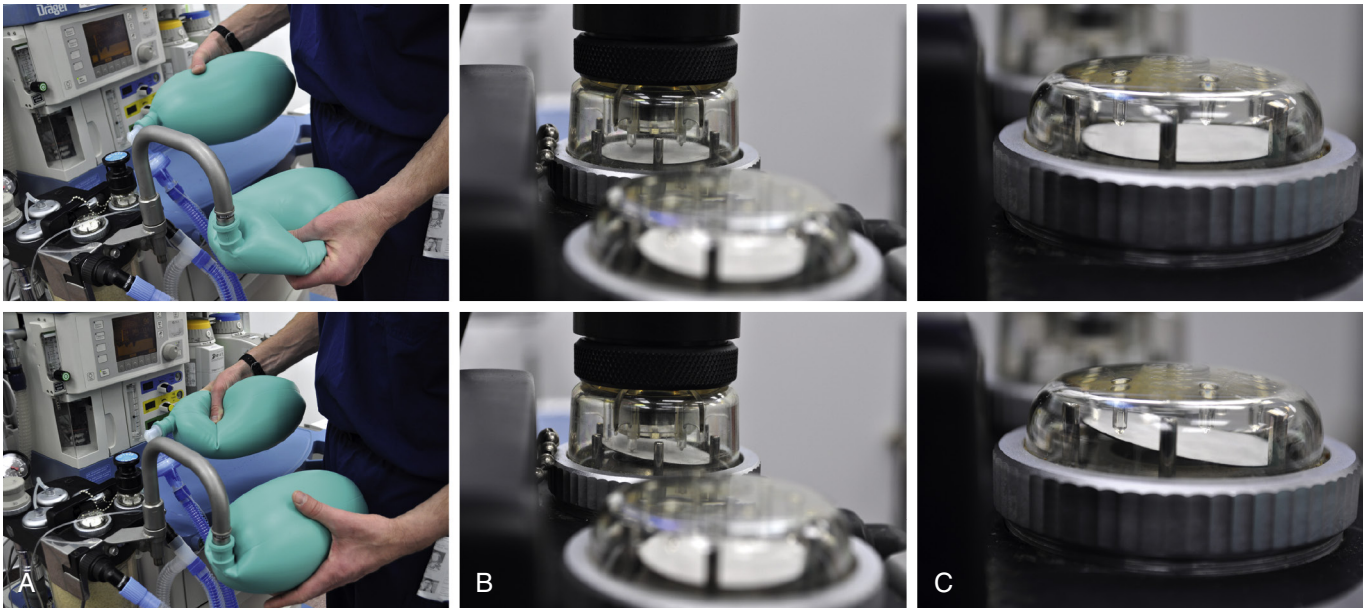

Figure 29-57. A to **C,** Verification that gas flows properly through the breathing circuit during both inspiration and exhalation with the to-and-fro "flow test." **Top row,** A test lung or second reservoir bag can is placed on the patient elbow piece. A squeeze of the breathing bag should cause flow through inspiratory limb, open the inspiratory valve, fill the test lung, and hold the expiratory valve closed. **Bottom row,** A reciprocal squeeze of the test lung should cause flow through expiratory limb, open the expiratory valve, fill the breathing bag, and hold the inspiratory valve closed. Circuit flow during the test should be smooth and unimpeded.

Item 15: Confirm Ventilator Settings and Evaluate Readiness to Deliver Anesthesia Care (Anesthesia Time Out)

Frequency: Immediately before initiating the anesthetic regimen

Responsible parties: Provider

> "This step is intended to avoid errors due to production pressure or other sources of haste. The goal is to confirm that appropriate checks have been completed and that essential equipment is indeed available. The concept is analogous to the "time out" used to confirm patient identity and surgical site prior to incision. Improper ventilator settings can be harmful especially if a small patient is following a much larger patient or vice versa. Pressure limit settings (when available) should be used to prevent excessive volume delivery from improper ventilator settings. Items to check: Monitors functional? Capnogram present? Oxygen saturation by pulse oximetry measured? Flowmeter and ventilator settings proper? Manual/ventilator switch set to manual? Vaporizer(s) adequately filled?"[240]

This last step serves as a recommended final preinduction check list of the machine and other important items including the application of essential monitors. It is a "pretakeoff" checklist for anesthesia providers. Some providers rely on final check mnemonic devices such as the MS MAIDS checklist (Box 29-2). Regardless of the specific steps, a final checklist that verifies the presence and function of key safety items is just as important in anesthesia as it is in aviation.

BOX 29-2 *The MS MAIDS Checklist**

- ❑ **Machine:** The machine checkout is complete; the vaporizers are filled, closed, and set to "0"; all gas flows knobs are set to zero flow; the ventilator and pressure settings are appropriate for the upcoming patient, with the machine in manual/spontaneous breathing mode, and the adjustable pressure-limiting valve is open.
- ❑ **Suction:** Patient suction is adequate to clear the airway.
- ❑ **Monitors:** All required standard monitors are present and ready to go.
- ❑ **Airway:** Primary airway equipment and appropriate backup equipment are ready to go.
- ❑ **IV:** Intravenous lines, fluids, and associated equipment are ready to go.
- ❑ **Drugs:** All necessary medications are available and are properly labeled.
- ❑ **Special:** Any special or unique items (i.e., additional monitors) required for the case are available and ready.

*An example of an "Anesthesia Time Out," which ensures that all appropriate checks have been completed, all essential equipment is available, and the machine is properly configured for the next patient.

Additional Comments Pertaining to the ASA's Pre-Anesthesia Checkout Procedure Recommendations (2008)

Although the 2008 PAC procedures are comprehensive, several steps that were part of the 1986 or 1993 recommendation did not appear in the current guideline; yet they are sometimes found within machine user's manuals. The use of these steps should be based on local needs or requirements because the 2008 recommendations are not restrictive or intended to be limiting. Some of these items are mentioned earlier in this section:

1. Disconnecting the central oxygen supply line to assess the low–oxygen supply pressure alarm and to purge the tank pressure gauges to zero
2. Inspecting the gas supply hoses for cracks or wear
3. Testing the flowmeters for smooth operation
4. Testing the proportioning system by attempting to create a hypoxic oxygen–nitrous oxide mixture

AUTOMATED ANESTHESIA MACHINE CHECKOUT PROCEDURES

Important points to consider regarding automated PAC features or "self-tests" are that (1) they differ between manufacturers and models, (2) it is sometimes difficult to determine precisely which segments or components are actually being checked by reading the user's manual, and (3) *no* machine automatically checks all the items on an effective PAC. At least some manual steps are required. Investigators have suggested that many providers do not understand exactly what is being checked by automated checks, or they make false assumptions regarding their respective machine's automated checkout procedure. It is easy to understand why the authors of the ASA's 2008 *Recommendations for Pre-Anesthesia Checkout Procedures* warned about an overreliance on the automated machine checkout. For example, one manufacturer's self-test screen reports a "leakage" amount, but the display or manual does not specify which section is responsible (e.g., the breathing circuit or the LPS). The operator must make an assumption that the low-pressure system is also being tested for leaks, and the manual does not state that any vaporizer should be turned "on" during leak testing. Finally, it is not clear in this unspecified manual whether the circuit is assessed for proper unidirectional flow or obstruction. When developing a local PAC procedure, providers should gain familiarity with their machine's automated checkout procedure through the user's manual. Once they are clear about the actual scope of the automated test, an effective departmental PAC checklist can be created. If an important item is not actually part of the described self-check or is not suggested in the user's manual, it should not be assumed that it is not important. Not requiring that conventional vaporizers be opened during a leak test of the low-pressure system is such an example.

MACHINE-IMBEDDED PREANESTHESIA MACHINE CHECKOUT CHECKLISTS

Some anesthesia machines have embedded PAC checklists, which are displayed during machine checkout. Like their paper counterparts, they help guide users through manual and self-test functions. If an embedded checklist provides a complete solution for a respective department, then it can be used exclusively. However, local requirements may exceed or depart, to some degree, from the workstation embedded checklist. In these cases, the use of the embedded checklist (or a modification thereof) can become a line item within the local PAC checklist.

DEVELOPING A LOCAL PREANESTHESIA MACHINE CHECKOUT CHECKLIST

The goal of a PAC is to evaluate and configure the anesthesia workstation properly so it performs its functions properly and safely. Similar to a pretakeoff checkout of an aircraft, it is a systematic task list with numerous critical steps. Therefore, it is the perfect situation in which to use a checklist. The goals of the PAC checklist are to guide the operator through an effective PAC and to promote compliance through ease of use. A checklist is a visual memory aid used to help overcome the limitations of short-term human memory, thus ensuring that particular series of specified actions or procedures are accomplished.[258] A PAC checklist can also serve as a quality control tool by codifying important items onto an organized list used by all providers.[258]

The essential items required for local PAC checklist development are the 2008 *Recommendations for Pre-Anesthesia Checkout Procedures,* the respective workstation user's manual, and an anesthesia machine reference text such as this book. PACs found in manufacturer's user's manuals tend to be several pages long and may contain items not specified in professional society recommendations, such as the ASA's guideline. Local PAC developers will quickly recognize the competing objectives of completeness and brevity during the design process. An excessively long checklist will probably not be routinely completed properly, and an underinclusive PAC could miss key items. Alternatively, some manufacturers omit important steps in their PAC recommendations. Not opening the vaporizers during leak testing is such an example.

Box 29-3 contains several checklist design principles, including many based on aviation standards. A checklist such as the PAC is a series of read-and-do tasks, which are either action items ("open the O_2 cylinder") or verification items ("…verify that the tank pressure reads >1000 psig").[259-261] In aviation it would be referred to as a "do-list," and like an aircraft checklist, it should avoid elaboration or explanation.[259,258] The design of the checklist must support its function to the fullest extent possible. The checkout procedure should be ergonomically ordered to minimize redundant movements and save time by placing procedures in a rational sequence. This is a well-recognized factor in the design of aviation checklists.[261] An example of an anesthesia workstation preuse checkout based on aviation checklist principles is shown in Box 29-4. The ASA's *Recommendations for Pre-Anesthesia Checkout Procedures (2008)* recommends an "Anesthesia Time Out," to ensure that appropriate checks have been completed, all essential equipment is available, and the machine is properly configured for the next patient. In the example checklist in Box 29-4, the MS MAIDS mnemonic is used to complete this step, which is further described in Box 29-2.

Finally, the checklist should be as short as possible, yet be detailed enough so critical items are not omitted. From a human perspective and performance point of view, a shorter and less elaborate checklist will encourage use, but it may not be sufficiently detailed to provide adequate guidance to personnel less familiar with the workstation. Unlike pilots, anesthesia providers do not spend countless hours on equipment-focused training, and this is where the aviation-anesthesia analogy weakens. PAC developers will quickly recognize this dilemma and may choose to create a slightly more detailed version for trainees or new employees, in addition to a standard version for those more familiar with their respective workstations. Because a PAC should be confined to one page, a laminated card with the detailed, instructional version on one side and the succinct, true checklist on the other may be optimal.

BOX 29-3 *Preanesthesia Machine Checkout Checklist Design and Use Tips*

PAC Checklist Design

- ❑ The PAC checklist should be designed in a read-and-do or read-and-confirm format (i.e., Ambu bag…Present and functional")
- ❑ The flow pattern of the checklist should lend itself to efficiency and compliance. The items should be in a logical sequence, to minimize redundant movements.
- ❑ The checklist should be as short as possible, yet it should include all key checks.
- ❑ When applicable, responses to checklist challenges should be provided to verify the value or status of an item, rather than simply confirm task completion (e.g., "Verify O_2 tank pressure…Done" is not adequate; "O_2 tank pressure…>1000 psig" is good).
- ❑ The challenges and responses on the checklist should be consistent with the labeling and text on the switches, screens, and controls of the machine.
- ❑ The font and character size should be pleasing.
- ❑ The overuse of *italics*, **bold**, underline, and UPPER CASE WORDS should be avoided.
- ❑ Language should be familiar, accessible, and unambiguous.
- ❑ Excessive verbiage should be avoided.
- ❑ For long checklists, pauses between key steps should be identified, or the checklist should be divided graphically into logical task groups, as opposed to one long continuous series of tasks.
- ❑ The checklist should fit onto one page. A large type size is preferred for legibility, but a small type size may be needed to keep the number of checklist pages to a minimum.

PAC Checklist Testing

- ❑ Rigorous testing and validation of the checklist should be performed before its implementation.
- ❑ Multiple individuals of different skill levels and backgrounds (e.g., technician, resident, CRNA, physician faculty) should give the checklist a trial.
- ❑ The checklist should be designed by a trial-and-error approach, with revisions anticipated.

PAC Checklist Use

- ❑ The checklist should be evaluated and updated periodically on the basis of user feedback, workstation modifications, manufacturer safety alerts, or compelling literature.
- ❑ PAC checklist users should be made aware that the PAC procedure is very vulnerable to production pressure. The checklist should not be relegated to a second level of importance.
- ❑ The checklist should be kept in sight each time it is used. Its benefit will be defeated if it dangles from the side of the machine during the checkout.
- ❑ A "checklist culture" should be developed through sound checklist design, leadership, and promotion of a positive departmental attitude regarding the procedure.

CRNA, Certified registered nurse anesthetist; *PAC*, preanesthesia machine checkout.

BOX 29-4 *Example of a Departmental Preanesthesia Machine Checkout for Dräger Fabius*

Ambu Bag	Present and Functional
AC power	Connected
Machine power	On
Breathing circuit	Intact
Vaporizers	Secured and filled
CO_2 absorbent color	White >½ the canister
Pipeline hoses	Properly connected
O_2 tank pressure	≥1000 psig
Pipeline pressures	Dark green range
"Run System Test"	Pass
"Calibrate Flow Sensor" test	Complete
O_2 sensor calibration	Complete
Inspiratory low O_2 alarm check	Alarm sounds (set low FiO_2 alarm limit between 25% and 30%)
"Leak/Compl Test" with vaporizer @ 1%	Pass
Vaporizer status after test	"0" volume % (off)
Deactivation of "DES COMP" if appropriate	Checked
APL valve function at 30 cm	Circuit pressure stays between 26 and 35 cm H_2O
APL valve function when open wide	Circuit pressure drops to 0 cm H_2O
Hand ventilation of breathing circuit	Unobstructed flow, good unidirectional valve function
Mechanical ventilation of breathing circuit	Test lung ventilates
O_2 flush	Gas flows from elbow

BOX 29-4 *Example of a Departmental Preanesthesia Machine Checkout for Dräger Fabius—cont'd*

Scavenger connections	Connected
Scavenger vacuum	Bobbin between the Min and Max marks
Scavenger integrity	<10 cm H_2O circuit pressure with O_2 flush button
Flow control valve function	Adjustable through full range
Attempt to create hypoxic mixture	Inability to create hypoxic mixture
Flow control valve position check	"0.0" flow after testing (off)
Test of CO_2 sample line	Exhaled CO_2 displayed
ASA standard and required monitors	Present and functional
ANESTHESIA TIME OUT: MS MAIDS CHECKLIST	
❑ **M**achine	Machine ready, vaporizers off and filled, ventilators set
❑ **S**uction	Functional
❑ **M**onitors	Present and functional
❑ **A**irway	Primary and alternate equipment ready
❑ **I**V	Lines, fluids, equipment ready
❑ **D**rugs	Ready and properly labeled
❑ **S**pecial	Special or unique items ready
ANESTHESIA APPARATUS CHECKOUT BEFORE EACH PROCEDURE	
CO_2 absorbent color	White >½ the canister
"Leak/Compl Test" with vaporizer @ 1%	Pass
Hand ventilation of breathing circuit	Unobstructed flow, good unidirectional valve function
Vaporizer status	Vaporizers set to "0," filled, ports closed
Flowmeters	Dialed clockwise to "0.0" flow
MS MAIDS Checklist	Completed

APL, Adjustable pressure-limiting; *ASA*, American Society of Anesthesiologists; *CO_2*, carbon dioxide; *IV*, intravenous; *O_2*, oxygen.

Chapter 30

Intravenous Anesthetics

JAAP VUYK • ELSKE SITSEN • MARIJE REEKERS

Acknowledgment: The editors and publisher would like to thank Drs. J.G. Reves, Peter Glass, David A. Lubarsky, Matthew D. McEvoy, and Ricardo Martinez-Ruiz for contributing a chapter on this topic to the prior edition of this work. It has served as the foundation for the current chapter.

Key Points

- The introduction of thiopental into clinical practice in 1934 marked the beginning of modern intravenous (IV) anesthesia. Today, IV anesthetics are used for induction and maintenance of anesthesia and for sedation in a wide variety of circumstances.
- The most commonly used IV anesthetic is propofol, an alkylphenol currently formulated in a lipid emulsion. Propofol provides rapid onset and offset with context-sensitive decrement times of approximately 10 minutes when infused for less than 3 hours and of less than 40 minutes when infused for up to 8 hours. Its mechanism of action is likely the enhancement of γ-aminobutyric acid (GABA)-induced chloride currents. Propofol causes a dose-dependent decrease in arterial blood pressure through a decrease in cardiac output and systemic vascular resistance and produces moderate respiratory depression. A unique action of propofol is its antiemetic effect, even at concentrations less than those producing sedation.
- Barbiturates were the most commonly used IV drugs administered to induce anesthesia before the introduction of propofol. Thiopental provides rapid onset and offset when used as a single dose, but it accumulates rapidly with repeated or prolonged administration and thus postpones recovery from anesthesia. Methohexital has a rapid onset and offset similar to those of propofol for procedures lasting less than 2 hours. The barbiturates are administered as sodium salts diluted in a water base at an alkaline pH. Similar to propofol, the barbiturates provide their hypnotic effects largely through action on the $GABA_A$ receptor. Barbiturates provide cerebral protection (see also Chapter 70), and they are, apart from induction of anesthesia, used primarily for this purpose. They cause a moderate dose-dependent decrease in arterial blood pressure (primarily as a result of peripheral vasodilation) and respiratory drive. The barbiturates are contraindicated in patients with porphyria.
- The benzodiazepines are used primarily for anxiolysis and amnesia or for conscious sedation. The water-soluble benzodiazepine midazolam is most frequently used intravenously because of its rapid onset and offset compared with those of other benzodiazepines (e.g., diazepam). The onset time of midazolam is slower than that of propofol and barbiturates, and its offset, especially with larger doses or a prolonged infusion, is considerably longer than that of propofol and may be prolonged in hepatic and renal failure. The benzodiazepines act through the GABA receptor. Flumazenil is a specific benzodiazepine antagonist. It can be used to reverse the effects of benzodiazepines but should be used with caution because the duration of its antagonizing effect often is shorter than the benzodiazepine effect it is supposed to antagonize. The benzodiazepines generally produce only a mild decrease in arterial blood pressure and mild to moderate respiratory depression. Remimazolam is the most recent benzodiazepine, with an ultrashort duration of action resulting from its rapid clearance by plasma esterases.
- Ketamine is a phencyclidine derivative that acts primarily, but not entirely, as an antagonist of the *N*-methyl-D-aspartate receptor. It produces a dissociative state of hypnosis and analgesia. It has been used for induction and maintenance of anesthesia. Ketamine is associated with significant adverse psychological effects from larger doses and has several other side effects. It is used now primarily for its analgesic properties. It has rapid onset and relatively rapid offset, even after an infusion of several hours. Its sympathomimetic effects preserve cardiac function. Ketamine has minimal effect on respiration and tends to preserve autonomic reflexes.

KEY POINTS—cont'd

- Etomidate is an imidazole derivative used primarily for induction of anesthesia, especially in older patients and in patients with cardiovascular compromise (see also Chapter 80). It has a rapid onset of effect and a rapid offset even after a continuous infusion. A dose used to induce anesthesia results in inhibition of adrenocortical synthesis and possible mortality in patients in the intensive care unit (ICU). The major advantage of etomidate is its minimal effect on the cardiovascular and respiratory systems.
- Dexmedetomidine is the most recently released IV anesthetic. It is a highly selective α_2-adrenergic agonist that produces sedation, sympatholysis, hypnosis, and analgesia. Dexmedetomidine is currently approved only for brief (<24 hours) postoperative sedation. Its use as an adjunct or sole hypnotic agent is rapidly emerging, most frequently in an ICU setting. It may be advantageous for its ability to prevent delirium. Dexmedetomidine is used as a sedative during invasive or radiologic procedures and as an adjunct in central or peripheral neural blockade. Its primary action is as an agonist on α_2 receptors in the locus coeruleus. It has minimal effect on respiration. Heart rate and cardiac output show a concentration-dependent decrease.
- Droperidol, a butyrophenone and major tranquilizer, was initially used to produce a state of neuroleptanesthesia. Its prolongation of the QT interval has resulted in its withdrawal in several countries and its limitation to the treatment of postoperative nausea and vomiting (PONV). It has a black box warning in the United States. Because the use of low-dose droperidol (<1.25 mg) for PONV has not been approved by the U.S. Food and Drug Administration, the black box warning does not relate to this use. Clinically significant prolongation of the QT interval by doses used for PONV (0.625 to 1.25 mg) has been challenged by several editorials, and this effect has not been substantiated by review of the reported cases or other literature. Low-dose droperidol remains an effective antiemetic therapy and is used as such in many European countries (see also Chapter 97).

Intravenous (IV) anesthesia can be traced back to 1656, when Percival Christopher Wren and Daniel Johann Major first experimented with IV administration using a goose quill and bladder to inject wine and ale into a dog's vein. In 1665, German naturalist and physician Sigismund Elsholz made the first attempt at IV anesthesia in humans and investigated the possibilities of IV injection with opiates. IV anesthesia further evolved when Fedoroff started using hedonal in St. Petersburg in 1905 and entered the era of modern anesthesia with the release of thiopental in 1936.[1] Since these beginnings, and in particular since the 1980s, the pharmacokinetics and pharmacodynamics of IV anesthetics and their interactions have been described in increasingly greater detail. This body of knowledge and the availability of increasingly shorter-acting drugs now allow the anesthesia provider to administer anesthesia not on the basis of the needs of the population but on the individual needs of the patient. Today's anesthesia provider is supported by modern IV drug administration techniques, such as target-controlled infusion, and central nervous system (CNS) monitoring devices to further optimize and individualize the application of IV anesthesia. This chapter describes the current status of the pharmacology of IV anesthetics and their place in modern anesthesia.

PROPOFOL

HISTORY

Since its introduction in the 1970s, propofol has become the most widely used IV hypnotic today. Building on work on the sedative properties of phenol derivatives in mice, propofol was developed in the United Kingdom by Imperial Chemical Industries as ICI 35868. The initial solution of propofol was released in 1977 in Cremophor EL.[2] It was withdrawn because of anaphylactic reactions and was replaced and reformulated as an emulsion of a soybean oil–propofol mixture in water and relaunched in 1986. Propofol is used for induction and maintenance of anesthesia and for sedation in and outside the operating room.

PHYSICOCHEMICAL CHARACTERISTICS

Propofol is one of a group of alkylphenols that were explored for their hypnotic properties in animals (Fig. 30-1).[3-5] The

alkylphenols are highly lipid soluble and are insoluble in an aqueous solution.[6] Numerous formulations of propofol are marketed today. The formulation most commonly used is that of 1% propofol, 10% soybean oil, and 1.2% purified egg phospholipid added as emulsifier, with 2.25% of glycerol as a tonicity-adjusting agent, and sodium hydroxide to change the pH. Following concerns regarding microbial growth in the emulsion, ethylenediaminetetraacetic acid (EDTA) was added for its bacteriostatic activities. Propofol has a pH of 7 and appears as a slightly viscous, milky white substance, a result of small lipid droplets in solution. In Europe, a 2% formulation and a formulation in which the emulsion contains a mixture of medium-chain and long-chain triglycerides also are available. All formulations commercially available are stable at room temperature, are not light sensitive, and may be diluted with 5% dextrose in water. Propofol concentrations may be measured both in whole blood and in the exhaled air.[7-10]

In December 2008, the U.S. Food and Drug Administration (FDA) approved fospropofol disodium (Lusedra), for monitored anesthesia care in adult patients undergoing diagnostic and therapeutic procedures. Fospropofol is a water-soluble prodrug of propofol that is metabolized by alkaline phosphatases in the liver to the active metabolite propofol. One millimole of propofol is generated for each millimole of fospropofol sodium administered. Approximately 1.86 mg of fospropofol sodium is the molar equivalent of 1 mg propofol. In April 2010, six studies on the pharmacokinetics and pharmacodynamics of fospropofol were retracted as a result of an analytic assay inaccuracy that was discovered after publication of these studies.[11,12] Since then, few data on the pharmacokinetics and pharmacodynamics of fospropofol have been published. Although fospropofol remains available for monitored anesthesia care, available data are scarce, and most pharmacokinetic and pharmacodynamic data that are available come from the United States, as described in one review.[13] In contrast to propofol, fospropofol is not associated with pain on injection, although mild to moderate perineal paresthesias and pruritus minutes after a bolus injection of fospropofol have been reported and may result from a phosphate metabolite.

PHARMACOKINETICS

Propofol is oxidized to 1,4-diisopropyl quinol in the liver. Propofol and 1,4-diisopropyl quinol are conjugated with glucuronic acid to propofol-1-glucuronide and quinol-1-glucuronide and quinol-4-glucuronide, which then may be excreted by the kidneys.[14,15] After a 2.5-hour anesthetic regimen with propofol, patients excrete propofol and propofol metabolites for more than 60 hours.[15] Less than 1% propofol is excreted unchanged in urine, and only 2% is excreted in feces. The metabolites of propofol are thought to be inactive. Because clearance of propofol (>1.5 L/minute) exceeds hepatic blood flow, extrahepatic metabolism or extrarenal elimination may occur. Extrahepatic metabolism has been confirmed during the anhepatic phase of patients receiving a transplanted liver with the determination of propofol metabolites after propofol administration in the absence of liver tissue. The most important extrahepatic site of propofol metabolism is the kidney.[16,17] Renal metabolism of propofol accounts for up to 30% of propofol clearance, and this explains the rapid clearance of propofol, which exceeds liver blood flow. The lungs also may play a role in extrahepatic propofol metabolism.[18,19] In sheep, the lungs are responsible for approximately 30% of the uptake and first-pass elimination after a bolus dose. In humans, a 20% to 30% decrease in propofol concentration measured across the lung exists with a higher concentration of the metabolite 2,6-diisopropyl 1,4-quinol on the arterial side of the circulation.

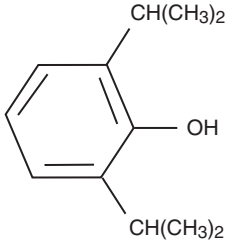

Figure 30-1. Structure of propofol, an alkylphenol derivative. *(From Reves JG, Glass P, Lubarsky DA, et al: Intravenous anesthetics. In Miller RD, Eriksson LI, Fleischer LA, et al, editors:* Miller's anesthesia, *ed 7. Philadelphia, 2010, Churchill Livingstone, pp 719-768.)*

Propofol is generally known for its hemodynamic depressant effects and may reduce hepatic blood flow. As such, it may reduce the clearance of other drugs metabolized by the liver, in particular those with a high extraction ratio.[20] In addition, propofol is known as a CYP3A4 inhibitor.[21] In contrast to enzyme induction that may take several days or weeks to develop, competitive inhibition of cytochrome P450 system activity may occur almost instantaneously because of the competition of two drugs (e.g., propofol and midazolam) for the enzyme's active site. Short-term exposure to propofol at a blood concentration of 3 μg/mL already reduces CYP3A4 activity by approximately 37%.

Fospropofol is a water-soluble prodrug of propofol and is chemically described as phosphono-*O*-methyl-2, 6-diisopropylphenol, disodium salt ($C_{13}H_{19}O_5PNa_2$).[22-28] Fospropofol is metabolized by alkaline phosphatases to propofol, formaldehyde, and phosphate. Formaldehyde is further metabolized to formate, which is then eliminated, primarily by oxidation to carbon dioxide. More than 71% of fospropofol is recovered in the urine within 192 hours following a single 400-mg IV dose. Renal elimination is less than 0.02%, and total body clearance is on the order of 0.28 L/hour/kg. The terminal elimination half-life of fospropofol is 0.88 hours. The pharmacokinetics of fospropofol and liberated propofol is not affected by race, sex, or mild to moderate renal impairment. Furthermore, fospropofol pharmacokinetics is not affected by age or alkaline phosphatase concentration. So far, no pharmacokinetic interactions have been found between fospropofol and fentanyl, midazolam, morphine, or propofol. This is probably because fospropofol is not subject to cytochrome P450 enzyme-mediated metabolism.[13]

TABLE 30-1 PHARMACOKINETIC VARIABLES FOR COMMONLY USED INTRAVENOUS ANESTHETICS

Elimination	Elimination Half-Life (hr)	Clearance (mL/kg/min)	Vd_{SS} (L/kg)
Dexmedetomidine	2-3	10-30	2-3
Diazepam	20-50	0.2-0.5	0.7-1.7
Droperidol	1.7-2.2	14	2
Etomidate	2.9-5.3	18-25	2.5-4.5
Flumazenil	0.7-1.3	5-20	0.6-1.6
Ketamine	2.5-2.8	12-17	3.1
Lorazepam	11-22	0.8-1.8	0.8-1.3
Methohexital	2-6	10-15	1.5-3
Midazolam	1.7-2.6	6.4-11	1.1-1.7
Propofol	4-7	20-30	2-10
Thiopental	7-17	3-4	1.5-3

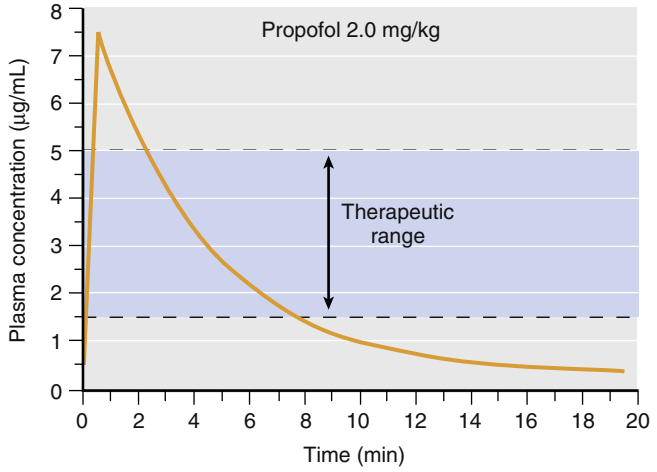

Figure 30-2. Simulated time course of whole blood levels of propofol after an induction dose of 2 mg/kg. Blood levels required for anesthesia during surgical procedures are 2 to 5 μg/mL, with awakening usually occurring at a blood level less than 1.5 μg/mL. *(From Reves JG, Glass P, Lubarsky DA, et al: Intravenous anesthetics. In Miller RD, Eriksson LI, Fleischer LA, et al, editors:* Miller's anesthesia, *ed 7. Philadelphia, 2010, Churchill Livingstone, pp 719-768.)*

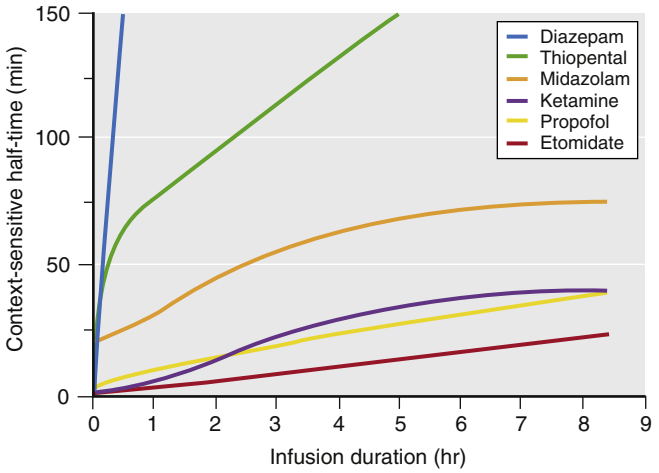

Figure 30-3. The context-sensitive half-times for commonly used intravenous anesthetic drugs. The context-sensitive half-time is the time for the plasma level of the drug to decrease 50% after cessation of infusion. The duration of infusion is plotted on the horizontal axis. The rapidity with which the drug level decreases is directly related to the time of infusion (i.e., the longer the drug is infused, the longer the half-time). Etomidate, propofol, and ketamine have significantly shorter half-times than do thiopental and diazepam, and this makes them more suitable for prolonged infusion. *(From Reves JG, Glass P, Lubarsky DA, et al: Intravenous anesthetics. In Miller RD, Eriksson LI, Fleischer LA, et al, editors:* Miller's anesthesia, *ed 7. Philadelphia, 2010, Churchill Livingstone, pp 719-768.)*

The pharmacokinetics of propofol has been described by two-compartment and three-compartment models (Table 30-1). After a single bolus dose, whole blood propofol levels decrease rapidly as a result of redistribution and elimination (Fig. 30-2). The initial distribution half-life of propofol is 2 to 8 minutes. Studies in which the disposition of propofol is described by a three-compartment model give initial and slow distribution half-lives of 1 to 8 minutes and 30 to 70 minutes, respectively, and an elimination half-life of 4 to 23.5 hours.[29-34] The context-sensitive half-time for propofol for infusions of up to 8 hours is less than 40 minutes (Fig. 30-3).[35] Because the required decrease in concentration for awakening after anesthesia or sedation with propofol is generally less than 50%, recovery from propofol remains rapid even after prolonged infusion. The volume of distribution of the central compartment has been calculated at between 6 and 40 L, and the volume of distribution at steady state has been calculated as 150 to 700 L. The central compartment generally is smaller in older adults as a result of reduced cardiac output in these patients. Reduced cardiac output is associated with a higher peak plasma concentration, which is reflected by a smaller central compartment in the pharmacokinetic analysis. The clearance of propofol is extremely high, 1.5 to 2.2 L/minute. As discussed earlier, this exceeds hepatic blood flow, and extrahepatic metabolism has been shown.

The equilibrium constant for propofol based on suppression of the activity in the electroencephalogram (EEG) is approximately 0.3 minutes, and the half-life of equilibrium ($t_{½ke0}$) between plasma concentration and EEG effect is 2.5 minutes. The time to peak effect is 90 to 100 seconds. The onset of EEG effect with propofol seems to be independent of age. The onset of decreasing arterial blood pressure is much slower (double the time) and increases with age.[36] For EEG and blood pressure changes, older patients show a concentration-dependent increasing sensitivity (see also Chapter 80). The pharmacokinetics of propofol may be altered by various factors (e.g., gender, weight, preexisting disease, age, and concomitant medication).[37-39] Some studies suggest that propofol may exhibit nonlinear pharmacokinetics.[40] Because propofol has a high extraction ratio, this may impair its own clearance by decreasing cardiac output and thus hepatic blood flow.[41] As a result, a doubling of the dose of propofol may lead to a drug concentration that may be more than twice that initially experienced. In contrast, an increase

in cardiac output induced by sympathomimetic administration may lead to a decrease in the propofol plasma concentration. In a hemorrhagic shock model, propofol concentrations increased 20% until uncompensated shock occurred, when a rapid and marked increase in propofol concentrations was noted.[42]

In term and preterm neonates, variability of propofol clearance was accounted for largely by postmenstrual and postnatal age with very fast maturation of clearance in neonatal life. Dosage in these neonates must be calculated with extreme care.[43,44] Women have a larger volume of distribution and higher clearance rates, but the elimination half-life is similar for male and female patients. Older individuals have decreased clearance rates and a smaller central compartment volume.[45] Both changes may be the result of reduced cardiac output. Because of these conditions and the increased sensitivity to the effect of propofol in older adults, patients 80 years old or older generally need 50% of the propofol dose of patients 20 years old to target the same level of sedation or hypnosis.[29,38,45,46] Children have a relatively larger central compartment volume (50%) and a more rapid clearance (25%).[31,47] In children older than 3 years old, volumes and clearances should be weight adjusted (see also Chapter 93). Children younger than 3 years of age also show weight-proportional pharmacokinetic parameters, but with larger central compartment and systemic clearance values than in adults or older children. This finding explains the larger dose requirements in this age group.[48,49] Hepatic disease seems to result in larger steady-state and central compartment volumes; clearance is unchanged, but the elimination half-life is slightly prolonged, as is time to recovery.[50,51] In clinical practice, no significant dose adjustment is required in patients with hepatic disease. The extrahepatic clearance of propofol that may compensate for a reduced hepatic function may be responsible for this situation.

Midazolam affects the pharmacokinetics of propofol.[52] In the presence of a sedative midazolam concentration of 200 ng/mL, blood propofol concentrations become elevated by approximately 25%. Midazolam reduces propofol metabolic clearance from 1.94 to 1.61 L/minute, Cl_2 (rapid distribution clearance) from 2.86 to 1.52 L/minute, and Cl_3 (slow distribution clearance) from 0.95 to 0.73 L/minute. The high extraction ratio of propofol of 0.79 to 0.92 suggests that the metabolic clearance of propofol may not be affected by enzyme inhibition but may be susceptible to changes in hepatic perfusion. The changes in the pharmacokinetics of propofol induced by midazolam thus may be the result of the hemodynamic alterations induced by the coadministration of midazolam.

Propofol, in turn, affects midazolam pharmacokinetics.[20] In the presence of sedative concentrations of propofol, plasma midazolam concentrations increased by 27%. In the presence of propofol, midazolam is administered in a smaller central compartment from which midazolam is cleared and distributed less rapidly to peripheral tissues. For example, alfentanil has been shown to increase blood propofol concentrations through a reduction in the elimination and distribution clearance of propofol.[53] This finding is in line with other pharmacokinetic interactions between hypnotics and opioids when combined with propofol. Propofol has been shown to increase alfentanil concentrations by decreasing the elimination and the rapid and slow distribution clearances of alfentanil. Coadministration of propofol increased remifentanil concentrations through both a decrease in the central volume of distribution and distributional clearance of remifentanil by 41% and elimination clearance by 15%. Propofol kinetics is unaltered by renal disease.

As previously stated, pharmacokinetic data on the disposition of fospropofol are scarce. Phase I and phase II studies were conducted in Europe when a detection error became apparent that resulted in the retraction of six published manuscripts. Currently, no further pharmacokinetic studies have been initiated. The pharmacokinetics of fospropofol in humans remains largely unknown.

Fospropofol protein binding is extensive (98%).[13] This drug has a small volume of distribution of 0.3 L/kg and a total body clearance of 0.36 L/kg/hour with a terminal elimination half-life of 0.88 hours. After a bolus dose of 6 mg/kg of fospropofol, the parent drug peaks at 4 minutes and is rapidly metabolized to propofol with a peak plasma propofol concentration at 12 minutes after administration of fospropofol. With this fospropofol dose, the maximum concentration of fospropofol was 78.7 μg/mL and the maximum concentration of propofol was 1.08 μg/mL. The total body clearance of fospropofol and of propofol was 0.36 and 3.2 L/kg/hour, respectively. The terminal half-lives were 0.88 and 1.13 hours, respectively.

PHARMACODYNAMICS

Effects on the Central Nervous System

The hypnotic action of propofol is mostly mediated by enhancing γ-aminobutyric acid (GABA)-induced chloride current through its binding to the β subunit of the $GABA_A$ receptor. Sites on the β_1, β_2, and β_3 subunits of the transmembrane domains are crucial for the hypnotic action of propofol.[54,55] The α subunit and γ_2 subunit subtypes also seem to contribute to modulating the effects of propofol on the GABA receptor. The effects of propofol have been described as indirect and direct. Propofol exhibits an indirect effect by potentiation of the ion channel activation by GABA, thereby shifting the concentration-response relationship to the left. At higher propofol concentrations, propofol is also thought to activate $GABA_A$ receptor channels directly.[56-58]

The exact mechanism and location of changes that are associated with the change from consciousness to the unconscious state are not yet fully understood. Some experts suggest that proper functioning of the brainstem-thalamocortical arousal circuits is critical, whereas other investigators state that consciousness is more related to frontoparietal association cortex activity. Through its action on $GABA_A$ receptors in the hippocampus, propofol inhibits acetylcholine release in the hippocampus and prefrontal cortex.[59] The α_2-adrenoreceptor system also seems to play an indirect role in the sedative effects of propofol.[60] Resting-state functional magnetic resonance imaging (fMRI) studies suggest that propofol's

action may be related to a CNS that reduces its discriminable state and switches into stereotypic patterns of firing under propofol sedation.[61] The so-called default mode network (DMN), including the posterior cingulate, medial frontal, and bilateral parietal cortices, is the anatomic substrate in which these stereotypical patterns become visible. By using positron emission tomography, propofol hypnosis has been found to be related to reduced activity in the thalamic and precuneus regions. These regions likely play an important role in propofol-induced unconsciousness.[62]

Propofol results also in widespread inhibition of the *N*-methyl-D-aspartate (NMDA) subtype of glutamate receptor through modulation of sodium channel gating, an action that also may contribute to the drug's CNS effects.[63,64] Propofol has a direct depressant effect on neurons of the spinal cord. In acutely dissociated spinal dorsal horn neurons, propofol acts on $GABA_A$ and glycine receptors.[65] The sense of well-being in patients with propofol is related to the increase in dopamine concentrations in the nucleus accumbens (a phenomenon noted with drugs of abuse and pleasure-seeking behavior).[66] Propofol's antiemetic action may be explained by the decrease in serotonin levels it produces in the area postrema, probably through its action on GABA receptors.[67]

The onset of hypnosis after a dose of 2.5 mg/kg is rapid (one arm–brain circulation), with a peak effect seen at 90 to 100 seconds. The median effective dose (ED_{50}) of propofol for loss of consciousness is 1 to 1.5 mg/kg after a bolus. The duration of hypnosis is dose dependent and is 5 to 10 minutes after 2 to 2.5 mg/kg. Age markedly affects the induction dose, which is highest at younger than 2 years (95% effective dose [ED_{95}], 2.88 mg/kg) and decreases with increasing age. This is a direct result of the altered pharmacokinetics in children and in older adults. Children exhibit a relatively larger central compartment and thus need a higher dose to ensure a similar blood drug concentration.[68-70] In addition, the rapid clearance of propofol in children requires a larger maintenance dose. Increasing age decreases the propofol concentration required for loss of consciousness.

At subhypnotic doses, propofol provides sedation and amnesia. Propofol infusions of at least 2 mg/kg/hour were necessary to provide amnesia in unstimulated volunteers. Awareness during surgical procedures at higher infusion rates has been reported. During surgical procedures, extremely high infusion rates producing blood propofol concentrations in excess of 10 μg/mL may be necessary to prevent awareness if propofol is used as the sole anesthetic. Propofol also tends to produce a general state of well-being. Hallucinations, sexual fantasies, and opisthotonos occur after propofol administration.

The effect of propofol on the EEG, as assessed after 2.5 mg/kg followed by an infusion, shows an initial increase in alpha rhythm followed by a shift to gamma and theta frequency. Rapid infusion rates produce burst suppression at blood propofol concentrations higher than 8 μg/mL. Propofol causes a concentration-dependent decrease in the bispectral index (BIS), with 50% and 95% of patients unable to respond to a verbal command at a BIS of 63 and 51, respectively. The propofol concentration at which 50% of volunteers failed to respond to verbal command was 2.35 μg/mL. Lack of recall was observed in 95% of patients at a BIS value of 77.[71] Propofol effect-site concentrations provide similar correlation with decreases in the spectral entropy variable derived from the EEG as with BIS, as well as a similar ability to titrate propofol anesthetic effect. The effect of propofol on epileptogenic EEG activity is controversial. Propofol may suppress seizure activity through GABA agonism, inhibition of NMDA receptors (NMDARs), and modulation of slow calcium ion channels. However, the same GABA agonism and glycine antagonism may also induce clinical seizures and EEG epileptiform changes,[72] especially during induction of and emergence from anesthesia. Propofol has a dose-dependent anticonvulsant action. Propofol has even been used to treat epileptic seizures. However, propofol can cause grand mal seizures and has been used for cortical mapping of epileptogenic foci.[73]

Unfortunately, propofol can be addictive. An important issue in the potential of abuse is the development of tolerance. Tolerance to a drug creates circumstances for abuse. Propofol is used as a sedative in the intensive care unit (ICU); in 20% to 40% of patients, the propofol dosage regimen must be repeatedly adjusted upward to maintain the same effect.[74] Data on propofol abuse in the general public are unknown, but the incidence of abuse is likely to be low compared with other substances. For health care workers, propofol is easy to access, and case reports of lethal self-administration do occur. Some investigators have suggested a greater incidence of propofol abuse by health care providers,[75,76] and these investigators support stricter propofol regulation. In contrast to propofol, fospropofol was classified in 2009 by the U.S. Drug Enforcement Administration (DEA) as a controlled substance.

Propofol decreases intracranial pressure (ICP) in patients with either normal or increased ICP (see also Chapter 70). The decrease in ICP (30% to 50%) is associated with significant decreases in cerebral perfusion pressure (CPP).[77] The use of propofol in head-injured patients should be restricted to doses providing mild to moderate sedation (i.e., blood concentration of 2 μg/mL, infusion of 1.5-4.5 mg/kg/hr).[78] Anesthetics are neuroprotective because they reduce the metabolic oxygen use that is beneficial for the balance between energy supply and demand and because they increase the tolerance to hypoxia by the neuronal tissue. Propofol has no direct preconditioning effect but may attenuate glutamate-mediated excitotoxicity.[79-81] Propofol acutely reduces intraocular pressure by 30% to 40%. Compared with thiopental, propofol produces a larger decrease in intraocular pressure and is more effective in preventing an increase in intraocular pressure secondary to succinylcholine and endotracheal intubation. Normal cerebral reactivity to carbon dioxide and autoregulation are maintained during a propofol infusion.

The neuroprotective effects of propofol remain controversial.[82] In an incomplete ischemia model in rats, propofol administered to burst suppression resulted in significantly better neurologic outcome and less brain tissue injury compared with fentanyl. Propofol administered at sedative concentrations started either

EC_{50}, Half-maximal effective concentration; EC_{95}, 95% maximal effective concentration.

*These optimal infusion schemes have been derived from data in female patients undergoing lower abdominal surgical procedures. These should be used as guidelines and be adjusted to the individual needs of the patient.

immediately after or at 1 hour after an ischemic insult significantly reduced infarct size compared with awake controls infused with intralipid.[83,84] Subanesthetic doses of propofol also induced neuroapoptosis in the infant mouse brain.[85] In addition, anesthetic doses of propofol in rats induced complex changes accompanied by cell death in the cortex and thalamus of the developing rat brain.[86] The neuronal protective effect of propofol may result from the attenuation of changes in ATP, calcium, sodium, and potassium caused by hypoxic injury and its antioxidant action by inhibiting lipid peroxidation. Current evidence indicates that propofol can protect neurons against ischemic injury caused by excitotoxicity, but neuroprotection may be sustained only if the ischemic insult is relatively mild and is not sustained after a prolonged recovery period. Prolonged propofol sedation in children is associated with adverse neurologic sequelae.[87]

Many anesthetic-related drugs decrease the required dose or blood concentrations of propofol's pharmacologic action. The "required dose" is usually directly related to the required concentration for a given effect. The propofol Cp_{50} (blood concentration needed for 50% of subjects to not respond to a defined stimulus) for loss of response to verbal command in the absence of any other drug is 2.3 to 3.5 μg/ mL.[88-90] The propofol Cp_{50} to prevent movement on skin incision is 16 μg / mL; this is markedly reduced by increasing concentrations (i.e., doses) of fentanyl or alfentanil. The propofol Cp_{50} for skin incision when combined with benzodiazepine premedication (lorazepam, 1 to 2 mg) and 66% nitrous oxide is 2.5 μg/mL (venous).[91] This concentration is reduced to 1.7 μg/mL when morphine (0.15 mg/kg) rather than lorazepam is used for premedication. The concentration of propofol (when combined with 66% nitrous oxide) required during minor surgical procedures is 1.5 to 4.5 μg/mL, and the concentration for major operations is 2.5 to 6 μg/mL.[92] Awakening usually occurs at concentrations less than 1.6 μg/mL and orientation occurs at concentrations less than 1.2 μg/mL when the propofol concentration is decreasing. Not surprisingly, awakening is postponed in the presence of high blood concentrations of opioids. Optimal propofol blood concentrations have been defined when the drug is combined with several opioids, including remifentanil, alfentanil, sufentanil, and fentanyl, that ensure adequate anesthesia and the most rapid return to consciousness postoperatively (Table 30-2). In the presence of remifentanil, a relatively large-dose opioid anesthetic regimen is recommended, whereas with fentanyl, an accompanying large dose of propofol should be used to ensure rapid return to recovery postoperatively (Fig. 30-4). When equilibration between blood and effect site is allowed, awakening concentrations (2.2 μg/mL) are similar to concentrations associated with loss of verbal command.[93]

Effects on the Respiratory System

Apnea occurs after administration of an induction dose of propofol; the incidence and duration of apnea depend on dose, speed of injection, and concomitant premedication.[94] An induction dose of propofol results in a 25% to 30% incidence of apnea from the respiratory depressant effects of propofol and yet a normal partial pressure of carbon dioxide in the blood ($Paco_2$) at induction in the absence of surgical stimulation. Metabolic depression further prevents the $Paco_2$ to increase. However, the duration of apnea occurring with propofol may be prolonged to more than 30 seconds. The incidence of prolonged apnea (>30 seconds) is increased further by addition of an opiate, either as premedication or just before induction of anesthesia.[92,95] A maintenance infusion of propofol (100 μg/kg/minute) results in a 40% decrease in tidal volume and a 20% increase in respiratory frequency, with

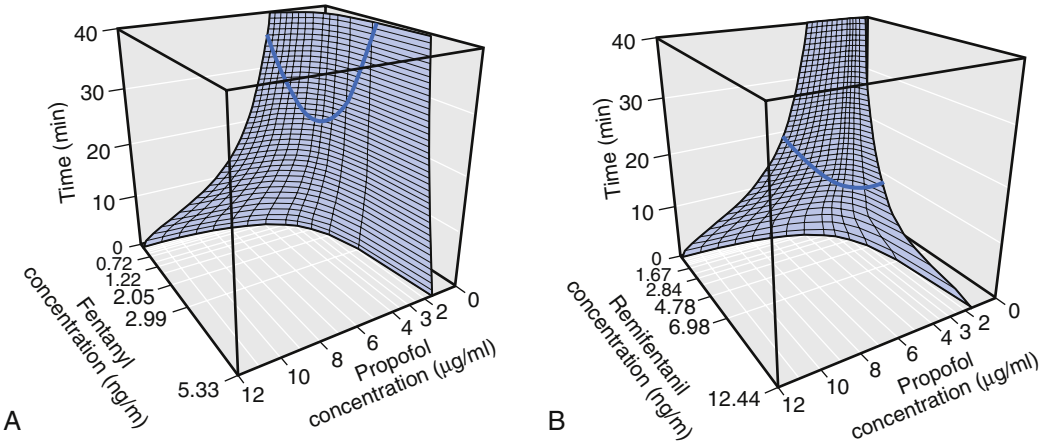

Figure 30-4. Computer simulation of effect-site propofol and fentanyl (**A**) or remifentanil (**B**) concentrations versus time during the first 40 minutes after termination of target-controlled infusions of propofol and fentanyl or remifentanil that had been maintained for 300 minutes at constant target blood or plasma concentration combinations associated with a 50% probability of no response to surgical stimuli. These concentration combinations are represented by the *curved line* on the bottom of the figure in the x-y plane. The decrease in concentrations following the intraoperative propofol-fentanyl and propofol-remifentanil combinations is represented by the curves running upward from the x-y plane. The *curved lines* parallel to the x-y plane represent consecutive 1-minute time intervals. The *bold blue curves* within the two figures represent the propofol-fentanyl-time and propofol-remifentanil-time relationships at which consciousness was regained in 50% of the patients. *(From Vuyk J, Mertens MJ, Olofsen E, et al: Propofol anesthesia and rational opioid selection: determination of optimal EC_{50}-EC_{95} propofol-opioid concentrations that assure adequate anesthesia and a rapid return of consciousness,* Anesthesiology *87:1549-1562, 1997.)*

an unpredictable change in minute ventilation. Doubling the infusion rate from 100 to 200 μg/kg/minute causes a further moderate decrease in tidal volume but no change in respiratory frequency.[96]

As with other hypnotic drugs, spontaneous ventilation is the result of the respiratory depressant effects of the hypnotic agents and the decrease in carbon dioxide production resulting from the metabolic depression versus the stimulatory effects of the increasing $Paco_2$ resulting from apnea and the level of nociception. Propofol (50 to 120 μg/kg/minute) also depresses the ventilatory response to hypoxia, presumably by a direct action on carotid body chemoreceptors.[97] Propofol induces bronchodilation in patients with chronic obstructive pulmonary disease. Propofol attenuates vagal (at low concentrations) and methacholine-induced (at high concentrations) bronchoconstriction, and it seems to have a direct action on muscarinic receptors. Propofol inhibits the receptor-coupled signal transduction pathway through inositol phosphate generation and inhibition of calcium mobilization. The preservative used with propofol is important because of its bronchodilator activity. Propofol with metabisulfite (compared with propofol without metabisulfite) does not inhibit vagal or methacholine-induced bronchoconstriction. Propofol potentiates hypoxic pulmonary vasoconstriction, an effect caused by inhibition of potassium–adenosine triphosphate (ATP)–mediated pulmonary vasodilatation. Propofol has an impact on the pulmonary pathophysiology of adult respiratory distress syndrome. In an animal model of septic endotoxemia, propofol (10 mg/kg/hour) significantly reduced free radical–mediated and cyclooxygenase-catalyzed lipid peroxidation. In addition, the partial pressure of arterial oxygen (Pao_2) and hemodynamics were maintained closer to baseline. These benefits of propofol have not yet been confirmed in humans.

Effects on the Cardiovascular System

The cardiovascular effects of propofol for induction and maintenance of anesthesia have been evaluated (Table 30-3).[98] The most prominent effect of propofol is a decrease in arterial blood pressure during induction of anesthesia. Independent of the presence of cardiovascular disease, an induction dose of 2 to 2.5 mg/kg produces a 25% to 40% reduction of systolic blood pressure. Similar changes are seen in mean and diastolic blood pressure. The decrease in arterial blood pressure is associated with a decrease in cardiac output and cardiac index (± 15%), stroke volume index (± 20%), and systemic vascular resistance (15% to 25%). Left ventricular stroke work index also is decreased (± 30%). When right ventricular function is considered specifically, propofol produces a marked reduction in the slope of the right ventricular end-systolic pressure-volume relationship.

In patients with valvular heart disease, pulmonary artery and pulmonary capillary wedge pressure also are reduced, a finding that implies the resultant decrease in pressure reflects a decrease in preload and afterload. Although the decrease in systemic pressure after an induction dose of propofol is caused by vasodilation, the direct myocardial depressant effects of propofol are more controversial. The decrease in cardiac output after propofol administration may result from its action on sympathetic drive to the heart. The hemodynamic response to propofol lags significantly behind that of the hypnotic effect. The effect-site equilibration half-life of propofol is on the order of 2 to 3 minutes for the hypnotic effect and approximately 7 minutes for the hemodynamic depressant effect.[36] This implies that hemodynamic depression increases the few minutes after a patient has lost consciousness from an induction of anesthesia.

High concentrations of propofol abolish the inotropic effect of α- but not β-adrenoreceptor stimulation, and

enhance the lusitropic (relaxation) effect of β-adrenoreceptor stimulation. Clinically, the myocardial depressant effect and the vasodilation depend on the dose and on the plasma concentration.[99] Propofol is a vasodilator because it reduces sympathetic activity. The mechanism of this activity is a combination of a direct effect on intracellular smooth muscle calcium mobilization, inhibition of prostacyclin synthesis in endothelial cells, reduction in angiotensin II–elicited calcium entry,[100,101] activation of potassium ATP channels, and stimulation of nitric oxide. The stimulation of nitric oxide may be modulated by any intralipid rather than propofol itself.

Heart rate does not change significantly after an induction dose of propofol. Propofol either may reset or may inhibit the baroreflex, thus reducing the tachycardic response to hypotension. Propofol also decreases cardiac parasympathetic tone in a dose-dependent manner. The drug has a minimal direct effect on sinoatrial node function or on normal atrioventricular and accessory pathway conduction. Propofol attenuates the heart rate response to atropine in a dose-dependent manner. It also suppresses atrial (supraventricular) tachycardias and probably should be avoided during electrophysiologic studies. The peak plasma concentrations obtained after a bolus dose are substantially higher than the concentrations seen with a continuous infusion and may reach concentrations up to 80 to 100 μg/mL. Because the vasodilatory and myocardial depressant effects are concentration dependent, the decrease in arterial blood pressure from propofol during the infusion phase (maintenance of anesthesia) is much less than that seen after induction of anesthesia by an IV bolus administration of propofol. An infusion of propofol reduces myocardial blood flow and oxygen consumption. Thus, global myocardial oxygen supply-to-demand ratio is likely preserved.

The cardioprotective effect of propofol versus volatile anesthetics in patients who undergo cardiac surgical procedures on or off cardiopulmonary bypass is less debatable. In two large studies comparing propofol with sevoflurane in patients undergoing cardiac surgical procedures, postoperative troponin levels were lower and hemodynamic function was better in patients receiving sevoflurane. A study comparing desflurane with propofol in patients undergoing off-pump coronary artery bypass showed similar results. In contrast, administration of a large dose of propofol (120 μg/kg/minute) or a small dose of propofol (60 μg/kg/minute) during cardiopulmonary bypass, or titrating isoflurane throughout the operation, showed improved troponin levels and better hemodynamic function in the large-dose propofol group compared with the isoflurane or small-dose propofol group. This study suggests that cardioprotection with propofol is dose dependent.[102] Finally, combinations of propofol with inhaled anesthetics may offer an optimal preconditioning and postconditioning strategy in patients scheduled for coronary bypass surgery. Isoflurane preconditioning, when combined with propofol postconditioning, acts synergistically in attenuating postischemic myocardial reperfusion injury as determined by surrogate markers of myocardial injury and function.[103] Heart rate changes are variable when anesthesia is maintained with propofol. The extent of hypotension, the ability for the patient to compensate, and the use of any other concomitant drugs are likely the most important factors in determining what happens to the heart rate after propofol administration.

Other Effects

Propofol, similar to thiopental, does not enhance neuromuscular blockade produced by neuromuscular blocking drugs. Propofol produces no effect on the evoked electromyogram or twitch tension; however, good or acceptable tracheal intubating conditions after propofol alone have been reported. Propofol does not trigger malignant hyperthermia and is an appropriate choice in patients with this condition.[104-106] After a single dose or a prolonged infusion, propofol does not affect corticosteroid synthesis or alter the normal response to adrenocorticotropic hormone stimulation. Propofol in the emulsion formulation does not alter hepatic, hematologic, or fibrinolytic function. Lipid emulsion itself reduces in vitro platelet aggregation, however. Anaphylactoid reactions to the present

formulation of propofol have been reported. In at least some patients, the immune response was entirely caused by propofol and not by the lipid emulsion. Most patients developing the anaphylactoid response to propofol had a previous history of allergic responses. Perhaps propofol should not be used in patients with multiple drug allergies.[107-109] Propofol alone in intralipid does not trigger histamine release. Fospropofol is metabolized to propofol and formate. Formate concentrations do not increase after fospropofol administration. Propofol also possesses significant antiemetic activity with small (subhypnotic) doses (i.e., 10 mg in adults). The median concentration of propofol with an antiemetic effect was 343 ng/mL, which also causes a mild sedative effect.[110] This concentration can be achieved by an initial dose of propofol infusion of 10 to 20 mg followed by 10 μg/kg/minute. Propofol used as a maintenance anesthetic during breast surgical procedures was more effective than 4 mg of ondansetron given as prophylaxis in preventing postoperative nausea and vomiting (PONV) (see also Chapter 97). Propofol as an infusion of 1 mg/kg/hour (17 μg/kg/minute) also has provided excellent antiemetic action after anticancer chemotherapy. At subhypnotic doses, propofol relieves cholestatic pruritus and is likely as effective as naloxone in treating pruritus induced by spinal opiates.

Propofol decreases polymorphonuclear leukocyte chemotaxis, but not adherence phagocytosis and killing. This action contrasts with the effect of thiopental, which inhibits all these chemotactic responses. However, propofol inhibits phagocytosis and killing of *Staphylococcus aureus* and *Escherichia coli*. Life-threatening systemic infections have been associated with the use of propofol.[111] In hospitals where these infections occurred, opened vials and syringes of propofol had positive culture results. The intralipid that acts as the solvent for propofol is an excellent culture medium. Disodium edetate or metabisulfite has been added to the formulation of propofol in an attempt to retard such bacterial growth. Strict aseptic technique still must be observed.

The administration of propofol is associated with the development of pancreatitis,[112] which may be related to hypertriglyceridemia. Patients who developed hypertriglyceridemia tended to be older, had a longer ICU stay, and received propofol for a longer duration. When propofol is used for prolonged sedation or at higher infusion rates (especially in older patients), serum triglyceride concentrations should be routinely monitored.

USES

Induction and Maintenance of Anesthesia

Propofol is suitable for the induction and maintenance of anesthesia (Box 30-1). The IV induction dose is 1 to 2.5 mg/kg. Physiologic characteristics that best determine the appropriate dose to induce anesthesia are age, lean body mass, and central blood volume.[113] Propofol may be titrated on the basis of the BIS value for maintenance of anesthesia to ensure adequacy of anesthesia and prevention of overdosing. Premedication with an opiate or a benzodiazepine, or both, markedly reduces the necessary induction dose.[114-116] The induction dose must be reduced in older patients, and a dose of 1 mg/kg (with premedication) to 1.75 mg/kg (without premedication) is recommended for inducing anesthesia in patients who are older than 60 years old. Furthermore, older and sicker (American Society of Anesthesiologists [ASA] class III to IV) patients develop more profound hypotension, especially when propofol is combined with an opiate (see also Chapter 80). To prevent hypotension in sicker patients or in patients presenting for cardiac surgical procedures, IV fluids should be given as tolerated, and propofol should be titrated to achieve the desired anesthetic state. In general, for both pharmacokinetic and pharmacodynamic reasons older patients (>80 years old) require half the dose of young patients (<20 years)[117] (see also Chapter 80). For induction in children, the ED_{95} (2 to 3 mg/kg) is increased, primarily because of pharmacokinetic differences (see Chapter 93). Children have a smaller central compartment, increased metabolic clearance, and larger volumes of distribution of propofol relative to adult patients.[69] When used for induction of anesthesia in short-lasting procedures, propofol results in a significantly quicker recovery and an earlier return of psychomotor function compared with thiopental or methohexital, regardless of the anesthetic used for maintenance of anesthesia.

Several infusion schemes have been used to achieve adequate plasma concentrations of propofol. After an induction dose, an infusion of 100 to 200 μg/kg/minute is usually needed. The infusion rate is titrated to individual requirements and the surgical stimulus. When combined with propofol, the required infusion rate and concentration of opiates, midazolam, clonidine, or ketamine should be reduced.[20,118] Because opioids alter the concentration of propofol required for adequate anesthesia, the time to awakening and recovery can be influenced by these drug combinations. Also, opioids affect both the pharmacokinetics and the pharmacodynamics of propofol. Alfentanil decreases the elimination clearance of propofol from 2.1 to 1.9 L/minute, the distribution clearance from 2.7 to 2.0 L/minute, and the peripheral volume of distribution from 179 to 141 L. The pharmacokinetic parameters of propofol are affected by cardiac output, heart rate, and plasma alfentanil concentration.[39] Similarly, midazolam reduces propofol's metabolic clearance from 1.94 to 1.61 L/minute, Cl_2 from 2.86 to 1.52 L/minute, and Cl_3 from 0.95 to 0.73 L/minute. Consequently, in the presence

BOX 30-1 ***Uses and Doses of Intravenous Propofol***

Induction of general anesthesia	1-2.5 mg/kg IV, dose reduced with increasing age
Maintenance of general anesthesia	50-150 μg/kg/min IV combined with N_2O or an opiate
Sedation	25-75 μg/kg/min IV
Antiemetic action	10-20 mg IV, can repeat every 5-10 min or start infusion of 10 μg/kg/min

From Reves JG, Glass P, Lubarsky DA, et al: Intravenous anesthetics. In Miller RD, Eriksson LI, Fleischer LA, et al, editors: Miller's anesthesia, *ed 7. Philadelphia, 2010, Churchill Livingstone, pp 719-768.*

IV, Intravenously; *N_2O,* nitrous oxide.

of both midazolam and alfentanil, propofol concentrations become elevated by 20% to 30%.[53] The infusion rate required to achieve the combination with the shortest recovery is propofol, 1 to 1.5 mg/kg followed by 140 μg/kg/minute for 10 minutes followed by 100 μg/kg/minute, and alfentanil, 30 μg/kg followed by an infusion of 0.25 μg/kg/minute, or fentanyl, 3 μg/kg followed by 0.02 μg/kg/minute.

As indicated previously, increasing age is associated with a decrease in propofol infusion requirements, whereas these requirements are larger in children and infants (see Chapter 93). The blood levels of propofol alone for loss of consciousness are 2.5 to 4.5 μg/mL, and the blood concentrations (when combined with nitrous oxide) required for surgery are 2.5 to 8 μg/mL. Similar concentrations are necessary when propofol is combined with an opioid for a total IV technique. The knowledge of these levels and of the pharmacokinetics of propofol has enabled the use of pharmacokinetic model–driven infusion systems to deliver propofol as a continuous infusion for the maintenance of anesthesia. A meta-analysis of recovery data after either propofol for maintenance or the newer volatile anesthetics indicated only minor differences in times to reach recovery goals; however, the incidence of nausea and vomiting remained significantly lower in the patients given propofol for maintenance of anesthesia (see also Chapter 97).

Propofol can be used as an infusion regimen for maintenance of anesthesia during cardiac surgical procedures (see also Chapter 67). With reduced and titrated doses of propofol for induction of anesthesia and titrated infusion rates of 50 to 200 μg/kg/minute combined with an opioid for maintenance, propofol provides intraoperative hemodynamic control and ischemic episodes similar to those with either enflurane combined with an opioid or a primary opioid technique.

Blood propofol concentrations increase in the presence of hemorrhagic shock. Shock affects the pharmacokinetics and pharmacodynamics of propofol. Shock also results in slower intercompartmental clearances and shifts the concentration effect relationship to the left, thereby demonstrating a 2.7-fold decrease in the effect-site concentration required to achieve 50% of the maximal effect in the BIS.[119] These pharmacokinetic changes may be reversed with IV fluid resuscitation. The propofol doses needed to reach a 50% decrease from baseline BIS and for no movement after noxious stimuli are reduced by hemorrhagic shock by 54% and 38%, respectively. Hemorrhagic shock decreases the effect-site concentration that produced 50% of the maximal BIS effect from 11.6 ± 3.8 to 9.1 ± 1.7 μg/mL and that producing a 50% probability of movement from 26.8 ± 1.0 to 20.6 ± 1.0 μg/mL.[120]

Sedation

Propofol has been evaluated for sedation during surgical procedures and for patients receiving mechanical ventilation in the ICU (see also Chapters 101 and 103).[121] As noted earlier, tolerance can occur with propofol. Increased propofol requirement occurs after repeated anesthetic administration in a limited time in individual patients and when propofol is infused for prolonged periods.[74] Infusion rates required for sedation to supplement regional anesthesia in healthy patients are half or less than the rates required for general anesthesia (i.e., 30 to 60 μg/kg/minute). In older patients (>65 years old) and in sicker patients, the necessary infusion rates are markedly reduced up to 50% compared with 20-year-old patients. The infusion should be individually titrated to the desired effect. The pharmacokinetic profile of propofol makes it a suitable choice for long-term (days) sedation. This choice should always be weighed, however, against the hemodynamic side effects, tolerance, and rare occurrences of hypertriglyceridemia (and potential pancreatitis) or propofol infusion syndrome. Maintaining the smallest possible dose required for the desired level of sedation with potential "sedation holidays" should be considered as part of a long-term propofol sedation regimen. In addition, the FDA has specifically recommended against the use of propofol for the prolonged sedation of pediatric patients (see also Chapter 93). The sedation guidelines of the American College of Critical Care Medicine also recommend "that patients receiving propofol for long term sedation should be monitored for unexplained metabolic acidosis or arrhythmias. Drugs other than propofol should be considered for patients with escalating vasopressor or inotrope requirements or cardiac failure during large-dose propofol infusions." The recommended maximal dose of propofol infusion rate is 80 μg/kg/minute (<5 mg/kg/hour).[122] Generally, at propofol infusion rates more rapid than 30 μg/kg/minute, patients are amnesic.

SIDE EFFECTS AND CONTRAINDICATIONS

Induction of anesthesia with propofol is often associated with pain on injection, apnea, hypotension, and, rarely, thrombophlebitis of the vein into which propofol is injected.[123] Pain on injection is reduced by using a large vein, avoiding veins in the dorsum of the hand, and adding lidocaine to the propofol solution or changing the propofol formulation. Multiple other drugs and distraction techniques have been investigated to reduce the pain on injection of propofol. Pretreatment with a small dose of propofol, opiates, nonsteroidal antiinflammatory drugs, ketamine, esmolol or metoprolol, magnesium, a flash of light, a clonidine-ephedrine combination, dexamethasone, and metoclopramide all have been tested with variable efficacy.

Propofol infusion syndrome is a rare but lethal syndrome associated with infusion of propofol at 4 mg/kg/hour or more for 48 hours or longer.[124] Yet, cases have been reported with smaller dosage schemes given for only 3 hours.[125] This syndrome was first described in children but subsequently has been observed in critically ill adults[126,127](see also Chapter 93). The clinical features of propofol infusion syndrome are acute refractory bradycardia leading to asystole in the presence of one or more of the following: metabolic acidosis (base deficit >10 mmol/L), rhabdomyolysis, hyperlipidemia, and enlarged or fatty liver. Other features include cardiomyopathy with acute cardiac failure, skeletal myopathy, hyperkalemia, hepatomegaly, and lipemia. The symptoms and signs are the result of muscle injury and the release of intracellular toxic contents. The major risk factors are poor oxygen delivery, sepsis, serious cerebral injury, and large propofol dosage.

Philadelphia, 2010, Churchill Livingstone, pp 719-768.)*

Predisposing factors are likely genetic disorders impairing fatty acid metabolism, such as medium-chain acyl coenzyme A (MCAD) deficiency and low carbohydrate supply. Because lipemia has been noted, a failure of hepatic lipid regulation, possibly related to poor oxygenation or a lack of glucose, may be the cause. In some cases, increasing lipemia was the first indication of impending propofol infusion syndrome onset; therefore, lipemia is a sign.

BARBITURATES

HISTORY

Barbiturates were discovered in the early twentieth century. The first barbiturate to cause loss of consciousness within one arm–brain circulation time was hexobarbital. After the clinical introduction of thiopental by Waters and Lundy in 1934, thiopental became preferred clinically because of its rapid onset of action and short duration, without the excitatory effects of hexobarbital.[128] Although criticized after many casualties during the attack on Pearl Harbor as "the cause of more fatal casualties among the servicemen at Pearl Harbor than were the enemy bombs," barbiturates continued to be widely used in clinical practice.[129] Many other barbiturate derivatives have been synthesized throughout the past decades, yet none have enjoyed the clinical success and popularity of thiopental.

PHYSICOCHEMICAL CHARACTERISTICS

Chemistry and Formulation

Barbiturates are hypnotically active drugs that are derivatives of barbituric acid (2,4,6-trioxohexahydropyrimidine), a hypnotically inactive pyrimidine nucleus that is formed by the condensation of malonic acid and urea (Fig. 30-5). The two major classes of barbiturates are the oxybarbiturates and thiobarbiturates with either an oxygen at position 2 or a sulfur in position 2, respectively. Through keto-enol tautomerization, the oxygen or sulfur in position 2 becomes a reactive species in the enol form. This process allows for the formation of water-soluble barbiturate salts in alkaline solutions and permits the IV use of barbiturates. Although tautomerization to the enol form allows for the creation of salts, the substitution of the hydrogen attached to the carbon atom in position 5 with aryl or alkyl groups gives the barbiturates their hypnotic activity. Only thiopental and thiamylal, thiobarbiturates, and methohexital, an oxybarbiturate, have been used for induction of anesthesia (Fig. 30-6). The formulation of barbiturates involves preparation as sodium salts (mixed with 6% by weight anhydrous sodium carbonate) and then reconstitution with water, glucose 5%, or normal saline to produce a 2.5% solution of thiopental, a 2% solution of thiamylal, or a 1% solution of methohexital. The thiobarbiturates are stable for 1 week if refrigerated after reconstitution, and methohexital remains available for use for 6 weeks after reconstitution. Barbiturates cannot be reconstituted with lactated Ringer's solution or mixed with other acidic solutions because a decrease in the alkalinity of the solution can result in precipitation of the barbiturates as free acids. Examples of drugs that are not to be coadministered or mixed in solution with the barbiturates are atracurium, vecuronium, rocuronium, suxamethonium, alfentanil, sufentanil, dobutamine, dopamine, S-ketamine, and midazolam. Mixing of thiopental with vecuronium or pancuronium results in the formation of precipitate, which may occlude the IV line during rapid-sequence induction of anesthesia.[130]

Structure-Activity Relationships

As noted earlier, substitutions at the 5, 2, and 1 positions confer different pharmacologic activities to the barbiturate nucleus. Substitutions at position 5 with either aryl or alkyl groups produce hypnotic and sedative effects; substitution at C5 with a phenyl group produces anticonvulsant activity. An increase in length of one or both side chains of an alkyl group at C5 increases hypnotic potency. Barbiturates used in clinical practice have either an oxygen or a sulfur at C2. Substitution of a sulfur at position 2 produces a more rapid onset of action, as with thiopental. The addition of a methyl or ethyl group at position 1 also may produce a more rapid onset of action,

as with methohexital. However, excitatory side effects, including tremor, hypertonus, and involuntary movement, may occur on administration.

PHARMACOKINETICS

Metabolism

The barbiturates (with the exception of phenobarbital) are metabolized hepatically. The metabolites are almost all inactive, water soluble, and excreted in the urine. Barbiturates are biotransformed by four processes: (1) oxidation of the aryl, alkyl, or phenyl moiety at C5; (2) *N*-dealkylation; (3) desulfuration of the thiobarbiturates at C2; and (4) destruction of the barbituric acid ring.[131] Oxidation, the most important pathway, produces polar (charged) alcohols, ketones, phenols, or carboxylic acids. These metabolites are readily excreted in the urine or as glucuronic acid conjugates in the bile. Hydrolytic cleavage of the barbituric acid ring forms a minimal contribution to the total metabolism of barbiturates because the ring is stable in vivo. Drugs that induce oxidative microsomes or long-term administration enhance the metabolism of barbiturates. The hepatic enzyme induction by barbiturates is the reason that they are not recommended for administration to patients with acute intermittent porphyria. Barbiturates may precipitate an attack by stimulating δ-aminolevulinic acid synthetase, the enzyme responsible for the production of porphyrins.[132]

As mentioned earlier, hepatic metabolism accounts for the elimination of all of the barbiturates with the exception of phenobarbital. Renal excretion accounts for 60% to 90% of phenobarbital excretion in an unchanged form. The alkalinization of urine with bicarbonate enhances the renal excretion of phenobarbital. Other barbiturates are excreted unchanged by the kidney only in trivial amounts.

Methohexital is metabolized in the liver by oxidation to an alcohol and *N*-dealkylation. Methohexital exhibits its distribution half-lives, volumes of distribution, and protein binding similar to those of thiopental. A marked difference exists, however, in plasma disappearance and elimination half-lives (4 hours for methohexital and 12 hours for thiopental). The reason for this difference is the threefold more rapid rate of hepatic clearance of methohexital (mean, 7.8 to 12.5 mL/kg/minute).[133] The hepatic extraction ratio of methohexital (clearance to hepatic blood flow) is approximately 0.5, indicating that the liver extracts 50% of the drug presented to it. This ratio differs from the smaller hepatic extraction ratio of thiopental (0.15).

Barbiturate pharmacokinetics has been described in physiologic and compartment models.[134] Both these pharmacokinetic models describe rapid redistribution as the primary mechanism that terminates the action of a single induction dose. Physiologic models of barbiturates describe a rapid mixing of the drug within the central blood volume followed by a quick distribution of the drug to highly perfused, low-volume tissues (i.e., brain), with a slower redistribution of the drug to lean tissue (muscle), which terminates the effect of the initial (induction of anesthesia) dose. In these models, adipose tissue uptake and metabolic clearance (elimination) play only minor roles in the termination of the effects of the induction dose. The reasons are the minimal perfusion ratio of adipose tissue compared with other tissues and the slow rate of removal. Compartment model values for thiopental and methohexital, the most commonly used barbiturates for induction of anesthesia, are given in Table 30-1. The compartment model explains the delay of recovery when a continuous infusion of a barbiturate is used. This model describes how the termination of effect becomes increasingly dependent on the slower process of uptake into and redistribution from adipose tissue and elimination clearance through hepatic metabolism. After prolonged infusions, the pharmacokinetics of barbiturate metabolism is best approximated by nonlinear Michaelis-Menten metabolism. In usual doses (4 to 5 mg/kg), thiopental exhibits first-order kinetics (i.e., a constant *fraction* of drug is cleared from the body per unit time); however, at very high doses of thiopental (300 to 600 mg/kg) with receptor saturation, zero-order kinetics occurs (i.e., a constant *amount* of drug is cleared per unit time). The volume of distribution is slightly larger in female patients, thus causing a longer elimination half-life.[135] Pregnancy also increases the volume of distribution of thiopental and prolongs the elimination half-life.[136] Even at advanced stages of liver cirrhosis, the clearance of thiopental is not altered. Because of its lipophilicity, relatively large volume of distribution, and low rate of hepatic clearance, thiopental can accumulate in tissues, especially if it is given in large doses over a prolonged period. The plasma drug level increases when repeated doses of drug are given. Although not used in routine clinical practice, appropriately designed infusion schemes ensure constant blood levels that maintain the desired hypnotic effect.

PHARMACOLOGY

Mechanism of Action

The mechanisms of action of barbiturates on the CNS are largely unknown, with the exception of their action on the $GABA_A$ receptor.[137,138] Perhaps the NMDARs are involved with the effects of barbiturates.[139-141] The effects of barbiturates on the CNS have been grouped into two categories: (1) enhancement of the synaptic actions of *inhibitory* neurotransmitters, and (2) blockade of the synaptic actions of *excitatory* neurotransmitters.[142] GABA is the principal inhibitory neurotransmitter in the mammalian CNS, and the $GABA_A$ receptor is the only site proven to be involved in barbiturate-induced anesthesia.[138] The $GABA_A$ receptor is a chloride ion channel, composed of at least five subunits, with specific sites of action for GABA, barbiturates, benzodiazepines, and other molecules. Barbiturate binding to the $GABA_A$ receptor enhances and mimics the action of GABA by increasing chloride conductance through the ion channel. This causes hyperpolarization of the cell membrane and increases the threshold of excitability of the postsynaptic neuron. At low concentrations, barbiturates enhance the effects of GABA, by decreasing the rate of dissociation of GABA from its receptor and increasing the duration of GABA-activated chloride ion channel openings. This

enhancement of the action of GABA is likely responsible for the sedative-hypnotic effects of the barbiturates. At larger concentrations, the barbiturates activate the chloride channels directly, without the binding of GABA, and act as agonists. The GABA-mimetic effect at slightly higher concentrations may be responsible for what is termed barbiturate anesthesia.[138]

The second mechanism of action of barbiturates involves the inhibition of the synaptic transmission of excitatory neurotransmitters, such as glutamate and acetylcholine. The actions of the barbiturates to block excitatory CNS transmission are specific for synaptic ion channels. Thiopental, however, may exert GABA-independent effects on the glutaminergic-NMDA system. In two studies of the effects in the rat prefrontal cortex, thiopental decreased extracellular glutamate levels in the CNS and decreased NMDA-gated currents in a concentration-dependent manner.[140,141]

Effects on Cerebral Metabolism

Barbiturates, like other CNS depressants, have potent effects on cerebral metabolism (see also Chapter 70). A dose-related depression of cerebral metabolic oxygen consumption rate ($CMRO_2$) progressively slows the EEG, reduces the rate of ATP consumption, and enhances protection from partial cerebral ischemia. The relationship between depressed metabolism and drug requirement was shown when thiopental was not eliminated (i.e., sustained with an extracorporeal circulation pump).[143] When the EEG became isoelectric, a point at which cerebral metabolic activity is roughly 50% of baseline,[144] no further decreases in $CMRO_2$ occurred. These findings support the hypothesis that metabolism and function of the brain are coupled. Barbiturates reduce the metabolic activity concerned with neuronal signaling and impulse traffic, not the metabolic activity corresponding to basal metabolic function. The only way to suppress baseline metabolic activity related to cellular activity is through hypothermia.[144] The effect of barbiturates on cerebral metabolism is maximized at a 50% depression of cerebral function, thus leaving all metabolic energy for the maintenance of cellular integrity. With the reduction in $CMRO_2$, a parallel reduction in cerebral perfusion occurs, as seen in decreased cerebral blood flow (CBF) and ICP. With reduced $CMRO_2$, cerebral vascular resistance increases, and CBF decreases.[145] The ratio of CBF to $CMRO_2$ remains unchanged. Even though the mean arterial pressure (MAP) decreases, barbiturates do not compromise the overall CPP because the CPP = MAP – ICP. In this relationship, ICP decreases more than MAP after barbiturate administration and thereby preserves CPP.

PHARMACODYNAMICS

Sufficient doses of barbiturates cause loss of consciousness, amnesia, and respiratory and cardiovascular depression, known as general anesthesia. The response to pain and other noxious stimulation during general anesthesia seems to be depressed. Pain studies reveal that barbiturates may decrease the pain threshold. This antianalgesic effect occurs only with low blood levels of barbiturates, which may be achieved with small doses of thiopental for induction of anesthesia or after emergence from thiopental. The amnestic effect of barbiturates is less pronounced than is that produced by benzodiazepines.

Effects on the Central Nervous System

Drugs with high lipid solubility and a low degree of ionization cross the blood-brain barrier rapidly and have a fast onset of action.[138] Most barbiturates exist in a nonionized form. Thiopental and methohexital are more lipid soluble than is pentobarbital, which is clinically reflected by the more rapid onset of action of thiopental and methohexital compared with pentobarbital.[146] Only the nonionized form of a drug can directly traverse the cellular membranes. Thiopental has a dissociation constant (pK_a) of 7.6. Approximately 50% of thiopental is nonionized at physiologic pH, which accounts partly for the rapid accumulation of thiopental in the cerebrospinal fluid (CSF) after IV administration.[147] Methohexital is 75% nonionized at pH 7.4, and this may explain the slightly more rapid effect of methohexital compared with thiopental. As pH decreases, with poor perfusion, barbiturates have a larger fraction of nonionized drug available to cross the blood-brain barrier.[147]

The onset of action in the CNS is affected by protein binding because only unbound drug (free drug) can cross the blood-brain barrier.[148] Barbiturates are highly bound to albumin and other plasma proteins, and the thiobarbiturates are more highly protein bound than are the oxybarbiturates. The degree of protein binding of a drug is influenced by the physiologic pH and disease states that alter the absolute amount of protein. Most barbiturates tend to experience peak protein binding at or near pH 7.5. The final factor governing the rapidity of drug penetration of the blood-brain barrier is the plasma drug concentration, which causes a concentration gradient. The two primary determinants of the plasma concentration are the *dose* administered and the *rate* (speed) of administration. As the dose of thiopental over the same time is increased, an increased percentage of patients will be anesthetized.[149] Concerning absolute dose, 2 mg/kg produced anesthesia in 20% of patients, whereas a dose of 2.4 mg/kg produced anesthesia in 80% of patients. Similarly, the speed of injection influences the effect of thiopental. A smaller amount of drug is required to produce anesthesia when the rate of the administration lasts 5 seconds as opposed to 15 seconds.

Because of the equilibrium between brain concentration and plasma concentration, factors that determine the rate of onset of barbiturate effects also affect their termination. Lipid solubility, degree of ionization, and CSF drug concentration affect the movement of drug from the CSF to plasma. As plasma levels decrease, drug levels in the brain and CSF decrease. The most important factors in the termination of drug effect are those that govern plasma disappearance of the drug. These are generally divided into a rapid redistribution phase and a slow metabolic and second redistribution phase. In a classic pharmacologic study, Brodie and co-workers showed that awakening from thiopental occurred because the plasma concentration rapidly declined.[150] These investigators further showed that the cause of the rapid plasma decay of thiopental was not metabolism of the drug, but was

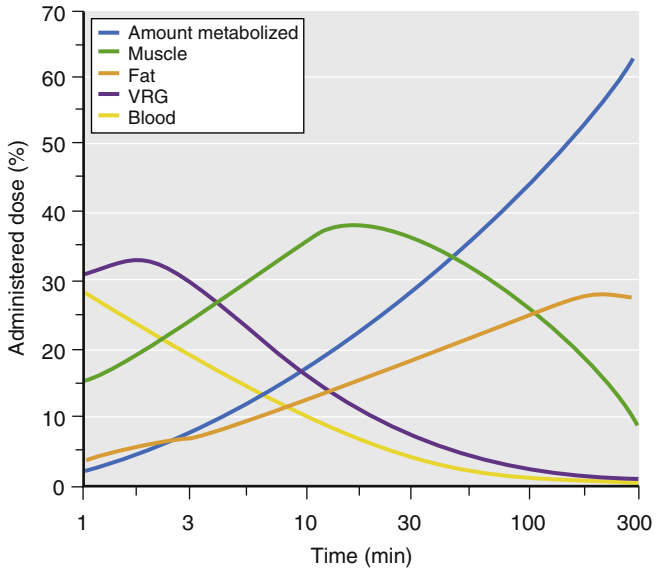

Figure 30-7. After delivery of an intravenous bolus, the percentage of thiopental remaining in blood rapidly decreases as drug moves from blood to body tissues. The time to attainment of peak tissue levels is a direct function of tissue capacity for barbiturate relative to blood flow. A larger capacity or smaller blood flow is related to a longer time to a peak tissue level. Initially, most thiopental is taken up by the vessel-rich group (VRG) of tissues because of their high blood flow. Subsequently, drug is redistributed to muscle and, to a lesser extent, to fat. Throughout this period, small but substantial amounts of thiopental are removed and metabolized by the liver. In contrast to removal by tissues, this removal is cumulative. The rate of metabolism equals the early rate of removal by fat. The sum of this early removal by fat and metabolism is the same as the removal by muscle. *(Redrawn from Saidman LJ: Uptake, distribution and elimination of barbiturates. In Eger EI, editor:* Anesthetic uptake and action. *Baltimore, 1974, Williams & Wilkins.)*

rather a redistribution of the drug to other tissues throughout the body. The relationship of the plasma drug level and drug redistribution with the onset and termination of effect is illustrated in Figure 30-7. Clinically, patients awaken from a single dose of thiopental 5 to 10 minutes after administration, as the drug is redistributed from highly perfused CNS tissues to well-perfused lean tissues. The termination of effect after multiple drug administrations or constant infusion depends on the elimination of the drug from the blood, which becomes increasingly more dependent on first-order metabolism than redistribution and is a function of its context-sensitive decrement time (see Fig. 30-3). Awakening may be delayed in older patients because of increased CNS sensitivity, alterations in metabolism, or decreased central volume of distribution relative to younger adults[151] (see also Chapter 80). The initial volume of distribution is less in older patients than in young patients, a feature that explains a smaller dose requirement for the onset effect. Pediatric patients (<13 years old) seem to have a more rapid rate of total clearance and a shorter rate of plasma thiopental clearance than do adults that theoretically could result in earlier awakening, especially after multiple doses of the drug[152] (see also Chapter 93).

The finding that little difference exists in distribution of thiopental and methohexital may explain the similar wakeup times. However, the rate of total body clearance is more rapid for methohexital. This disparity explains the difference found in the psychomotor skills of patients and the earlier full recovery after methohexital. Despite some residual effects, methohexital is cleared more rapidly than thiopental. This faster clearance explains why methohexital is preferred for use by some clinicians when rapid awakening is desirable, such as in outpatient anesthesia. Prolongation of early and late recovery by the barbiturates is the primary reason that these drugs have been largely replaced by propofol.

Effects on the Respiratory System

Barbiturates produce dose-related central respiratory depression. The evidence for central depression is a correlation between EEG suppression and diminished minute ventilation. Peak respiratory depression (as measured by the slope of carbon dioxide concentration in the blood) and maximum depression of minute ventilation after delivery of thiopental (3.5 mg/kg) occurs 1 to 1.5 minutes after administration. These variables return to predrug levels rapidly, and within 15 minutes the drug effects are barely detectable.[153] Patients with chronic lung disease are slightly more susceptible to the respiratory depression of thiopental. The ventilatory pattern with thiopental induction has been described as "double apnea," which is an initial episode of apnea lasting a few seconds on drug administration, succeeded by a few breaths of reasonably adequate tidal volume, and followed by a more prolonged period of apnea, typically lasting approximately 25 seconds. This apnea occurs in at least 20% of cases. During the induction of anesthesia with thiopental, ventilation must be assisted or controlled to provide adequate respiratory exchange. Like thiopental, methohexital is a central respiratory system depressant.[153] Induction doses (1.5 mg/kg) significantly decrease the slope of the ventilatory response to carbon dioxide, with a maximal reduction at 30 seconds after drug administration.[154] The peak decrease in tidal volume occurs 60 seconds after methohexital administration. All variables return to baseline within 15 minutes. In contrast to the effects on ventilation, patients awaken within approximately 5 minutes after the administration of methohexital (1.5 mg/kg).

Effects on the Cardiovascular System

Cardiovascular depression from barbiturates is a result of central and peripheral (direct vascular and cardiac) effects. The primary cardiovascular effect of a barbiturate during induction of anesthesia is peripheral vasodilation causing a pooling of blood in the venous system. Mechanisms for the decrease in cardiac output include (1) direct negative inotropic action resulting from a decrease of calcium influx into the cells, (2) decreased ventricular filling caused by increased capacitance, and (3) transiently decreased sympathetic outflow from the CNS.[155] The increase in heart rate (10% to 36%) that accompanies thiopental administration probably results from the baroreceptor-mediated sympathetic reflex stimulation of the heart in response to the decrease in output and pressure. The cardiac index, as well as the MAP, is unchanged or reduced. Hemodynamic changes depend on infusion rate of thiopental. In the dose ranges hitherto studied,

no relationship between plasma thiopental level and hemodynamic effect has been found. Little difference is noted in the responses after thiopental and methohexital administration in patients with heart disease. The increase in heart rate (11% to 36%) encountered in patients with coronary artery disease who are anesthetized with thiopental (1 to 4 mg/kg) is potentially deleterious because of the obligatory increase in myocardial oxygen consumption that accompanies the increased heart rate.

In a more recent study in dogs, thiopental prolonged the QT interval, flattened T waves, and increased QT dispersion during and after induction.[151] Thiopental may not be the most appropriate choice for patients with a susceptibility to ventricular dysrhythmias or a prolonged QT interval, such as acidotic patients or patients with conditions that prolong the QT interval, such as long-term dialysis or advanced cirrhosis. Patients who have normal coronary arteries have no difficulty in maintaining adequate coronary blood flow to meet the increased myocardial oxygen consumption.[156] Thiopental should be avoided in hypovolemic patients because of the significant reduction in cardiac output (69%) and the significant decrease in arterial blood pressure.[157] Patients without adequate compensatory mechanisms may have serious hemodynamic depression with thiopental induction of anesthesia.

Other Effects

The side effects of injecting barbiturates include a garlic or onion taste (40% of patients), allergic reactions, local tissue irritation, and rarely, tissue necrosis. A transient urticarial rash may develop on the head, neck, and trunk. More severe reactions, such as facial edema, hives, bronchospasm, and anaphylaxis, can occur. Treatment of anaphylaxis is symptomatic. Thiopental and thiamylal produce fewer excitatory symptoms with induction than does methohexital, which produces cough, hiccup, tremors, and twitching approximately five times more often. Tissue irritation and local complications may occur more frequently with the use of thiopental and thiamylal than with methohexital.

The consequences of accidental arterial injection may be severe. The degree of injury is related to the concentration of the drug. Treatment consists of (1) dilution of the drug by the administration of saline into the artery, (2) heparinization to prevent thrombosis, and (3) brachial plexus block. Overall, the proper IV administration of thiopental is remarkably free of local toxicity.

Phenobarbital is used experimentally as an inducer of the cytochrome P450 (CYP) system in rodents, in particular of the CYP2B enzymes. In human hepatocyte culture, phenobarbital acts as an inducer of the CYP2B6, CYP2C9, CYP2C19, and CYP3A4 enzymes through the constitutive androstane receptor (CAR).[158] This phenomenon may cause changes in the metabolism of drugs that are administered concomitantly.[159] Conversely, the metabolism of thiopental can be influenced by concomitant drugs such as selective serotonin reuptake inhibitors (SSRIs). These drugs are used frequently by patients who are treated by electroconvulsive therapy and in whom induction of anesthesia with thiopental or thiamylal is performed.[160]

USES

Induction and Maintenance of Anesthesia

Barbiturates are used clinically for induction and maintenance of anesthesia and premedication. Methohexital is the drug of choice for providing anesthesia during electroconvulsive therapy.[161] Other barbiturates used in this field are thiopental and thiamylal. Less frequently, barbiturates are used to provide cerebral protection in patients at risk of developing incomplete ischemia. The three barbiturates that are used most commonly for IV anesthesia induction and maintenance are thiopental, thiamylal, and methohexital. Thiopental is an excellent drug to use for induction of anesthesia. The prompt onset (15 to 30 seconds) of action and smooth induction are benefits of this drug. Rapid emergence, particularly after single use for induction, also is a reason for the widespread use of thiopental in this setting. Thiopental can be used to maintain general anesthesia because repeated doses reliably sustain unconsciousness and contribute to amnesia, but it should not be the drug of first choice as the hypnotic component in balanced anesthesia.

Methohexital is the only IV barbiturate used for induction of anesthesia that can compete with thiopental. With a dose of 1 to 2 mg/kg, induction and emergence from anesthesia are rapid. Methohexital also may be used as a hypnotic component to maintain anesthesia. Like thiopental, it is not an analgesic. Additional opioids or volatile anesthetics are required to provide a balanced technique satisfactory for general anesthesia during surgical procedures. Because methohexital is cleared more rapidly than thiopental, it may be preferred to thiopental for the maintenance of anesthesia, given that accumulation and saturation of peripheral sites take longer. For brief infusion (<60 minutes), recovery from a methohexital infusion titrated to maintain hypnosis (50 to 150 μg/kg/minute) is similar to that provided by propofol. The upper limits of safe infusion doses probably have yet to be defined, but seizures have occurred in neurosurgical patients after large doses of methohexital (24 mg/kg).[155] Methohexital may be given rectally and is absorbed rapidly, and it can be used for premedication in pediatric patients. The dose recommended for this use is 25 mg/kg by rectal instillation (10% solution through a 14-French catheter, 7 cm into rectum).[162] With this method of administration, sleep onset is rapid: mean peak plasma levels occur within 14 minutes.

DOSING

Dosing regimens for the two most commonly used barbiturates are listed in Table 30-4. The usual doses of thiopental (3 to 4 mg/kg) and thiamylal (3 to 4 mg/kg) are approximately twice the dose of methohexital (1 to 2 mg/kg). In dose-response studies, the ED_{50} for thiopental ranged from 2.2 to 2.7 mg/kg, and the ED_{50} for methohexital was 1.1 mg/kg.[148] Less interpatient variability is seen in the dose response to barbiturates than to benzodiazepines when used for anesthesia induction, but significant variability remains in the dose of thiopental required to induce anesthesia.[149] Interpatient dose variability is related to the presence of hemorrhagic shock, cardiac output, lean body mass, obesity, gender, and age (see

also Chapters 71 and 80). Hemorrhagic shock, lean body mass, age, and obesity explain the variability of patients' responses resulting from a decrease in the central volume of distribution. Finally, patients who have severe anemia, burns, malnutrition, widespread malignant disease, uremia, ulcerative colitis, or intestinal obstruction also require smaller induction doses of barbiturates.

CONTRAINDICATIONS

The following conditions should be considered contraindications to the use of IV barbiturates:

1. When the patient has respiratory obstruction or an inadequate airway, thiopental may worsen respiratory depression.
2. Severe cardiovascular instability or shock contraindicates barbiturate use.
3. Status asthmaticus is a condition in which airway control and ventilation may be worsened by thiopental.
4. Porphyria may be precipitated or acute attacks may be accentuated by the administration of thiopental.
5. Without proper equipment (IV instrumentation) and airway equipment (means of artificial ventilation), thiopental should not be administered.

TABLE 30-4 RECOMMENDED DOSES OF BARBITURATES FOR ANESTHESIA INDUCTION AND MAINTENANCE

Drug	Induction Dose (mg/kg)*†	Onset (sec)	Intravenous Maintenance Infusion
Thiopental	3-4	10-30	50-100 mg every 10-12 min
Methohexital	1-1.5	10-30	20-40 mg every 4-7 min

From Reves JG, Glass P, Lubarsky DA, et al: Intravenous anesthetics. In Miller RD, Eriksson LI, Fleischer LA, et al, editors: Miller's anesthesia, *ed 7. Philadelphia, 2010, Churchill Livingstone, pp 719-768.*

*Adult and pediatric intravenous doses are roughly the same in milligrams per kilogram.

†Methohexital can be given rectally in pediatric patients as a 20 to 25 mg/kg/dose.

BENZODIAZEPINES

The benzodiazepines comprise a category of drugs widely used in anesthesia as anxiolytics, sedatives, and hypnotics. They exert their action through $GABA_A$ receptors, which are the key targets that mediate most of the clinically important effects of IV anesthetics.[163] In the clinical practice of daily anesthesia, midazolam is often used immediately before induction of anesthesia. The other agonists, diazepam, lorazepam, and temazepam and the antagonist flumazenil are sometimes used. Remimazolam, an ultrashort-acting $GABA_A$ receptor agonist, may be a useful benzodiazepine in future anesthetic practice.

Benzodiazepines were discovered in 1954 by Sternbach, and in 1959 chlordiazepoxide (Librium) was the first benzodiazepine patented. Diazepam was synthesized in 1963 in a search for a better compound and was used by the IV route to induce anesthesia in 1965.[164] Oxazepam (Serax), a metabolite of diazepam, was synthesized in 1961 by Bell. Lorazepam (Ativan), a 2′chloro-substitution product of oxazepam, was synthesized in 1971 in an attempt to produce a more potent benzodiazepine. The next major achievement was Fryer and Walser's synthesis in 1976 of midazolam (Versed, Dormicum), the first clinically used water-soluble benzodiazepine, produced primarily for use in anesthesia.[165]

PHYSICOCHEMICAL CHARACTERISTICS

Four benzodiazepine receptor agonists are commonly used in anesthesia: midazolam, diazepam, lorazepam, and temazepam (Fig. 30-8). The physicochemical characteristics of the benzodiazepines used in anesthesia are

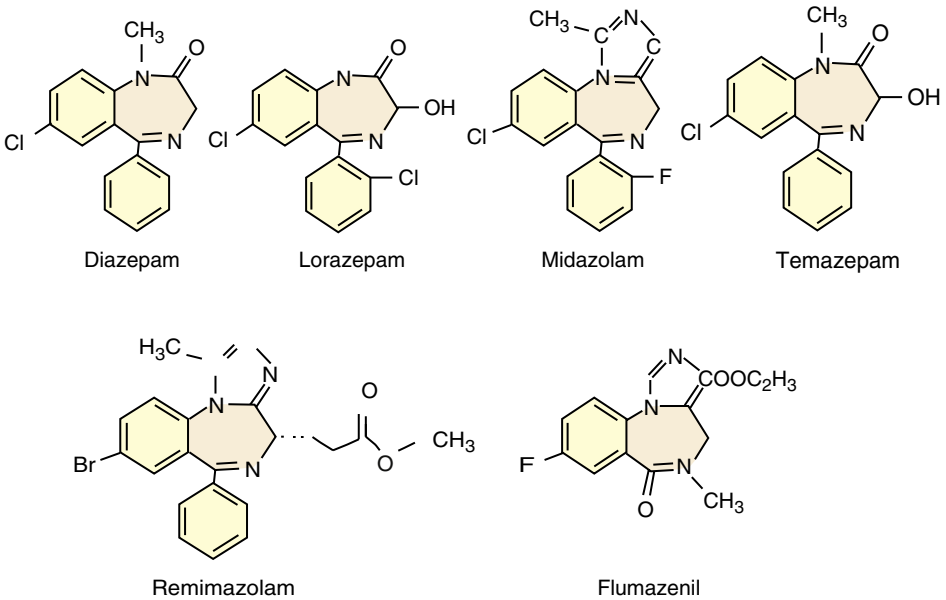

Figure 30-8. The structures of five benzodiazepines.

listed in Table 30-5. These six molecules are relatively small and are lipid soluble at physiologic pH.

Of the clinically used benzodiazepines, midazolam is the most lipid soluble in vivo,[166] but because of its pH-dependent solubility, it is water soluble when formulated in a buffered acidic medium (pH 3.5). The imidazole ring of midazolam accounts for its stability in solution and its lipophilicity as a result of rapid closing of the imidazole ring at physiologic pH. The high lipophilicity of the compounds is the basis for the rapid CNS effect and relatively large volumes of distribution.

PHARMACOKINETICS

The four benzodiazepines used in anesthesia are classified as a short-acting agent (midazolam), intermediate-acting agents (lorazepam, temazepam), and a long-acting agent (diazepam), according to their metabolism and plasma clearance (Table 30-6). The plasma disappearance curves of all benzodiazepines can be best described by a two- or three-compartment model.

Protein binding and volumes of distribution are not much different among these four benzodiazepines, but clearance is significantly different. Factors that may influence the pharmacokinetics of benzodiazepines are age, gender, race, enzyme induction, and hepatic and renal disease. In addition, the pharmacokinetics of the benzodiazepines is affected by obesity (see also Chapter 71). The volume of distribution is increased because drug diffuses from the plasma into the adipose tissue. Although clearance is not altered, elimination half-lives are prolonged by the increased volume of distribution and the delayed return of the drug to the plasma in obese patients.[167] Generally, sensitivity to benzodiazepines in some patient groups, such as older patients, is greater despite relatively modest pharmacokinetic changes; factors other than pharmacokinetics must be considered when these drugs are used.

Midazolam

After oral ingestion, midazolam is absorbed completely, and the peak plasma concentration is achieved in 30 to 80 minutes.[168] The bioavailability of less than 50% results from significant first-pass metabolism in the intestinal wall and the liver.[168,169] After IV administration, midazolam is rapidly distributed, with a distribution half-life of 6 to 15 minutes. [169] The plasma protein binding is high: 94% to 98%.

The hepatic extraction ratio is low, ranging from 0.30 to 0.44, but it is higher than the unbound free fraction of midazolam in plasma.[168] Thus, protein binding is not a restrictive factor in drug extraction by the liver. With this intermediate hepatic extraction ratio, the metabolic clearance of midazolam may be susceptible both to changes in enzyme activity and to changes in hepatic blood flow.

The elimination half-life ranges from 1.7 to 3.5 hours.[169,170] Plasma clearance ranges from 5.8 to 9.0 mL/kg/minute and is higher compared with that of the other benzodiazepines. This is related to the fused imidazole ring, which is rapidly oxidized in vivo, much more rapidly than the methylene group of the diazepine ring of other benzodiazepines.[171]

The pharmacokinetics of midazolam is affected by obesity, age (see also Chapters 71 and 80), and hepatic cirrhosis. Because of its high lipophilicity (at physiologic pH), midazolam distributes preferably to adipose tissue,

TABLE 30-5 PHYSICOCHEMICAL CHARACTERISTICS OF BENZODIAZEPINES

	Molecular Weight (Da)	pK_a	Water Solubility* (g/L)	Lipid Solubility (Log P)
Diazepam	284.7	3.4	0.051	2.801
Lorazepam	321.2	1.3	0.12	2.382
Temazepam	300.7	1.6, 11.7	0.28	2.188
Midazolam	325.8 (hydrochloride 362.2)	6.0	0.004 (2.0, pH 1)	3.798
Remimazolam	439.3 (besylate 597.5)	5.3	0.008 (7.5, pH 1)	3.724

with a resulting prolonged elimination half-life in obese patients.[167] Habitual alcohol consumption increases the metabolism of midazolam.[171a] While liver cirrhosis reduces plasma clearance of midazolam because of decreased metabolism.[172]

Midazolam is metabolized by CYP3A4 and CYP3A5 to its main metabolite 1-hydroxymidazolam and minor metabolite 4-hydroxymidazolam and 1,4-hydroxy midazolam.[173,174] These are subsequently conjugated to glucuronides and renally excreted. 1-Hydroxymidazolam possesses similar sedative activities compared to the parent compound. The metabolites are cleared more rapidly than midazolam, thus making them of little concern in patients with normal hepatic and renal function. In patients with renal impairment, however, the main metabolite and its conjugated metabolite can cause profound sedation.[175]

Diazepam

After oral ingestion, the bioavailability is approximately 94%.[176] Time to peak plasma concentrations after oral ingestion is approximately 60 minutes.[177] Diazepam is extensively bound to plasma proteins, and the volume of distribution ranges from 0.7 to 4.7 L/kg. The plasma clearance of diazepam ranges from 0.2 to 0.5 mL/kg/minute.[178]

The pharmacokinetics of diazepam is affected by obesity and liver dysfunction and particularly by age. Increasing age reduces the clearance of diazepam significantly.[179]

Metabolism occurs in the liver and is mediated mainly by CYP2C19 and CYP3A4. This accounts for 80% of the biotransformation of diazepam.[180-182] One of the main metabolites is *N*-desmethyldiazepam; it has pharmacodynamic characteristics similar to those of diazepam, but it has a much slower elimination half-life extending to 200 hours. *N*-desmethyldiazepam is further metabolized to oxazepam, which is also pharmacologically active; the metabolites add to and prolong the drug's effect.

Temazepam, another main metabolite of diazepam, is mainly conjugated to temazepam glucuronide, and a much smaller part is demethylated to oxazepam and thereafter conjugated to oxazepam glucuronide.[183]

Lorazepam

The oral bioavailability of lorazepam is high, nearly 90%. Peak plasma concentrations are reached approximately 2 hours after oral ingestion, and the mean elimination half-life is 15 hours, with a range of 8 to 25 hours.[184] Lorazepam has a large volume of distribution from 0.8 to 1.3 L/kg,[185] and it is highly bound to plasma proteins (>90%).

Clearance of lorazepam is 0.8 to 1.8 mL/kg/minute. Lorazepam is conjugated in the liver to an inactive glucuronide. This metabolite is water soluble and rapidly excreted in urine. The pharmacokinetics of lorazepam is not altered by age, gender, or renal disease, but clearance is decreased by hepatic dysfunction.[186]

Remimazolam (CNS 7056)

Remimazolam, a newer short-acting $GABA_A$ receptor agonist with high affinity to the GABA receptor, is rapidly degraded in plasma by nonspecific esterases to its carboxylic acid metabolite CNS 7054. The incorporation of a carboxylic ester moiety into the benzodiazepine core of remimazolam renders it susceptible to nonspecific tissue esterases.[187] Preclinical studies in sheep showed a more rapid onset of action, greater depth of sedation, and more rapid recovery than with midazolam. In sheep, remimazolam showed no dose-dependent depth of sedation such as occurs with propofol.[188] In humans, clearance of remimazolam was rapid (overall mean clearance, 70.3 ± 13.9 L/hour), and the volume of distribution was moderately large (steady-state volume of distribution, 34.8 ± 9.4 L). No clear relationship exists between body weight and systemic clearance. Level and duration of sedation are dose dependent in humans.[189]

PHARMACODYNAMICS

Benzodiazepines act selectively at the $GABA_A$ receptor, which mediates fast inhibitory synaptic transmission in the CNS. Benzodiazepines enhance the response to GABA by facilitating the opening of the GABA-activated chloride channels, with resulting hyperpolarization. Series of compounds (e.g., diazepam binding inhibitor and other substances) are candidates as endogenous ligands of the $GABA_A$ receptor. This is an area of ongoing research.[190]

Peripheral binding sites for benzodiazepines (renamed translocator protein (18kDa or TSPO), which are not associated with GABA receptors, exist in many tissues, including peripheral immune cells and the gastrointestinal tract. Although their precise function and pharmacologic significance remain only partly known, TSPO seems related to inflammatory activation.[191]

Effects on the Central Nervous System

All benzodiazepines have hypnotic, sedative, anxiolytic, amnestic, anticonvulsant, and centrally produced muscle-relaxing properties. They may differ to some extent in their potency and efficacy with regard to some of these pharmacodynamic actions (e.g., anticonvulsive action). The neurotransmitter GABA is an inhibitory neurotransmitter that controls the state of a chloride ion channel. Activation of this chloride ion channel results in neuronal hyperpolarization (increased membrane potential in the direction away from the threshold potential) and accounts for the classification of the GABA system as "inhibitory." Benzodiazepines bind to their receptors with high affinity. The binding is stereospecific and saturable; the order of receptor affinity (potency) of three agonists is lorazepam > midazolam > diazepam. Midazolam is approximately 3 to 6 times, and lorazepam 5 to 10 times, as potent as diazepam.[192] As indicated previously, the mechanism of action of benzodiazepines is reasonably well understood.[193,194] The interaction of benzodiazepine ligands with the $GABA_A$ receptor is one of the few examples in which the complex systems of biochemistry, molecular pharmacology, genetic mutations, and clinical behavioral patterns can to some extent be explained.

$GABA_A$ subtypes mediate the different effects (amnestic, anticonvulsant, anxiolytic, and sleep).[194] The $GABA_A$ receptor is a pentameric assembly built from 18 or more subunits (Fig. 30-9). Many different combinations of this pentameric assembly occur in different parts of the brain; linking this diversity to physiologic function and pharmacologic specificity may be possible. The α subunit of the pentameric complex occurs in six isoforms (α_1 to

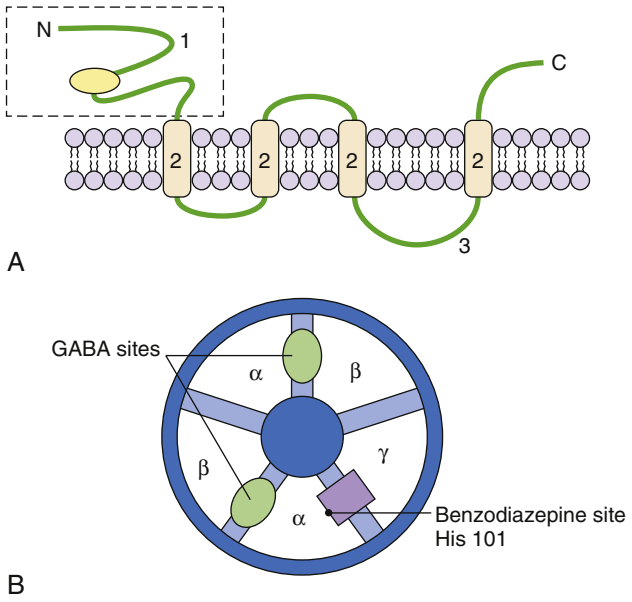

Figure 30-9. Schematics of γ-aminobutyric acid A ($GABA_A$) receptor structure and function. **A,** Topography of a $GABA_A$ receptor subunit partially embedded in the lipid bilayer: *1,* the N-terminal extracellular domain is responsible for transmitter and ligand binding and coupling of the binding sites with the ion channel; this part is also important for the assembly of various receptor subunits into functional receptors; *2,* four transmembrane segments forming the anion channel are responsible for binding of hydrophobic ligands, ion selectivity, and channel binding sites; *3,* an intracellular loop between transmembrane segments 3 and 4 forms the domain for regulatory phosphorylation sites and for the intracellular factors anchoring the receptors in appropriate locations. **B,** Hypothetic binding sites for GABA and benzodiazepine ligands in a pentameric receptor complex. *(From Saari TI, Uusi-Oukari M, Ahonen J, Olkkola KT: Enhancement of GABAergic activity: neuropharmacological effects of benzodiazepines and therapeutic use in anesthesiology,* Pharmacol Rev *63:243-267, 2011.)*

α_6).[186] Sedation, anterograde amnesia, and anticonvulsant properties are mediated by α_1 subunits of the $GABA_A$ receptors,[194] and anxiolysis and muscle relaxation are mediated by the α_2 subunits. The "benzodiazepine receptors" are found in highest densities in the olfactory bulb, cerebral cortex, cerebellum, hippocampus, substantia nigra, and inferior colliculus, whereas lower densities are found in the striatum, lower brainstem, and spinal cord. Spinal cord benzodiazepine receptors can play an important role in analgesia; however, further elucidation of the mechanism of action of this drug class is required.[195] Intrathecal midazolam reduces excitatory GABA-mediated neurotransmission in interneurons and leads to a decrease in the excitability of spinal dorsal horn neurons.[195] A meta-analysis showed that intrathecal midazolam improves perioperative analgesia and reduces nausea and vomiting.[196]

The benzodiazepines reduce the $CMRO_2$ in a dose-related manner. Midazolam and diazepam maintain a relatively normal ratio of CBF to $CMRO_2$.[197] Midazolam, diazepam, and lorazepam all increased the seizure initiation threshold to local anesthetics and decreased the mortality rate in mice exposed to lethal doses of local anesthetics. Midazolam has neuroprotective effects by preventing lipid peroxidation and mitochondrial damage. Indications suggest that the peripheral benzodiazepine receptor is involved in these actions.[198]

Effects on the Respiratory System

Benzodiazepines, similar to most IV anesthetics, produce dose-related central respiratory system depression. The benzodiazepines affect respiration in two different ways. First, they have an effect on the muscular tone leading to an increased risk of upper airway obstruction.[199] Second, they flatten the response of the respiratory curve to carbon dioxide.[200] In addition, sedative doses of midazolam depress the hypoxic ventilatory response in humans.[201]

Benzodiazepines and opioids produce additive or supra-additive (synergistic) respiratory depression, even though they act at different receptors.[202] Old age, debilitating disease, and other respiratory depressant drugs increase the incidence and degree of respiratory depression and apnea by benzodiazepines.

Effects on the Cardiovascular System

The hypothalamic paraventricular nucleus is an important site for autonomic and endocrine homeostasis of the cardiovascular system. The paraventricular nucleus integrates afferent stimuli to regulate blood volume; the rostral ventrolateral medulla is the dominant brain region for tonic regulation of arterial blood pressure.[203] Under normal circumstances, the sympathetic nervous system is tonically inhibited. This inhibition depends on GABAergic signaling and nitric oxide.[204]

When used alone, benzodiazepines have modest hemodynamic effects. The predominant hemodynamic change is a modest decrease in arterial blood pressure resulting from a decrease in systemic vascular resistance. The mechanism by which benzodiazepines maintain relatively stable hemodynamics involves preservation of homeostatic reflex mechanisms, but the baroreflex may be impaired by midazolam and diazepam. The hemodynamic effects of midazolam and diazepam are dose related; however, a plateau plasma drug effect is seen above which little change in arterial blood pressure occurs. The plateau plasma level for midazolam is 100 ng/mL, and that for diazepam is approximately 900 ng/mL. Heart rate, ventricular filling pressures, and cardiac output are maintained after induction of anesthesia with benzodiazepines. In patients with increased left ventricular filling pressures, diazepam and midazolam produce a "nitroglycerin-like" effect by decreasing the filling pressure and increasing cardiac output. Notably, the stresses of endotracheal intubation and surgery are not blocked by midazolam.

DRUG INTERACTIONS

Pharmacokinetic Drug Interactions

The pharmacokinetics of benzodiazepines may be altered by drug interactions. Because cytochrome P450 is often involved in the metabolism of the benzodiazepines, drugs inducing or inhibiting CYP function often cause alterations in the pharmacokinetics of the benzodiazepines.

CYP-mediated drug interactions have extensively been examined using midazolam, which is almost completely metabolized by the CYP system, particularly CYP3A4.

The inhibition of CYP3A by concomitantly administered drugs such as the azole antifungal agents (among many others) results in significant inhibition of the metabolism of midazolam.[205] Orally administered midazolam is especially affected by these inhibitors because of a reduction of first-pass metabolism elimination.[206]

Diazepam is primarily metabolized by CYP2C19 and CYP3A4. Different CYP2C19 alleles have varying activity, which results in ultrarapid, extensive, intermediate, and poor metabolizer genotypes.[207,208] Pharmacokinetics and pharmacodynamics vary among these different metabolizers.[209,210] Strong inhibitors of CYP3A4 have a minor effect on the pharmacokinetics of diazepam.[211,212] Inhibitors of CYP2C19 such as omeprazole, fluvoxamine, and ciprofloxacin consequently increase the plasma half-life of diazepam substantially.[213-215] The clearance of lorazepam is affected by probenecid and valproic acid, both of which decrease the formation and clearance of lorazepam glucuronide.[216,217] Because remimazolam is not metabolized by CYP-dependent mechanisms, the chance of significant drug interactions is less.

Pharmacodynamic Drug Interaction

All benzodiazepines act on the CNS and interact with other drugs targeting the CNS, in particular those causing CNS depression.

In anesthetic practice, opioids are often combined with benzodiazepines, which interact in a synergistic manner.[218] The interaction between midazolam and ketamine is additive,[219] whereas the interaction between the hypnotic effects of thiopental and midazolam and those of propofol and midazolam is synergistic.[20,220]

USES

Premedication

Benzodiazepines are the most commonly applied drugs for premedication (see also Chapter 38). The goals of this application are anxiolysis, sedation, amnesia, vagolysis and sympatholysis and reduction of PONV.[221] The amnestic effects are anterograde; retrograde memory is not affected.

Diazepam, lorazepam, and midazolam are given by the oral or IV route for preoperative sedation. Midazolam is the most frequently used benzodiazepine for premedication in both adults and children.[222] The usual oral dose for adults ranges from 7.5 to 15 mg for midazolam, from 5 to 10 mg for diazepam and from 10 to 20 mg for temazepam.[223] Many factors such as age, ASA physical status, level of anxiety, and type and length of surgical procedure determine the dose. Lorazepam is mostly used when prolonged and intense anxiolysis is pursued, such as in cardiac surgery. Typically, 2 to 4 mg lorazepam is administered orally 2 hours before anesthesia and surgery.[224]

For pediatric patients, midazolam is available in several preparations (including a formulation for intranasal administration in some countries) and is well tolerated. The dose is effective from 0.25 mg/kg and produces sedation and anxiolysis in 10 to 20 minutes (see also Chapter 93).

TABLE 30-7 USES AND DOSES OF INTRAVENOUS BENZODIAZEPINES

	Midazolam	Diazepam	Lorazepam

IM, Intramuscularly; *prn,* as required to keep patient hypnotic and amnesic.

*Incremental doses given until desired degree of sedation is obtained.

Midazolam has minimal effects on respiration and oxygen saturation, even in doses up to 1.0 mg/kg (maximum, 20 mg).

Sedation

Relief of anxiety and lack of recall of unpleasant events during minor surgical and diagnostic procedures are the primary objectives of good sedation. Appropriately used sedation improves patients' satisfaction.[221] Patients are seemingly conscious and coherent during sedation with benzodiazepines, yet they are amnesic for the procedure and events.[225] For this use, drugs should be given by titration; endpoints of titration are adequate sedation and dysarthria (Table 30-7). The onset of action is rapid with midazolam, usually with a peak effect reached within 2 to 3 minutes of administration; time to peak effect is slightly longer with diazepam and is even longer still with lorazepam.

The duration of action of these drugs is dose dependent. Although the onset is more rapid with midazolam than with diazepam after bolus administration, the recovery is similar, probably because both drugs have similar early plasma decay (redistribution) patterns[226] (Fig. 30-10). With lorazepam, sedation and particularly amnesia are slower in onset and are longer lasting than with the other two benzodiazepines.[227] Lorazepam is particularly unpredictable with regard to duration of amnesia, and this feature is undesirable in patients who wish or need to have recall in the immediate postoperative period. The degree of sedation and the reliable amnesia and the preservation of respiratory and hemodynamic function are better with benzodiazepines than with other sedative-hypnotic drugs used for conscious sedation. When midazolam is compared with propofol for sedation during procedures, the two are generally similar, except that emergence or wake-up is more rapid with propofol. Sedation with propofol is safe in the hands of well-trained professionals who are not anesthesia practitioners. However, decisions about which providers should administer propofol remain controversial. Although propofol is a wonderful drug, only individuals who are well trained should administer it, and training in airway management is an absolute requirement.[228,229]

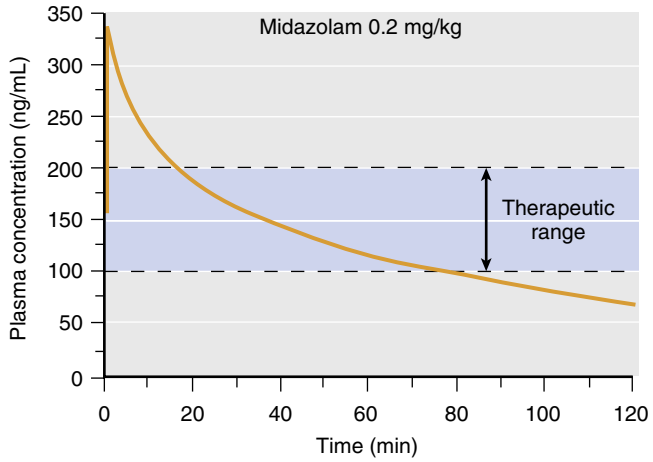

Figure 30-10. Simulated time course of plasma levels of midazolam after an induction dose of 0.2 mg/kg. Plasma levels required for hypnosis and amnesia during surgical procedures are 100 to 200 ng/mL, with awakening usually occurring at levels less than 50 ng/mL. *(From Reves JG, Glass P, Lubarsky DA, et al: Intravenous anesthetics. In Miller RD, Eriksson LI, Fleischer LA, et al, editors:* Miller's anesthesia, *ed 7. Philadelphia, 2010, Churchill Livingstone, pp 719-768.)*

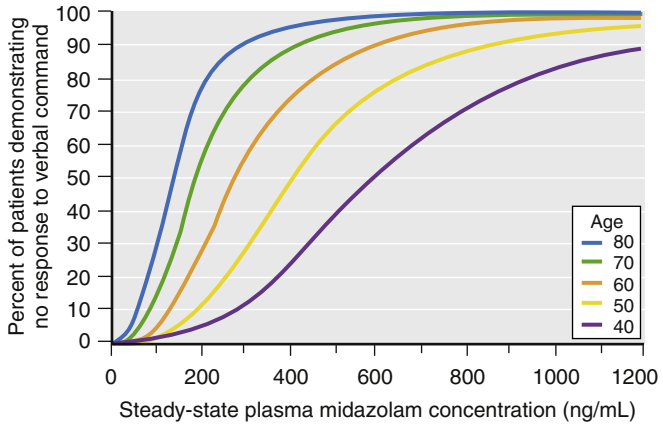

Figure 30-11. Simulated quantal concentration-response curves generated by the parameterized pharmacodynamic model for midazolam. *(Redrawn from Jacobs JR, Reves JG, Marty J, et al: Aging increases pharmacodynamic sensitivity to the hypnotic effects of midazolam,* Anesth Analg *80:143-148, 1995.)*

Reports suggested that remimazolam has a favorable profile as a sedative agent for upper gastrointestinal endoscopy in patients because the time to recovery was shorter and more consistent than that observed after the use of midazolam.[187,189] The use of midazolam for sedation during regional and epidural anesthesia requires vigilance with regard to depth of sedation and respiratory function.[230]

Two studies reported the use of midazolam during cesarean section either for sedation or prevention of nausea and vomiting; the results showed that use of a single IV dose of midazolam was a safe practice, with no detriment in Apgar scores, neurobehavioral scores, continuous oxygen saturation, or the ability of the mother to recall the birth events.[231] Nitsun and associates found that 0.005% of the maternal dose of midazolam is transferred into the breast milk during a 24-hour milk collection.[232] Although verification of these findings is needed, they highlight an important clinical use of midazolam that may be safe for mother and infant (see also Chapter 77).

Sedation for longer periods, such as in the ICU, can also be accomplished with benzodiazepines. The February 1, 2014 issue of the *New England Journal of Medicine* sets the standard for overall sedation in the ICU.[121] Prolonged infusion may result in accumulation of drug and, in the case of midazolam, significant concentration of the active metabolite. Reviews have pointed out both concerns and advantages of benzodiazepine sedation.[233] The main advantages are amnesia and hemodynamic stability, and the disadvantage is the potential lingering sedative effect after termination of the infusion, when compared with propofol. In 2013, the Society of Critical Care Medicine's (SCCM) American College of Critical Care Medicine (ACCM) published a revised version of its pain, agitation, and delirium clinical practice guidelines for adult patients in the ICU. These guidelines suggest that sedation strategies using nonbenzodiazepine sedatives may be preferred over sedation with benzodiazepines, either midazolam or lorazepam, to improve clinical outcome in mechanically ventilated patients in the ICU.[234] To prevent overdosing and prolonged mechanical ventilation, evidenced-based sedation algorithms have evolved. Daily interruption of sedation has not proven to decrease the time to extubation of the trachea or the length of hospital stay.[235]

Induction and Maintenance of Anesthesia

Midazolam is the benzodiazepine of choice for induction of anesthesia. Numerous factors influence the rapidity of action of midazolam and the other benzodiazepines when used for induction of general anesthesia, including dose, speed of injection, degree of premedication, age, ASA physical status, and concurrent anesthetic drugs. The usual induction dose of midazolam is 0.1 to 0.2 mg/kg in premedicated patients, and up to 0.3 mg/kg in unpremedicated patients. The onset of anesthesia is within 30 to 60 seconds. The half-time of equilibrium between the plasma concentration and the EEG effects is approximately 2 to 3 minutes.[236]

Older patients require smaller doses of midazolam than do younger patients[237] (Fig. 30-11) (see also Chapter 80).

When midazolam is combined with other anesthetic drugs (coinduction), often a synergistic interaction occurs, similar to that seen with propofol. This synergy is observed when midazolam is used with opioids or other hypnotics, similar to propofol in combination with opioids[20,52,238] (Fig. 30-12).

Emergence time is related to the dose of midazolam and to the dose of adjuvant anesthetic drugs.

Benzodiazepines lack analgesic properties and must be used with other anesthetic drugs to provide sufficient analgesia; however, as maintenance anesthetic drugs during general anesthesia, benzodiazepines provide hypnosis and amnesia. The amnesic period after an anesthetic dose is approximately 1 to 2 hours.

A plasma level of more than 50 to 100 ng/mL occurs when benzodiazepines are used with adjuvant opioids (e.g., fentanyl) or inhaled anesthetics (e.g., nitrous oxide, volatile anesthetics) with a bolus initial dose of 0.05 to 0.15 mg/kg and a continuous infusion of 0.25 to 1 μg/kg/minute.[239] This plasma level is sufficient to keep the

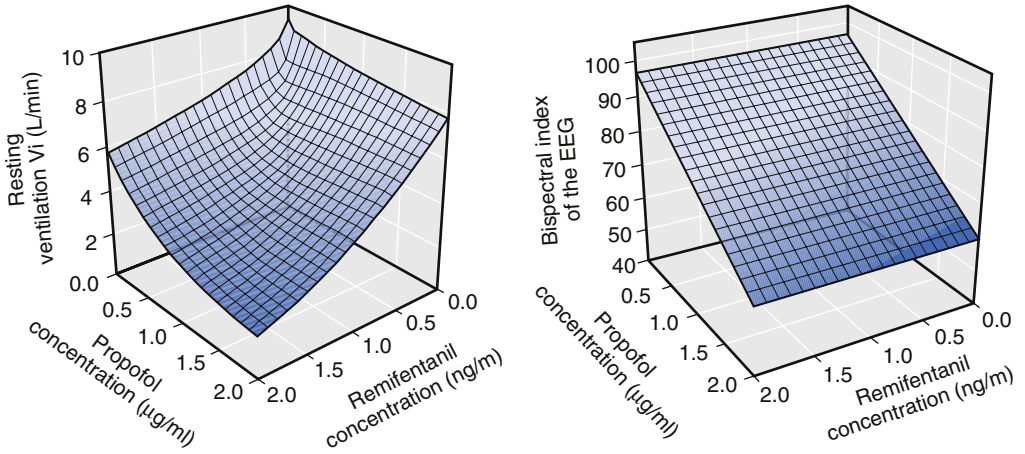

Figure 30-12. Response surface modeling of the interaction of remifentanil and propofol on resting ventilation and the bispectral index (BIS) of the electroencephalogram. Population response surface showing that the propofol-remifentanil interaction on respiration is synergistic and on BIS is inert because remifentanil had no effect on the BIS irrespective of the propofol concentrations. Over this dose range, propofol causes a linear decrease in BIS, with a 25% decrease occurring at 1.4 µg/mL. *(From Nieuwenhuijs DJ, Olofsen E, Romberg RR, et al: Response surface modeling of remifentanil-propofol interaction on cardiorespiratory control and bispectral index,* Anesthesiology *98:312-322, 2003.)*

patient asleep and amnesic but arousable at the end of surgery. Smaller infusion doses may be required in some patients or in combination with opioids. Midazolam, diazepam, and lorazepam accumulate in the blood after repeated bolus administrations or with continuous infusion. If the benzodiazepines do accumulate with repeated administration, prolonged arousal time can be anticipated. This is less of a problem with midazolam than with diazepam and lorazepam because of the shorter context-sensitive half-time and greater clearance of midazolam. Remimazolam may be a good alternative; it is rapidly metabolized and had a faster recovery profile than midazolam in sheep.[188,189]

Nausea and Vomiting Prophylaxis

Numerous studies have highlighted the role that benzodiazepines, and specifically midazolam, may play in the prevention of PONV (see also Chapter 97). Jung and colleagues found that in women undergoing middle ear surgery, IV midazolam, 0.075 mg/kg after induction of anesthesia, reduced the incidence of PONV and the need for rescue antiemetics, with no difference from placebo in pain intensity or drowsiness.[240] Furthermore, the combination of midazolam and dexamethasone proved more effective in preventing PONV than did midazolam alone.[241] The incidence of PONV after minor gynecologic or urologic surgical procedures was the same when comparing IV ondansetron, 4 mg, and IV midazolam, 2 mg.[242]

In children (see also Chapter 93), IV midazolam, 0.05 mg/kg, reduced PONV significantly after pediatric (4 to 12 years old) surgical procedures to treat strabismus compared with placebo or IV dexamethasone, 0.5 mg/kg. No child vomited with midazolam alone or with the midazolam-dexamethasone combination.[243,244]

Finally, in a 2010 three-arm, placebo-controlled, double-blind clinical trial, Fujii and associates compared midazolam 0.050 mg/kg with 0.075 mg/kg for PONV prophylaxis in patients undergoing laparoscopic gynecologic surgical procedures. The two doses of midazolam were not significantly different with regard to PONV (30% versus 27% of patients experienced PONV), and both proved better than placebo (67%).[245]

SIDE EFFECTS AND CONTRAINDICATIONS

Benzodiazepines have limited allergenic effects and do not suppress the adrenal gland. The most significant side effect of midazolam is respiratory depression. The major side effects of lorazepam and diazepam, in addition to respiratory depression, are venous irritation and thrombophlebitis, problems related to aqueous insolubility and requisite solvents.[165] When used as sedatives or for induction and maintenance of anesthesia, benzodiazepines may produce an undesirable degree or prolonged interval of postoperative amnesia, sedation, and, rarely, respiratory depression. These residual effects can be reversed with flumazenil.[246]

FLUMAZENIL

Flumazenil (Anexate, Romazicon) is the first benzodiazepine antagonist approved for clinical use.[247] It is a benzodiazepine receptor ligand with high affinity, great specificity, and by definition minimal intrinsic effect. Flumazenil, similar to the agonists it replaces at the benzodiazepine receptor, interacts with the receptor in a concentration-dependent manner. It is a competitive antagonist at the benzodiazepine receptor and produces antagonism that is reversible and surmountable. In humans, flumazenil has minimal agonist activity, which means that its benzodiazepine receptor agonist effects are very weak, significantly less than those of clinical agonists.[248] Flumazenil, like all competitive antagonists at receptors, does not displace the agonist, but rather occupies the receptor when an agonist dissociates from the receptor. The half-time (or half-life) of a receptor-ligand bond is a few milliseconds to a few seconds, and new ligand-receptor bonds are immediately formed. This

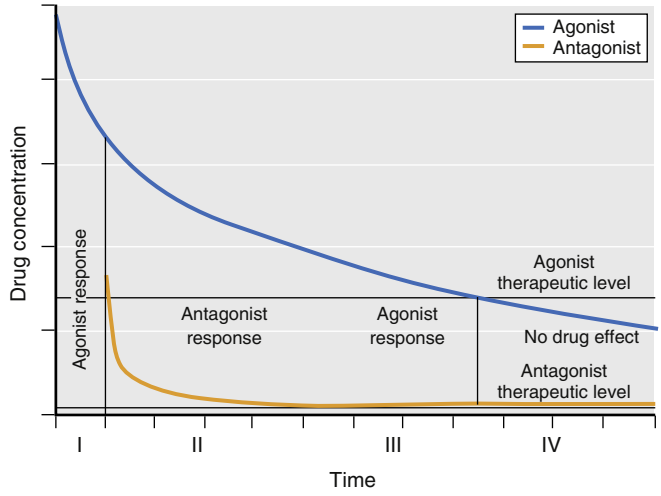

Figure 30-13. Schematic representation of the interaction of a short-acting antagonist with a longer-acting agonist, with resulting resedation. The *blue curve* shows disappearance of agonist from blood, and the *gold curve* shows disappearance of antagonist from plasma. Four conditions are represented: I, agonist response; II, antagonist response (the antagonist reverses the agonist effect); III, agonist response (resedation or resumption of agonist response with disappearance of short-lasting antagonist); and IV, no drug effect, with disappearance of agonist and antagonist (both drugs are below the therapeutic level). *(From Reves JG, Glass P, Lubarsky DA, et al: Intravenous anesthetics. In Miller RD, Eriksson LI, Fleischer LA, et al, editors:* Miller's anesthesia, *ed 7. Philadelphia, 2010, Churchill Livingstone, pp 719-768.)*

dynamic situation accounts for the ability of either an agonist or an antagonist to occupy the receptor readily. The ratio of agonist to total receptors produces the effects of the agonist drug, but the antagonist can alter this ratio, depending on its concentration and dissociation constant. Flumazenil, which is an avid (high-affinity) ligand, replaces a relatively weak agonist, such as diazepam, as long as it is given in sufficient dose. Flumazenil is rapidly metabolically cleared, however, and the proportion of receptors occupied by the agonist then increases again, with the potential for rebound sedation and respiratory suppression (Fig. 30-13). This situation is less likely to occur when flumazenil is used to reverse midazolam, which has a more rapid clearance than that of the other benzodiazepine agonists.

Another important finding is that in the presence of extremely large doses of agonist (e.g., when a mistake in dosing has occurred or if suicide by means of an overdose is attempted), a small dose of flumazenil attenuates the deep CNS depression (loss of consciousness, respiratory depression) by reducing the fractional receptor occupancy by the agonist without decreasing the agonist effects that occur at low fractional receptor occupancy (drowsiness, amnesia).

Conversely, large doses of flumazenil in the presence of small doses of agonist completely reverse all the agonist effects. Flumazenil can precipitate withdrawal symptoms in animals or in humans physically dependent on a benzodiazepine receptor agonist.[249] However, this is not a problem when flumazenil is used to reverse clinical effects of benzodiazepine receptor agonists applied in the practice of anesthesia.

PHYSICOCHEMICAL CHARACTERISTICS

Flumazenil is similar to midazolam and other classic benzodiazepines except for the absence of the phenyl group, which is replaced by a carbonyl group (see Fig. 30-8). It forms a colorless, crystalline powder. It has a dissociation constant of 1.7 and weak but sufficient water solubility to permit its preparation in aqueous solution. Its octanol/aqueous buffer (pH 7.4) partition coefficient is 14, showing moderate lipid solubility at pH 7.4.[250]

PHARMACOKINETICS

Flumazenil, similar to the other benzodiazepines, is completely (99%) metabolized in the liver. It is rapidly cleared from the plasma, and it has three known metabolites: *N*-desmethylflumazenil, *N*-desmethylflumazenil acid, and flumazenil acid.[251] The metabolic end product (i.e., flumazenil acid) has no pharmacologic activity. The major metabolites identified in urine are the deethylated free acid and its glucuronide conjugate. Flumazenil is a short-lived compound. Table 30-5 includes a summary of its pharmacokinetic properties, which are described in various clinical settings. The volume of distribution is high, and extravascular distribution is rapid.

Compared with most benzodiazepine receptor agonists, flumazenil has very rapid clearance and a short elimination half-life.[252] Only remimazolam has more rapid clearance and a shorter half-life. The plasma half-life of flumazenil is approximately 1 hour, the shortest of all benzodiazepines used in anesthetic practice. The rapid blood clearance of flumazenil approaches hepatic blood flow, a finding that indicates that liver clearance partially depends on hepatic blood flow. Compared with other benzodiazepines, flumazenil has a high proportion of unbound drug; plasma protein binding is approximately 40%. The potential exists for the antagonist to be cleared, thus leaving sufficient concentrations of agonist at the receptor site to cause recurrent sedation.[253] To maintain a constant therapeutic blood level over a prolonged time, either repeated administration or a continuous infusion is required. An infusion rate of 30 to 60 μg/minute (0.5 to 1 μg/kg/minute) has been used for this purpose.[254]

PHARMACODYNAMICS

When given in the absence of a benzodiazepine receptor agonist, flumazenil has little discernible CNS effect. When given to healthy subjects and patients in clinically relevant doses, flumazenil has no effect on the EEG or cerebral metabolism. Flumazenil is free of anticonvulsant properties, and it reverses the anticonvulsant properties of benzodiazepines in local anesthetic–induced seizures.[255] When administered to patients who have benzodiazepine-induced CNS depression, flumazenil produces rapid and dependable reversal of unconsciousness, respiratory depression, sedation, amnesia, and psychomotor dysfunction.[256] Flumazenil can be given before, during, or after the agonist to block or reverse the CNS effects of the agonist.

Flumazenil has successfully reversed the effects of benzodiazepines such as midazolam, diazepam, lorazepam,

and flunitrazepam. It has also been used successfully to reverse the effects of chloral hydrate and cannabis intoxication in children (see also Chapter 95),[257,258] carbamazepine and alcohol overdose,[259] and antihistamine overdose.[260] The onset is rapid, with peak effect occurring in 1 to 3 minutes, which coincides with the detection of C-flumazenil in human brain.[256] Flumazenil reverses the agonist by replacing it at the benzodiazepine receptor, and its onset and duration are governed by the law of mass action. When flumazenil is given in the presence of agonists, it has significant respiratory effects because it reverses respiratory depression caused by the agonists (e.g., when given to volunteers made apneic with midazolam). For example, the reversal of midazolam-induced (0.13 mg/kg) respiratory depression with flumazenil (1 mg) lasts 3 to 30 minutes. Other agonists and other doses would have different durations of antagonism of respiratory depression.

Incremental IV doses up to 3 mg in patients with ischemic heart disease had no significant effect on cardiovascular variables.[256,261] Administration of flumazenil to patients given agonists is remarkably free of cardiovascular effects, in contrast to the experience of opioid reversal with naloxone.[262] Although flumazenil does reverse sedation, it does not increase blood concentrations of catecholamines. However, catecholamine levels may increase when arousal is more rapid after flumazenil.[263] The reversal of sedation by midazolam with flumazenil also restores the attenuated cardiac baroreflex function.[264]

In healthy subjects, flumazenil did not alter intraocular pressure but reversed the decrease in intraocular pressure observed after administration of midazolam (Romazicon package insert; www.fda.gov).

USES AND DOSES

Application of a benzodiazepine antagonist includes the diagnostic and therapeutic reversal of benzodiazepine receptor agonists (Box 30-2). For diagnostic use in suspected benzodiazepine overdose, flumazenil may be given in incremental IV doses of 0.2 to 0.5 mg up to 2 mg. More commonly in anesthesia, flumazenil is used to reverse residual sedation in a patient after administration of a benzodiazepine for premedication of a short surgical procedure, conscious sedation, or general anesthesia. Flumazenil reliably reverses the sedation, respiratory depression, and amnesia caused by benzodiazepines. Differential reversal effects on the different agonist actions are noted. Flumazenil tends to reverse the hypnotic and respiratory effects more than the amnestic effects of the benzodiazepine agonist.[265,266]

The dose varies with the particular benzodiazepine being reversed, and the duration of reversal depends on the kinetics of the agonist and of flumazenil. Surveillance is recommended if a long-lasting benzodiazepine is reversed with a single administration of flumazenil because of the relatively short-lived effect. If a patient shows no signs of recurrent sedation within 2 hours after a 1-mg reversal dose of flumazenil, serious recurrent sedation at a later time is unlikely. Flumazenil may be administered by continuous infusion to prevent recurrent sedation by longer-lasting benzodiazepine receptor agonists. The pharmacokinetic profile of flumazenil is unaltered in the presence of benzodiazepine agonists (diazepam, flunitrazepam, lormetazepam, midazolam) and vice versa.

*The dose required to reverse each benzodiazepine (BZD) depends on residual BZD and the particular BZD (i.e., higher doses are required for more potent BZDs) (see text).

†The degree of reversal should be titrated by repeating 0.2-mg increments every 1 to 2 minutes until the desired level of reversal is achieved.

SIDE EFFECTS AND CONTRAINDICATIONS

Flumazenil has been given in large oral and IV doses with remarkably few toxic reactions.[256] It is free of local or tissue irritant properties, and it has no known organ toxicities. Like all benzodiazepines, flumazenil apparently has a high safety margin, probably higher than the safety margins of the agonists, because it does not produce prominent CNS depression. In patients using large doses of benzodiazepines over several weeks or longer, the administration of flumazenil may elicit symptoms of benzodiazepine withdrawal, including seizures.

PHENCYCLIDINES (KETAMINE)

HISTORY

Ketamine (Ketalar) was synthesized in 1962 by Stevens and was first used in humans in 1965 by Corssen and Domino. Ketamine was released for clinical use in 1970 and is still used in various clinical settings. It produces dissociative anesthesia, rather than generalized depression of the CNS, through antagonistic actions at the phencyclidine (PCP) site of the NMDAR. Ketamine is a racemic mixture of the isomers R(−)-ketamine and S(+)-ketamine. It usually does not depress the cardiovascular and respiratory systems, but it does have some of the adverse psychological effects found with the other phencyclidines.[267] The S(+)-isomer (Ketanest) is three to four times more potent as an analgesic with a faster clearance and recovery and with fewer psychomimetic side effects. Nonetheless, S-ketamine produces psychotropic effects, cognitive impairment, memory impairment, and a reduced reaction time, in addition to analgesia. Interest in ketamine has increased because of its effects on hyperalgesia and opiate tolerance, use in chronic pain states, potential neuroprotective effects, increasing popularity of total IV anesthesia, and the availability in some countries of S(+)-ketamine.[268]

PHYSICOCHEMICAL CHARACTERISTICS

Ketamine has a molecular weight of 238 kDa, is partially water soluble, and forms a white crystalline salt with a

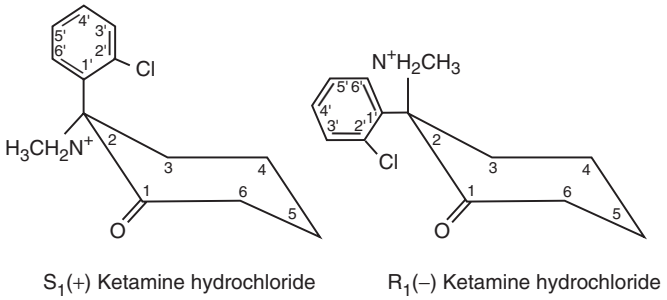

Figure 30-14. Stereoisomers of ketamine as it is formulated. *(From Reves JG, Glass P, Lubarsky DA, et al: Intravenous anesthetics. In Miller RD, Eriksson LI, Fleischer LA, et al, editors:* Miller's anesthesia, *ed 7. Philadelphia, 2010, Churchill Livingstone, pp 719-768.)*

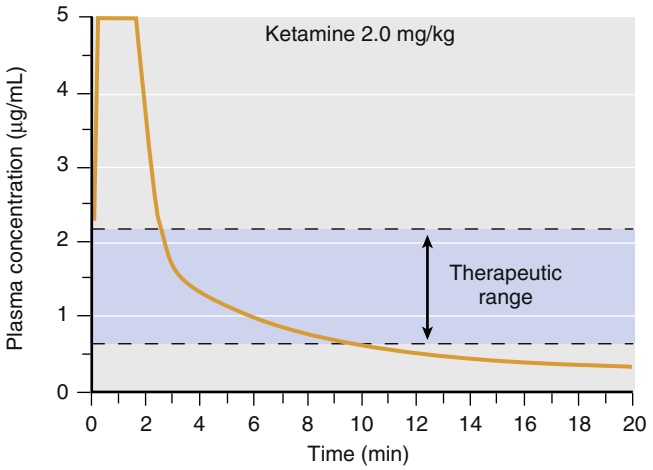

Figure 30-15. Simulated time course of plasma levels of ketamine after an induction dose of 2 mg/kg. Plasma levels required for hypnosis and amnesia during surgical procedures are 0.7 to 2.2 μg/mL, with awakening usually occurring at levels less than 0.5 μg/mL. *(From Reves JG, Glass P, Lubarsky DA, et al: Intravenous anesthetics. In Miller RD, Eriksson LI, Fleischer LA, et al, editors:* Miller's anesthesia, *ed 7. Philadelphia, 2010, Churchill Livingstone, pp 719-768.)*

pK_a of 7.5 (Fig. 30-14). It has a lipid solubility 5 to 10 times that of thiopental. Ketamine is only for 12% bound to proteins. Its bioavailability is 93% after parenteral administration but only 20% after oral use, as a result of its high first-pass metabolism.[269]

PHARMACOKINETICS

Ketamine is metabolized by hepatic microsomal enzymes.[270,271] The major pathway involves *N*-demethylation to form norketamine (metabolite I), which is then hydroxylated to hydroxynorketamine, which is further conjugated to water-soluble glucuronide derivatives and excreted in the urine. The activity of the principal metabolites of ketamine has not been well studied, but norketamine (metabolite I) has significantly less (20% to 30%) activity than the parent compound. More recent modeling of norketamine suggests that it contributes in prolonging the analgesia provided by either a bolus or infusion of ketamine, although this conclusion is being questioned.[270,272,273] In contrast to previous reports, S-norketamine may have a negative contribution to S-ketamine–induced analgesia but shows absence of contribution to the cognitive impairment. This may explain the observation of ketamine-related excitatory phenomena (e.g., hyperalgesia and allodynia) upon the termination of ketamine infusions.[270,272,273]

Ketamine's pharmacokinetics has been examined after bolus administration of anesthetizing doses (2 to 2.5 mg/kg IV), after a subanesthetic dose (0.25 mg/kg IV), and after continuous infusion (steady-state plasma level 2000 ng/mL).

Regardless of the dose, the plasma disappearance of ketamine can be described by a two-compartment model. Table 30-1 contains the pharmacokinetic values from bolus administration studies. Of note is the rapid distribution reflected in the relatively brief distribution half-life of 11 to 16 minutes (Fig. 30-15). The high lipid solubility of ketamine is reflected in its large volume of distribution of nearly 3 L/kg.[271,274] Clearance also is high, 890 to 1227 mL/minute, which accounts for the short elimination half-life of 2 to 3 hours. Mean total body clearance (1.4 L/minute) is approximately equal to liver blood flow. Low-dose alfentanil increases the volume of distribution and clearance of ketamine. In addition, alfentanil increases the distribution of ketamine into the brain. The pharmacokinetic model of Clements provided the best accuracy when it was used to administer low-dose ketamine to volunteers using a target-controlled infusion device.[271] The pharmacokinetics of the two isomers is different. S(+)-ketamine has a larger elimination clearance and larger volume of distribution than R(–)-ketamine. When the pharmacokinetics of S(+)-ketamine was tested in a target-controlled infusion device for procedures of 1 hour and in combination with propofol, the investigators found that the accuracy of the pharmacokinetic parameters was improved with a much smaller Vc central volume of distribution (167 mL/kg).[275] The investigators also noted that ketamine clearance was not normally distributed, and this was not related to age. The S(+) enantiomer also seems to be more potent in suppressing the EEG than either R(–) or the racemic mixture. Ketamine is increasingly being given by alternative routes, especially orally and through an intranasal spray. Administration by either of these routes is subject to significant first-pass metabolism. The bioavailability by oral administration is 20% to 30%, and by the intranasal route it is approximately 40% to 50%. In clinical and experimental studies, hyperalgesic responses were noted after the withdrawal of S(+)-ketamine.[272-274,276,277] Furthermore, no delay between concentration and effect has been observed for any of the antinociceptive endpoints. This finding indicates an almost immediate passage of S(+)-ketamine across the blood-brain barrier and rapid receptor kinetics.

PHARMACODYNAMICS

Effects on the Central Nervous System

Ketamine produces dose-related unconsciousness and analgesia. Ketamine acts at multiple receptors, including the NMDARs, opioid receptors, and monoaminergic receptors. At high ketamine concentrations, σ opioid receptors

are also affected, muscarinic receptors are blocked, and GABA-ergic neurotransmission is facilitated. The most important action of ketamine is inhibition of NMDAR-mediated glutamergic input to the GABA-ergic system that leads to changing excitatory activity in the cortex and limbic system that in the end results in unconsciousness. At the spinal cord level, ketamine has potent antinociceptive effects on the NMDAR and inhibits acetylcholine release.[272-274] The anesthetized state has been termed *dissociative anesthesia* because patients who receive ketamine alone appear to be in a cataleptic state, in contrast to other states of anesthesia that resemble normal sleep. Patients anesthetized with ketamine have profound analgesia, but they keep their eyes open and maintain many reflexes. Corneal, cough, and swallow reflexes all may be present, but they should not be assumed to be protective. The patient has no recall of surgery or anesthesia, but amnesia is not as prominent with ketamine as with the benzodiazepines. Because ketamine has a low molecular weight, a pK_a near the physiologic pH, and relatively high lipid solubility, it crosses the blood-brain barrier rapidly and has an onset of action within 30 to 60 seconds of administration. The maximal effect occurs in approximately 1 minute.

After ketamine administration, pupils dilate moderately, and nystagmus occurs. Lacrimation and salivation are common, as is increased skeletal muscle tone, often with coordinated but seemingly purposeless movements of the arms, legs, trunk, and head. Although interindividual variability is great, plasma levels of 0.6 to 2 μg/mL are considered the minimum concentrations for general anesthesia; children may require slightly higher plasma levels (0.8 to 4 μg/mL) (see also Chapter 93). The duration of ketamine anesthesia after a single IV administration of a general anesthetic dose (2 mg/kg) is 10 to 15 minutes (see Fig. 30-15), and full orientation to person, place, and time occurs within 15 to 30 minutes. The S(+) enantiomer enables quicker recovery (by a couple of minutes) than does the racemic mixture,[278,279] as a result of the smaller dose necessary to produce an equianesthetic effect and the 10% faster hepatic biotransformation. Because of the good correlation between blood concentration of ketamine and the CNS effect, the relatively short duration of action of ketamine probably reflects its redistribution from the brain and blood to the other tissues in the body.

Concomitant administration of benzodiazepines, which is a common practice, may prolong the effect of ketamine. When used in combination with a benzodiazepine, the S(+) enantiomer was no different in terms of awareness at 30 minutes, but it was significantly better at 120 minutes than the racemic mixture. Analgesia occurs at considerably lower blood concentrations than does loss of consciousness.

Ketamine provides important postoperative analgesia. The plasma level at which pain thresholds are elevated is 0.1 μg/mL or greater.[276,280,281] This means that a considerable period of postoperative analgesia occurs after ketamine general anesthesia, and subanesthetic doses can consequently be used to produce analgesia. Ketamine inhibits nociceptive central hypersensitization. Ketamine also attenuates acute tolerance after opiate administration. The NMDAR plays an important role in the induction of hyperalgesia and antinociceptive tolerance as induced by opioids. Prophylactic ketamine administration may thus prevent both central sensitization and long-lasting enhancement in pain sensitivity as induced by opioids. Ketamine, like other NMDAR antagonists, may thus prevent opioid-induced hyperalgesia.[282] The primary site of CNS action of ketamine seems to be the thalamoneocortical projection system. The drug selectively depresses neuronal function in parts of the cortex (especially association areas) and thalamus while stimulating parts of the limbic system, including the hippocampus. This process creates what is termed a *functional disorganization* of nonspecific pathways in midbrain and thalamic areas. Ketamine acts by antagonism of the excitatory glutamatergic NMDAR. The NMDAR has high expression in the temporal cortex, hippocampus, basal ganglia, cerebellum, and brainstem, all regions significantly affected by ketamine.

Evidence also indicates that ketamine depresses transmission of impulses in the medial medullary reticular formation, which is important for transmission of the affective-emotional components of nociception from the spinal cord to higher brain centers. In volunteers experiencing heat pain, fMRI studies showed that ketamine produced a dose-dependent effect on pain processing by decreasing activation of the secondary somatosensory cortex (S2), insula, and anterior cingulate cortex. Ketamine occupies opiate receptors in the brain and spinal cord, and this property could account for some of the analgesic effects.[283,284] The S(+) enantiomer has some opioid μ-receptor activity, thus accounting for part of its analgesic effect. NMDAR interaction may mediate the general anesthetic effects and some analgesic actions of ketamine. The spinal cord analgesic effect of ketamine is postulated to be caused by inhibition of dorsal horn wide dynamic range neuronal activity. In a resting-state fMRI study, low-dose ketamine induced connectivity changes in brain areas involved in motor function, psychedelic effects, and pain processing. Ketamine's analgesic effect may arise from multiple pathways: decreased connectivity in regions of the pain matrix responsible for the perception of pain (pain sensing) and the affective processing of pain. In addition, ketamine affects connectivity in brain areas involved in endogenous pain inhibition.[285,286]

Although some drugs have been used to antagonize ketamine, no specific receptor antagonist reverses all the CNS effects of ketamine.

Ketamine increases cerebral metabolism, CBF, and ICP (see Chapter 70). Because of its excitatory CNS effects, which can be detected by generalized EEG development of theta wave activity and by petit mal seizure-like activity in the hippocampus, ketamine increases $CMRO_2$. The increase in CBF appears higher than the increase in $CMRO_2$ would mandate. With the rise in CBF and the generalized increase in sympathetic nervous system response, ICP increases after ketamine use. The increase in $CMRO_2$ and CBF can be blocked by the use of thiopental or diazepam. Cerebrovascular responsiveness to carbon dioxide seems to be preserved with ketamine; reducing $Paco_2$ attenuates the rise in ICP after ketamine.

S(+)-ketamine may influence the expression of apoptosis-regulating proteins in rat brains 4 hours after cerebral ischemia and reperfusion. The neuroprotection observed

with ketamine may involve antiapoptotic mechanisms in addition to reducing necrotic cell death.

In contrast, ketamine and other anesthetic agents such as propofol and volatile anesthetic agents accentuate apoptosis in the newborn brain of animals and cause changes in the morphology of dendritic spines. This finding has sparked controversy over the use of ketamine in neonates. An editorial in the journal *Anesthesiology* and the Anesthetic and Life Support Drugs Advisory Committee of the FDA cautioned changing clinical practice based on present available data (see also Chapter 93).

Ketamine, like other phencyclidines, produces undesirable psychological reactions, which occur during awakening from ketamine anesthesia and are termed *emergence reactions*. The common manifestations of these reactions, which vary in severity and classification, are vivid dreaming, extracorporeal experiences (sense of floating out of body), and illusions (misinterpretation of a real, external sensory experience). These incidents of dreaming and illusion are often associated with excitement, confusion, euphoria, and fear. They occur in the first hour of emergence and usually abate within 1 to several hours. These psychic emergence reactions are secondary to ketamine-induced depression of auditory and visual relay nuclei, thus leading to misperception or misinterpretation of auditory and visual stimuli. The incidence of the psychic emergence reactions ranges from 3% to 100%. A clinically relevant range is probably 10% to 30% of adult patients who receive ketamine as a sole or major part of the anesthetic technique. Factors that affect the incidence of emergence reactions are age, dose, gender, psychological susceptibility, and concurrent drugs. Pediatric patients do not report as high an incidence of unpleasant emergence reactions as do adult patients; men also report a less frequent incidence compared with women.

Larger doses and rapid administration of large doses seem to predispose patients to a frequent incidence of adverse effects. Finally, certain personality types seem prone to the development of emergence reactions. Patients who score high in psychotism on the Eysenck Personality Inventory are prone to develop emergence reactions, and individuals who commonly dream at home are more likely to have postoperative dreams in the hospital after ketamine. Although numerous drugs have been used to reduce the incidence and severity of postoperative reactions to ketamine, the benzodiazepines seem to be the most effective group of drugs.

Effects on the Respiratory System

Ketamine has minimal effects on the central respiratory drive as reflected by an unaltered response to carbon dioxide. A transient (1 to 3 minutes) decrease in minute ventilation can occur after the bolus administration of an induction IV dose of ketamine (2 mg/kg). Unusually large doses can produce apnea, but this is seldom seen. In a μ-opioid knockout mouse model, however, at supraspinal sites S(+)-ketamine interacted with the μ-opioid receptor system. This interaction contributed significantly to S(+)-ketamine–induced respiratory depression and supraspinal antinociception.[287,288] With the use of adjuvant sedatives or anesthetic drugs, respiratory depression may become clinically significant. Ketamine depresses ventilatory control in children, especially with bolus doses. Ketamine is a bronchial smooth muscle relaxant. When it is given to patients with reactive airway disease and bronchospasm, pulmonary compliance is improved.

Ketamine is as effective as halothane or enflurane in preventing experimentally induced bronchospasm. The mechanism for this effect is probably a result of the sympathomimetic response to ketamine, but isolated bronchial smooth muscle studies showed that ketamine can directly antagonize the spasmogenic effects of carbachol and histamine. Because of its bronchodilating effect, administration of ketamine can treat status asthmaticus unresponsive to conventional therapy. A potential respiratory problem, especially in children, is the increased salivation that follows ketamine administration; this effect can be modulated by an anticholinergic drug such as atropine or glycopyrrolate (see also Chapter 93).

Effects on the Cardiovascular System

Ketamine increases arterial blood pressure, heart rate, and cardiac output in a biphasic manner. It has a direct cardiodepressant, negative inotropic effect next to an indirect stimulatory effect secondary to activation of the sympathetic system. Ketamine causes the systemic release of catecholamines, inhibition of the vagal nerve, inhibition of norepinephrine reuptake at peripheral nerves and nonneuronal tissues such as the myocardium, and norepinephrine release from sympathetic ganglia.[289] Cardiodepression precedes stimulation after large-dose ketamine administration or occurs after repeated administrations when presynaptic catecholamine stores become depleted. Cardiovascular stimulation already occurs after small-dose ketamine infusion and is characterized by tachycardia, systemic and pulmonary hypertension, increases in cardiac output, and myocardial oxygen consumption. Whereas the cardiovascular stimulatory effects of ketamine generally are dominant, after termination of S-ketamine infusion, cardiovascular depression may become evident because cardiac output may decrease to less than preinfusion values.[272] The cardiovascular stimulatory effect of S(+)-ketamine is characterized by an increase in the cardiac output of 1 L/minute in the presence of 243 ng/mL S(+)-ketamine.[272] The cardiovascular stimulatory effect of S(+)-ketamine is induced very rapidly with a half-life for onset and offset of the effect of ketamine on cardiac output of 1 to 2 minutes.

The increase in hemodynamic variables is associated with increased work and myocardial oxygen consumption. The healthy heart augments oxygen supply by increased cardiac output and decreased coronary vascular resistance, so that coronary blood flow is appropriate for the increased oxygen consumption. Patients with congenital heart disease have no significant changes in shunt directions or fraction, or systemic oxygenation, after ketamine induction of anesthesia (see also Chapter 94). In patients who have increased pulmonary artery pressure (e.g., patients with mitral valvular and some congenital lesions), ketamine causes a more pronounced increase in pulmonary than systemic vascular resistance. Ketamine injected directly into the CNS produces an immediate sympathetic nervous system hemodynamic response. Ketamine also causes the sympathoneuronal release of

norepinephrine, which can be detected in venous blood. Blockade of this effect is possible with barbiturates, benzodiazepines, and droperidol. The centrally mediated sympathetic responses to ketamine usually override the direct depressant effects of ketamine. Some peripheral nervous system actions of ketamine play an undetermined role in the hemodynamic effects of the drug. Ketamine inhibits intraneuronal uptake of catecholamines by a cocaine-like effect, and it inhibits extraneuronal norepinephrine uptake.

Stimulation of the cardiovascular system is not always desirable, and certain pharmacologic methods have been used to block ketamine-induced tachycardia and systemic hypertension. Probably the most fruitful approach has been prior administration of benzodiazepines. Modest doses of diazepam, flunitrazepam, and midazolam all attenuate the hemodynamic effects of ketamine. It also is possible to decrease the tachycardia and hypertension caused by ketamine by using a continuous infusion technique with or without a benzodiazepine. Inhalation anesthetics and propofol blunt the hemodynamic effect of ketamine.

USES

The many unique features of ketamine pharmacology, especially its propensity to produce unwanted emergence reactions in 10% to 20% of patients, have limited its use for routine anesthesia. Nevertheless, ketamine has an important niche in the practice of anesthesiology when its unique sympathomimetic activity and bronchodilating capabilities are indicated during induction of anesthesia. It is used for premedication, sedation, induction, and maintenance of general anesthesia. Interest in the use of ketamine in small doses for preventive analgesia and for the treatment or prevention of opiate tolerance and hyperalgesia and in treatment of acute and chronic pain has increased.

Induction and Maintenance of Anesthesia

The cardiovascular stimulatory effects make ketamine a desirable drug for the induction of anesthesia in unstable cardiovascular patients suffering from hypovolemia, hemorrhagic shock, or cardiovascular depression in sepsis. Ketamine bronchodilation and profound analgesia allowing the use of high oxygen concentrations make ketamine an excellent choice for induction of anesthesia in patients with reactive airway disease. Patients who have sustained trauma with extensive blood loss are typical candidates for rapid-sequence anesthesia induction with ketamine (see also Chapter 81). Patients with septic shock also may benefit from ketamine. The intrinsic myocardial depressant effect of ketamine may manifest in this situation if trauma or sepsis has caused depletion of catecholamine stores before the patient's arrival in the operating room. Use of ketamine in these patients does not obviate the need for appropriate preoperative preparation, including restoration of intravascular blood volume.

Other cardiac diseases that can be well managed with ketamine anesthesia are cardiac tamponade and restrictive pericarditis. The finding that ketamine preserves heart rate and right atrial pressure through its sympathetic stimulating effects makes ketamine an excellent anesthetic induction and maintenance drug in this setting. Ketamine also is often used in patients with congenital heart disease, especially patients with a propensity for right-to-left shunting (see also Chapter 94). Ketamine has been successfully used in a patient susceptible to malignant hyperthermia. Ketamine combined with propofol or midazolam can be given by continuous infusion to produce satisfactory cardiac anesthesia for patients with valvular and ischemic heart disease. The combination of a benzodiazepine or of a benzodiazepine and sufentanil with ketamine attenuates or eliminates the unwanted tachycardia and hypertension and postoperative psychological derangements. With this technique, patients have minimal hemodynamic perturbations, profound analgesia, dependable amnesia, and an uneventful convalescence. The use of propofol in combination with small-dose ketamine also has gained increasing popularity as a total IV anesthesia technique for patients undergoing noncardiac surgical procedures. The advantages of this combination are maintenance of stable hemodynamics and minimal ventilatory depression when allowing spontaneous ventilation.

Pain Management

Postoperative pain is a major concern of many patients, and it is inadequately treated in as many as 30% to 50% of all postoperative patients (see also Chapter 98). Multimodal analgesia combining various analgesic agents that act through different pathways is the way to manage postoperative pain. Ketamine is increasingly used as one of the constituents of this multimodal analgesia therapy. Over the years, the ketamine dose used for perioperative analgesia has gradually been decreasing. Ketamine administered in small doses decreases postoperative analgesic consumption by 33%. Several meta-analyses of the use of small-dose ketamine (20 to 60 mg) perioperatively have been performed. These meta-analyses showed an overall decrease in opiate use or improved analgesia and a decrease in opiate-induced side effects, especially PONV. Side effects, especially psychomimetic effects, were minimal, especially if a benzodiazepine also was administered.

The action of ketamine on opiate tolerance and hyperalgesia combined with its direct analgesic activity has led to its use in chronic pain states. Ketamine may be effective in the treatment of cancer pain, chronic peripheral and central neuropathic pain, phantom and ischemic limb pain, fibromyalgia, complex regional pain syndrome, visceral pain, and migraine. The epidural or caudal administration of ketamine (0.5 to 1 mg/kg) is effective. Although the efficacy of these doses of ketamine seems to be established, the safety of this technique has not yet received regulatory approval. The preservative of racemic mixture is potentially neurotoxic, whereas studies to date indicate that preservative-free S(+)-ketamine may be safe. Epidural preservative-free S(+)-ketamine has been shown to be safe and of value as an adjunct to corticosteroids in patients for the treatment of chronic low back pain secondary to radiculopathy.[290] The favorable hemodynamic effects and conservation of respiration make ketamine, administered by the IV route and even intranasally, useful for analgesia after extremity fractures.

IM, Intramuscularly; *IV,* intravenously; *N_2O,* nitrous oxide.

*Lower doses are used if adjuvant drugs such as midazolam or thiopental also are given.

Sedation

Ketamine is often combined with premedication with a barbiturate or benzodiazepine and an antisialagogue (e.g., glycopyrrolate) to facilitate management. The premedications reduce the dose requirement for ketamine, and the antisialagogue reduces the sometimes troublesome salivation. In adults and children, ketamine can be used as a supplement or an adjunct to regional anesthesia, thereby extending the usefulness of the primary (local anesthetic) form of anesthesia. In addition, ketamine is increasingly used for short, painful procedures in the emergency department. The dose used then is between 0.1 and 0.6 mg/kg. As previously described, ketamine also may be considered for sedation of patients in a critical care unit because of its combined sedative and analgesic properties and favorable effects on hemodynamics. Ketamine can even be used safely in head-injured patients when they are adequately ventilated.[291,292]

Ketamine is particularly suitable for sedation of pediatric patients undergoing procedures outside the operating room. Pediatric patients have fewer adverse emergence reactions than adults, and this feature makes the use of ketamine in pediatric patients more versatile (see also Chapter 93).

DOSES AND ROUTES OF ADMINISTRATION

Ketamine has been administered by the IV, intramuscular (IM), transcutaneous, oral, nasal, and rectal routes and as a preservative-free solution epidurally or intrathecally. Most clinical use involves the IV and IM routes, by which the drug rapidly achieves therapeutic concentrations. The dose depends on the desired therapeutic effect and on the route of administration. Box 30-3 contains general recommended doses for the IV and IM administration of ketamine for various therapeutic goals. Intranasal administration has an onset closer to that of IV administration; an oral dose of 3 to 10 mg/kg generates a sedative effect in 20 to 45 minutes. For sedation, ketamine may be given in an IM dose of 2 to 4 mg/kg. It also has been administered orally in doses of 3 to 10 mg/kg, with 6 mg/kg providing optimal conditions in 20 to 25 minutes in one study and 10 mg/kg providing sedation in 87% of children within 45 minutes in another study.

SIDE EFFECTS AND CONTRAINDICATIONS

Contraindications to ketamine relate to specific pharmacologic actions and diseases. In patients with increased ICP who are breathing spontaneously, ketamine should be used with caution because it can increase ICP and has been reported to cause apnea. Ketamine is increasingly used clinically in emergency airway management in patients with brain injury with or without other bodily injuries. In this setting, the current knowledge of safe management of increased ICP is continuing to grow.[291,292]

In mechanically ventilated patients, ketamine retains the response of CBF to carbon dioxide, a property that makes it useful in head-injured patients because of its potential neuroprotective effect. Ketamine may be contraindicated in patients with an open eye injury or other ophthalmologic disorder, in which a ketamine-induced increase in intraocular pressure would be detrimental (see also Chapter 84). Because ketamine has a propensity to cause hypertension and tachycardia, with a commensurate increase in myocardial oxygen consumption, it may be contraindicated as the sole anesthetic agent in patients with ischemic heart disease. Similarly, it is unwise to give ketamine to patients with vascular aneurysms because of the possible sudden change in arterial blood pressure. Psychiatric disease, such as schizophrenia, and a history of adverse reaction to ketamine or one of its congeners also are contraindications. One also should consider carefully using ketamine when the patient may develop postoperative delirium from other causes (e.g., delirium tremens, possibility of head trauma), and a ketamine-induced psychomimetic effect would confuse the differential diagnosis.

As mentioned earlier, ketamine or other NMDAR antagonists accentuate apoptosis in the newborn brain of animals, and the clinical implications of this are unknown. Finally, because ketamine's preservative, chlorobutanol, is neurotoxic, this formulation of ketamine for subarachnoid or epidural administration is contraindicated. S(+)-ketamine is available in a preservative-free solution. The FDA has not approved the use of intrathecal or epidural ketamine. Caudal ketamine has been used for perioperative analgesia in children and neonates with 0.5 mg/kg as the optimal dose (see also Chapter 93). Caudal analgesia, by combinations of ketamine and a local anesthetic, prolongs analgesia from 2.26 to 5.3 hours and reduces the need for nonopioid analgesics.[293-297]

Finally, liver and renal toxicity occurs in the recreational abuse of ketamine. In addition, when ketamine was repeatedly administered in the treatment of chronic pain in patients with complex regional pain syndrome type 1, hepatotoxicity developed in patients who received two 100-hour infusions of S(+)-ketamine with a 16-day interval.[295,298,299]

ETOMIDATE

HISTORY

The first report of etomidate was published in 1965.[300] Etomidate was introduced into clinical practice in 1972. The unique properties of etomidate include hemodynamic stability, minimal respiratory depression, cerebral

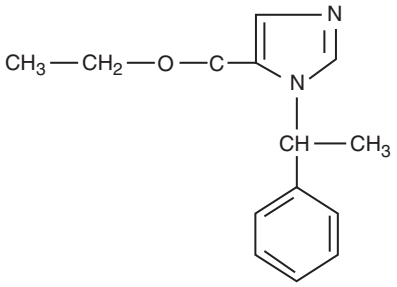

Figure 30-16. Structure of etomidate, an imidazole derivative. *(From Reves JG, Glass P, Lubarsky DA, et al: Intravenous anesthetics. In Miller RD, Eriksson LI, Fleischer LA, et al, editors:* Miller's anesthesia, *ed 7. Philadelphia, 2010, Churchill Livingstone, pp 719-768.)*

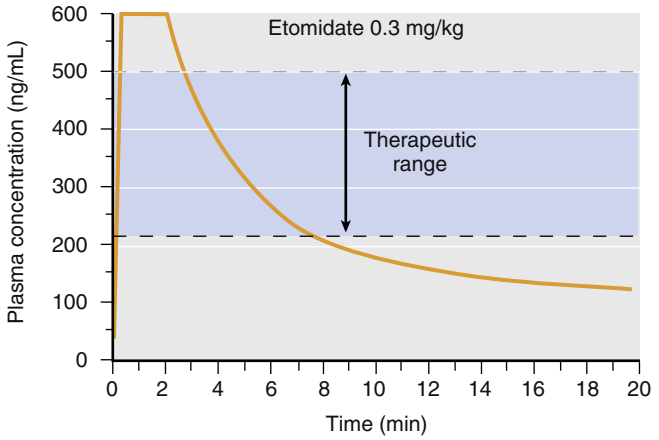

Figure 30-17. Simulated time course of plasma levels of etomidate after an induction dose of 0.3 mg/kg. Plasma levels required for hypnosis during surgical procedures are 300 to 500 ng/mL, with awakening usually occurring at levels less than 225 ng/mL. *(From Reves JG, Glass P, Lubarsky DA, et al: Intravenous anesthetics. In Miller RD, Eriksson LI, Fleischer LA, et al, editors:* Miller's anesthesia, *ed 7. Philadelphia, 2010, Churchill Livingstone, pp 719-768.)*

protection, favorable toxicity profile, and pharmacokinetics enabling rapid recovery after either a single dose or a continuous infusion. In the 1970s, these beneficial properties led to widespread use of etomidate for induction, for maintenance of anesthesia, and for prolonged sedation in critically ill patients. The enthusiasm among clinicians for etomidate was tempered in the 1980s by reports that the drug can cause temporary inhibition of steroid synthesis after single doses and infusions.[301,302] This effect, combined with other minor disadvantages (e.g., pain on injection, superficial thrombophlebitis, myoclonus, and a frequent incidence of nausea and vomiting), led to several editorials questioning the role of etomidate in modern anesthetic practice.[303,304] Use of the drug decreased after those editorials, but it has expanded again as a result of the rediscovery of etomidate's beneficial physiologic profile and a widening use in emergency departments and ICUs, combined with a lack of novel reports describing clinically significant adrenocortical suppression after induction or brief infusions.

PHYSICOCHEMICAL CHARACTERISTICS

Etomidate is an imidazole derivative (R-(+)-pentylethyl-1H-imidazole-5 carboxylate sulfate). Its chemical structure is illustrated in Figure 30-16. Etomidate has a pK_a of 4.2 and is hydrophobic at physiologic pH. To increase its solubility, it is formulated as a 0.2% solution either in 35% propylene glycol (Amidate, Hospira, Inc., Lake Forest, Ill) or in a lipid emulsion (Etomidate-Lipuro, B. Braun, Melsungen, Germany).[305]

PHARMACOKINETICS

The pharmacokinetics of etomidate has been determined after single bolus doses and after continuous infusion. The time course of plasma disappearance after a 0.3 mg/kg bolus is shown in Figure 30-17. The pharmacokinetics of etomidate is best described by an open three-compartment model.[306]

The drug has an initial distribution half-life of 2.7 minutes, a redistribution half-life of 29 minutes, and an elimination half-life of 2.9 to 5.3 hours.[307] Clearance of etomidate by the liver is high (18 to 25 mL/kg/minute), with a hepatic extraction ratio of 0.5 ± 0.9.[306] Because redistribution is the mechanism whereby the effect after a bolus of etomidate is dissipated, hepatic dysfunction should not appreciably alter recovery from a single induction dose. Etomidate is 75% protein bound.

A hemorrhagic shock model in pigs bled to an MAP of 50 mm Hg did not alter etomidate pharmacokinetics or pharmacodynamics.[308] This finding contrasts with the marked changes seen in this same model with other IV anesthetics. In patients with cirrhosis, the volume of distribution is doubled, whereas clearance is normal; the result is an elimination half-life that is twice normal.[309] The initial distribution half-life and clinical effect are likely unchanged. Increasing age is associated with a smaller initial volume of distribution and decreased clearance of etomidate.[310]

The short elimination half-life and rapid clearance of etomidate did make it suitable for administration in a single dose, in multiple doses, or in a continuous infusion with its context-sensitive half-time being shorter than that of propofol.[311] However, continuous infusion was only practiced in the first decade of its clinical availability, but the now widely recognized adrenal suppression limits this application. Etomidate is mainly metabolized in the liver by ester hydrolysis to the corresponding carboxylic acid and an ethanol leaving group (main metabolite).[312] The main metabolite is inactive. Only 2% of the drug is excreted unchanged; the remaining part is excreted as metabolites by the kidney (85%) and bile (13%). Pathologic conditions altering serum proteins (e.g., hepatic or renal disease) affect the amount of the free (unbound) fraction and may cause a dose to have an exaggerated pharmacodynamic effect.[313]

PHARMACODYNAMICS

Effects on the Central Nervous System

The primary action of etomidate on the CNS is through the $GABA_A$ receptor and results in hypnosis,[314,315] which

is achieved in one arm–brain circulation after a normal induction dose (0.3 mg/kg). The mechanism by which etomidate produces hypnosis is almost exclusively through $GABA_A$ receptor facilitation.[315,316] This mechanism includes two effects produced by different concentrations of etomidate. The first is the positive modulation of the $GABA_A$ receptor: activation of the receptor by agonists at concentrations associated with clinical doses. A lower dose of GABA is required in the presence of etomidate to activate the $GABA_A$ receptor.[317] The second action is called the direct activation or allosteric agonism. In supraclinical concentrations, etomidate can directly, thus in absence of GABA, activate the $GABA_A$ receptor.[318] These two actions suggest two independent binding sites at the $GABA_A$ receptor.[315] The $GABA_A$ receptors containing β_2 and β_3 subunits are modulated and activated by etomidate, whereas those containing β_1 are much less affected.

At a dose of 0.2 to 0.3 mg/kg, etomidate reduces CBF by 34% and $CMRO_2$ by 45% without altering MAP. CPP is maintained or increased, and a beneficial net increase in the cerebral oxygen supply-to-demand ratio occurs.[319] When given in doses sufficient to produce EEG burst suppression, etomidate acutely decreases ICP by 50% in patients with already increased ICP, thereby returning increased ICP to almost normal values.[320] The decrease in ICP is maintained in the period immediately after intubation. To maintain the effects of etomidate on ICP, high infusion rates (60 μg/kg/minute) are necessary. Controversy remains on the neuroprotective qualities of etomidate. A dose-dependent increase in latency and a decreasing amplitude of the auditory evoked potentials are noted.[321]

Preliminary animal experiments suggested that in a case of acute fetal distress and hypoxic injury, propofol and midazolam may be preferred over etomidate to protect the fetal brain as the first-choice anesthetic agent in cesarean delivery.[198,322,323] Etomidate has been associated with grand mal seizures and produces increased EEG activity in epileptogenic foci. This feature has proven useful for intraoperative mapping of seizure foci before surgical ablation.[324,325] BIS monitor values decrease after etomidate bolus administration and return to baseline during recovery.[326] During etomidate infusion, the BIS values reliably predict the depth of sedation and hypnosis.[327]

Effects on the Respiratory System

Etomidate has less effect on ventilation than do other anesthetics used to induce anesthesia. It does not induce histamine release in healthy patients or in patients with reactive airway disease.[328] Ventilatory response to carbon dioxide is depressed by etomidate, but the ventilatory drive at any given carbon dioxide tension is greater than that following an equipotent dose of methohexital.[154] Induction of anesthesia with etomidate produces a brief period of hyperventilation, sometimes followed by a similarly brief period of apnea,[329] which results in a slight (± 15%) increase in $Paco_2$, but no change in Pao_2.[330] Etomidate's actions on pulmonary vascular tone are similar to the actions observed with ketamine and propofol; that is, they attenuate the vasorelaxant responses to acetylcholine and bradykinin.[331]

Effects on the Cardiovascular System

The hemodynamic stability seen with etomidate is caused by its lack of effect on the sympathetic nervous system and on the function of the baroreceptor.[332] The minimal effect of etomidate on cardiovascular function sets it apart from other rapid-onset anesthetics.[333,334] Etomidate has proven useful in patients with valvular or ischemic heart disease who are undergoing noncardiac surgical procedures and in patients with poor cardiac function.[335,336] In patients receiving etomidate during induction of anesthesia, more hypertension and tachycardia occur after etomidate compared with propofol.[337] The myocardial oxygen supply-to-demand ratio is well maintained.[338] Etomidate lacks analgesic efficacy, however, and must be combined with an opiate to prevent hemodynamic perturbations during laryngoscopy and intubation.

In the setting of hemorrhagic shock, etomidate has advantages for induction of anesthesia. In contrast to other drugs, the pharmacodynamics and pharmacokinetics of etomidate were minimally altered in a pig model of hemorrhagic shock.[308]

Endocrine Effects

In 1983, Ledingham and Watt reported retrospective data showing increased mortality among patients in the ICU who were receiving long-term etomidate infusion compared with patients receiving benzodiazepines.[301] These investigators postulated that adrenocortical suppression could be the cause of this increased mortality. Soon after this publication, clinical investigators confirmed the adrenocortical suppression by etomidate.[302,339]

The specific endocrine effects manifested by etomidate consist of a dose-dependent reversible inhibition of the enzyme 11β-hydroxylase, which results in decreased biosynthesis of cortisol. Blockade of the cytochrome P450–dependent enzyme 11β-hydroxylase also results in decreased mineralocorticoid production and increased formation of intermediaries (11-deoxycorticosterone) (Fig. 30-18). Subsequent research has shown that etomidate is far more potent as an inhibitor of steroid synthesis than as a sedative-hypnotic agent.[339,340] The etomidate concentrations associated with adrenocortical suppression are less than 10 ng/mL, which are much lower than the concentrations needed for hypnosis (>200 ng/mL). The disparate concentrations for hypnosis and adrenotoxicity may explain the dramatic difference in duration of these two actions.[57]

Concerns about the use of etomidate and etomidate-induced adrenal toxicity in critically ill patients have reemerged. The literature is conflicting regarding the potential benefits of etomidate over other induction agents in critically ill patients, and its safety in patients with sepsis is a matter of strong debate in the critical care community. As indicated earlier, etomidate is associated with suppression of adrenal steroidogenesis, which can last up to 72 hours. However, the clinical impact of this adrenal suppressive effect is not certain.[341]

The Corticosteroid Therapy of Septic Shock (CORTICUS) study followed 500 patients with septic shock who were randomized to receive either low-dose

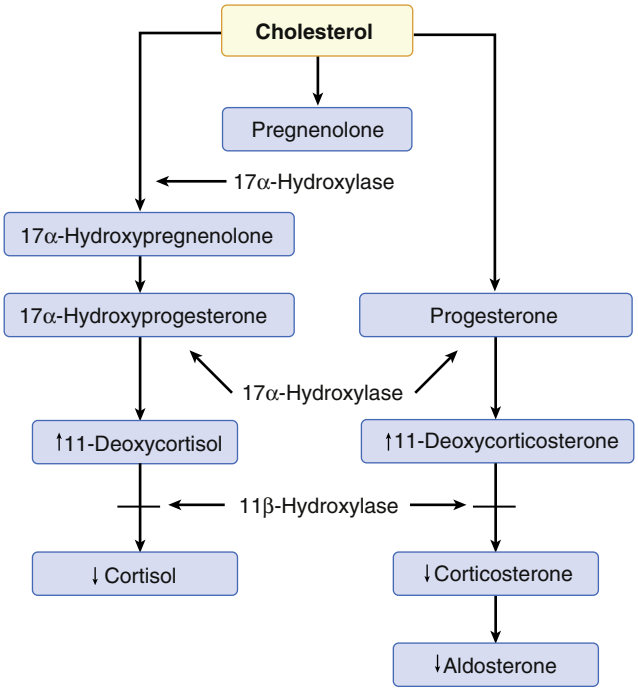

Figure 30-18. Pathway for the biosynthesis of cortisol and aldosterone. The sites at which etomidate affects cortisol-aldosterone synthesis by its action on 11β-hydroxylase (major site) and 17α-hydroxylase (minor site) are illustrated. *(From Reves JG, Glass P, Lubarsky DA, et al: Intravenous anesthetics. corticosteroid therapy or placebo. Twenty percent of the patients received etomidate. The study concluded that low-dose corticosteroid therapy had no benefit with regard to long-term outcome.[342] Retrospective analyses of the CORTICUS population suggest that patients receiving etomidate before enrollment had a 28-day mortality significantly higher and that steroid supplements provided no benefit.[343,344] Results of other studies designed to evaluate the effect of etomidate on morbidity and mortality and hospital and ICU length of stay are not conclusive.[345-348] In conclusion, the impact of the use of a single dose of etomidate in critically ill patients remains unclear.

USES

Induction of Anesthesia

The induction dose of etomidate is 0.2 to 0.6 mg/kg (Box 30-4).[349] The induction dose is reduced by premedication with an opiate, a benzodiazepine, or a barbiturate. Onset of anesthesia after a routine induction dose of 0.3 mg/kg of etomidate is rapid (one arm–brain circulation). In the past, various infusion schemes were devised to use etomidate as a maintenance anesthetic agent for the hypnotic component of anesthesia. After the publications on the adrenocortical suppressive effects of etomidate, continuous infusion was abandoned.

Etomidate is most appropriate in patients with cardiovascular disease, reactive airway disease, intracranial

hypertension, or any combination of disorders indicating the need for an induction agent with limited or beneficial physiologic side effects. The hemodynamic stability of etomidate is unique among the rapid-onset anesthetic agents used to induce anesthesia. In multiple studies, etomidate has been used for induction in patients with a compromised cardiovascular system who are undergoing coronary artery bypass surgery or valve surgery, as well as in patients requiring induction of general anesthesia for percutaneous transluminal coronary angioplasty, aortic aneurysm repair, and thoracic surgery. For cardioversion, the rapid onset, quick recovery, and maintenance of arterial blood pressure in these sometimes hemodynamically tenuous patients, combined with continued spontaneous respiration, make etomidate an acceptable choice.[350] Etomidate has been successfully used in neurosurgical procedures such as giant aneurysm clipping and is a reasonable choice during induction of anesthesia for neurosurgical procedures.[351] In addition, etomidate should be considered as an anesthetic induction agent to reduce increased ICP when maintenance of cerebral or coronary perfusion pressure is important.

Patients with trauma who have questionable intravascular volume status may be well served by an induction of anesthesia with etomidate. Although the indirect sympathomimetic effect seen with ketamine induction is absent, no direct myocardial depression occurs. When etomidate is used in patients with trauma, loss of consciousness by itself can be associated with decreased adrenergic output, and controlled ventilation can exacerbate the cardiovascular effects of a decreased preload. Both these factors may cause a significant decrease in arterial blood pressure during induction of anesthesia even though etomidate has no direct cardiovascular drug effect.

Short-term sedation with etomidate is useful in hemodynamically unstable patients, such as patients requiring cardioversion or patients requiring sedation after an acute myocardial infarction or with unstable angina for a minor operative procedure.[350] When used during electroconvulsive therapy, etomidate can produce longer seizures compared with other hypnotic agents.[352,353] Induction of anesthesia with etomidate is an independent risk factor in the development of emergence delirium.[354]

Treatment in Hypercortisolemia

Etomidate has a special place in the treatment of endogenous hypercortisolemia. It is proven to be an effective

parenteral treatment for this indication. In patients with unstable hemodynamic factors, patients with sepsis, or patients with psychosis, treatment should be performed under intensive care conditions.[355]

SIDE EFFECTS

Although etomidate provides stable hemodynamics and minimal respiratory depression, it is associated with several adverse effects when it is used for induction, including nausea and vomiting, pain on injection, myoclonic movement, and hiccups. Etomidate has been associated with PONV. More recently, etomidate in a lipid emulsion was associated with equal or an increased incidence of postoperative nausea compared with propofol.[356-358]

The lipid formulation of etomidate is associated with a much less frequent incidence of pain on injection, thrombophlebitis, and histamine release.[359,360] Pain on injection may be reduced by injecting IV lidocaine, 20 to 40 mg immediately before injection of etomidate.

The incidence of muscle movement (myoclonus) and of hiccups is highly variable (0% to 70%), but myoclonus is reduced by premedication with a hypnotic agent such as midazolam or a small dose of magnesium 60 to 90 seconds before the induction dose of etomidate is given.[361,362]

NOVEL ETOMIDATE DERIVATIVES

Etomidate is a well-known and widely used anesthetic agent for induction of anesthesia. The limitations of etomidate are, as mentioned earlier, adrenocortical suppression, myoclonus, and PONV. Modifying etomidate could improve its clinical utility and produce etomidate derivatives with a better profile.

Methoxycarbonyletomidate (MOC) is an etomidate derivative and is rapidly metabolized to methoxycarbonyletomidate carboxylic acid (MOC-ECA). The hypnotic potency of MOC is almost equal to that of etomidate, and the duration of the induced anesthesia is short because of rapid metabolism by nonspecific esterase enzymes. In preclinical studies, MOC may not act as an inhibitor of adrenal steroid synthesis.[363] Carboetomidate, another derivative, contains a five-membered pyrrole ring instead of an imidazole. In tadpoles and rats, carboetomidate reduced the adrenal suppression potency by three orders. Carboetomidate has potent hypnotic properties by activating $GABA_A$ receptors and thus causing minimal hemodynamic changes.[364]

DEXMEDETOMIDINE

HISTORY

The α_2-adrenergic receptor agonists have sedative, anxiolytic, hypnotic, analgesic, and sympatholytic effects. The potential for use in anesthesia was recognized in patients who were treated with clonidine.[365] Soon thereafter, a reduction of the minimum alveolar concentration (MAC) of halothane by clonidine was described.[366] Dexmedetomidine is a more selective α_2-agonist with a selectivity ratio for the α_2 receptor compared with the α_1 receptor of 1600:1, as compared with a ratio of 220:1 for clonidine. It was introduced in clinical practice in the United States in 1999 and was approved by the FDA only as a short-term (<24 hours) sedative for mechanically ventilated adult patients in the ICU. Dexmedetomidine is used for prolonged sedation and anxiolysis in the ICU, as well as outside the ICU in various settings, including sedation and adjunct analgesia in the operating room and sedation in diagnostic and procedure units, as well as for other applications such as withdrawal or detoxification amelioration in adult and pediatric patients.[367,368]

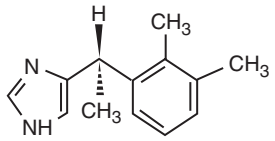

Figure 30-19. Chemical structure of dexmedetomidine. *(From Reves JG, Glass P, Lubarsky DA, et al: Intravenous anesthetics. In Miller RD, Eriksson LI, Fleischer LA, et al, editors:* Miller's anesthesia, *ed 7. Philadelphia, 2010, Churchill Livingstone, pp 719-768.)*

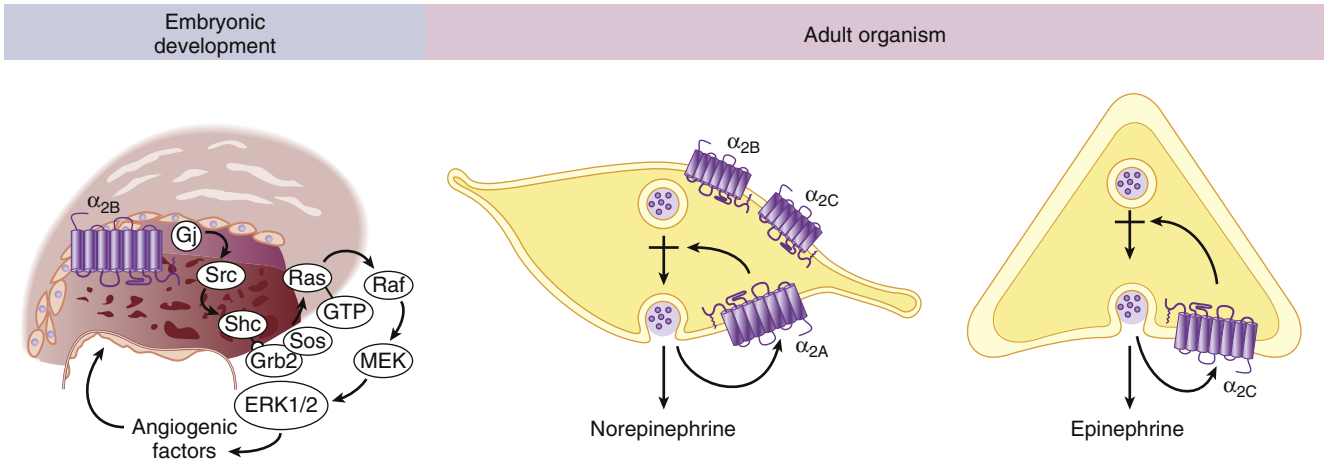
PHYSICOCHEMICAL CHARACTERISTICS



Dexmedetomidine is the S-enantiomer of medetomidine, a substance that has been used for sedation and analgesia in veterinary medicine for many years.[369] It shows a high ratio of specificity for the α_2 receptor (α_2/α_1 1600:1) compared with clonidine (α_2/α_1 220:1), thus making it a complete α_2-agonist.[370] The pK_a is 7.1. Dexmedetomidine belongs to the imidazole subclass of α_2-receptor agonists, similar to clonidine, and its structure is illustrated in Figure 30-19. It is freely soluble in water and is available as a clear isotonic solution containing 100 μg/mL and 9 mg sodium chloride per milliliter of water.

METABOLISM AND PHARMACOKINETICS

Dexmedetomidine undergoes almost complete biotransformation with very little unchanged dexmedetomidine excreted in urine and feces. Biotransformation involves both direct glucuronidation and cytochrome P450–mediated metabolism. The major metabolic pathways of dexmedetomidine are direct *N*-glucuronidation to inactive metabolites, hydroxylation (mediated primarily by CYP2A6), and *N*-methylation.

Dexmedetomidine is 94% protein bound, and its concentration ratio between whole blood and plasma is 0.66. Dexmedetomidine has effects on cardiovascular variables, potentially causing bradycardia, transient hypertension or hypotension, and may alter its own pharmacokinetics. With large doses, marked vasoconstriction occurs and probably reduces the drug's volumes of distribution. In essence, dexmedetomidine displays nonlinear pharmacokinetics.[371] Its pharmacokinetics in volunteers is best described by a three-compartment model (see Table 30-1).

In subjects with varying degrees of hepatic impairment (Child-Pugh class A, B, or C), clearance values for dexmedetomidine are slower than in healthy subjects. The mean clearance values for patients with mild,

The *top panel* depicts the three α_2-receptor subtypes acting as presynaptic inhibitory feedback receptors to control the release of norepinephrine and epinephrine from peripheral or central adult neurons. A negative feedback loop is also seen in the adrenal gland. α_{2B} Receptors have been shown to be involved in the development of the placental vascular system during prenatal development. The *lower panel* lists a series of physiologic effects with their associated α_2 adrenoreceptors. *(From Paris A, Tonner PH: Dexmedetomidine in anaesthesia,* Curr Opin Anaesthesiol *18:412-418, 2005.)*

moderate, and severe hepatic impairment are 74%, 64%, and 53% of those observed in the normal healthy subjects, respectively.

The pharmacokinetics of dexmedetomidine is not influenced by renal impairment (creatinine clearance <30 mL/minute) or age. In patients with severe renal disease, the sedative effect may be stronger as a result of a lower degree of plasma protein binding. Clearance is a function of height.[371,372] The elimination half-life of dexmedetomidine is 2 to 3 hours, with a context-sensitive half-time ranging from 4 minutes after a 10-minute infusion to 250 minutes after an 8-hour infusion. Postoperative patients sedated with dexmedetomidine display pharmacokinetic features similar to those seen in volunteers.[373] No clinically relevant cytochrome P450–mediated drug interaction has been found.

PHARMACOLOGY

Dexmedetomidine acts nonselectively on various subtypes of membrane-bound G protein–coupled α_2-adrenoreceptors. Intracellular pathways include inhibition of adenylate cyclase and modulation of calcium and potassium ion channels. Three subtypes of α_2 adrenoreceptors have been described in humans: α_{2A}, α_{2B}, and α_{2C} (Fig. 30-20).[374] The α_{2A} adrenoreceptors are primarily distributed in the periphery, whereas α_{2B} and α_{2C} are in the brain and spinal cord. Postsynaptic α_2 adrenoreceptors located in peripheral blood vessels produce vasoconstriction, whereas presynaptic α_2 adrenoreceptors inhibit the release of norepinephrine and potentially attenuate the vasoconstriction. The overall response to α_2-adrenoreceptor agonists is related to the stimulation of α_2 adrenoreceptors located in the CNS and spinal cord. These receptors are involved in the sympatholysis, sedation, and antinociceptive effects of α_2 adrenoreceptors.[375] The α_2-agonists have the advantage that their effects are readily reversible by α_2-adrenergic antagonists (e.g., atipamezole).[376] Atipamezole is currently not approved for use in humans.

Effects on the Central Nervous System

Sedation. The α_2-agonists produce their sedative-hypnotic effect by an action on α_2 receptors in the locus coeruleus and by an analgesic action at α_2 receptors within the locus coeruleus and within the spinal cord.[377] Dexmedetomidine produces a decrease in activity of the projections of the locus coeruleus to the ventrolateral preoptic nucleus. As a result, GABA and galanin release in the tuberomammillary nucleus is increased, producing a decrease in histamine release in cortical and subcortical projections.[378] The α_2-agonists inhibit ion conductance through L-type or P-type calcium channels and facilitate conductance through voltage-gated calcium-activated potassium channels. Dexmedetomidine induces sedation through different receptors than the sedative drugs propofol and benzodiazepines, which exert their action through the GABA system. The sedative effect of dexmedetomidine acts through the endogenous sleep-promoting pathways, thus generating natural sleep patterns (Fig. 30-21).[379] Patients have been described as being very easy to wake up

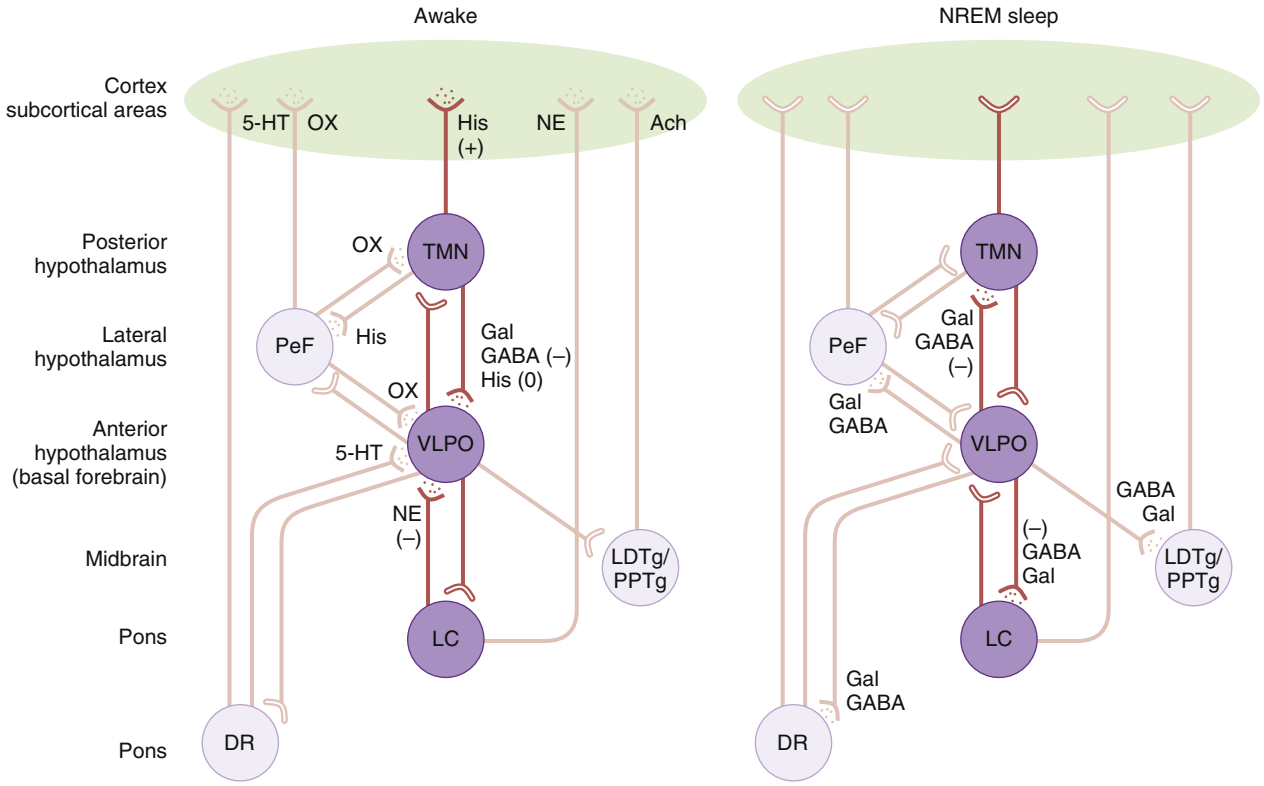

Figure 30-21. Dexmedetomidine has been shown to induce a non–rapid eye movement (NREM) sleeping pattern. The stimulation of the locus coeruleus (LC) by dexmedetomidine *(right)* releases the inhibition the LC has over the ventrolateral preoptic nucleus (VLPO). The VLPO subsequently releases γ-aminobutyric acid (GABA) onto the tuberomammillary nucleus (TMN). This inhibits the release of the arousal-promoting histamine on the cortex and forebrain, thus inducing the loss of consciousness. *Ach*, Acetylcholine; *DR,* dorsal raphae nuclei; *Gal,* galanin; *His,* histamine; *5-HT,* 5-hydroxytryptamine (serotonin); *LDTg,* laterodorsal tegmental nuclei; *NE,* norepinephrine; *OX,* orexin (hypocretin); *PeF,* perifornical area; *PPTg,* pedunculopontine tegmental nucleus; *TDTg,* laterodorsal tegmental nucleus. *(From Ebert T, Maze M: Dexmedetomidine: another arrow for the clinician's quiver,* Anesthesiology *101:569-570, 2004.)*

and having the ability to follow commands and cooperate while being tracheally intubated. Undisturbed, patients were noted to fall asleep momentarily.[380] This characteristic allows for "daily wake-up" tests to be done in a safe fashion. This critical test, in which ventilated patients in the ICU are taken off all sedatives to assess their mental status and titrate sedation, shortens their ventilated and ICU length of stay.[381,382] The number of patients experiencing delirium in the ICU is significantly lower when dexmedetomidine is used for sedation, compared with propofol or lorazepam[383] or with midazolam.[384]

Analgesia. The analgesic effect of the α_2-agonists is mediated through stimulation of the α_{2C} and α_{2A} receptor in the dorsal horn, thus directly suppressing pain transmission by reducing the release of pronociceptive transmitters, substance P and glutamate, and hyperpolarization of interneurons.[385] Systemic use of dexmedetomidine has an opioid-sparing effect during surgery and postoperatively.[386] This effect is advantageous in patients who are prone to postoperative apnea or hypoventilation, such as patients undergoing bariatric surgical procedures.[387] In the postoperative ICU setting, narcotic requirements are reduced by 50% when patients are receiving a dexmedetomidine infusion compared with placebo.[380] During general anesthesia, dexmedetomidine reduces the MAC of inhaled anesthetics.[388,389]

Like clonidine, dexmedetomidine is frequently used as an adjuvant in central or peripheral neural blockade. When it is administered caudally, 1 μg/kg as an adjuvant to bupivacaine 0.25% 1 mL/kg, in children undergoing inguinal hernia repair, response to hernial sac traction is reduced, and postoperative analgesia is prolonged.[390] Dexmedetomidine administered as an adjuvant to ropivacaine in ulnar nerve block[391] and tibial nerve block[392] was investigated in volunteers. Both studies showed intensification and foremost prolongation of the sensory blockade. This effect is likely elicited by prolonged hyperpolarization of the unmyelinated C fibers (sensory), and to a lesser extent the A fibers (motor function).

Central Nervous System Protection and Other Central Nervous System Effects. The CNS protective effects are not well defined. In animal models of incomplete cerebral ischemia and reperfusion, dexmedetomidine reduced cerebral necrosis and improved neurologic outcome. The prevalent idea is that dexmedetomidine reduces the intracerebral catecholamine outflow during injury. The neuroprotection may be attributed to modulation of proapoptotic and antiapoptotic proteins.[393] In addition, the reduction of the excitatory neurotransmitter glutamate during injury may explain some of the protective effects.[394]

In patients undergoing transsphenoidal hypophysectomy, dexmedetomidine had no effect on lumbar

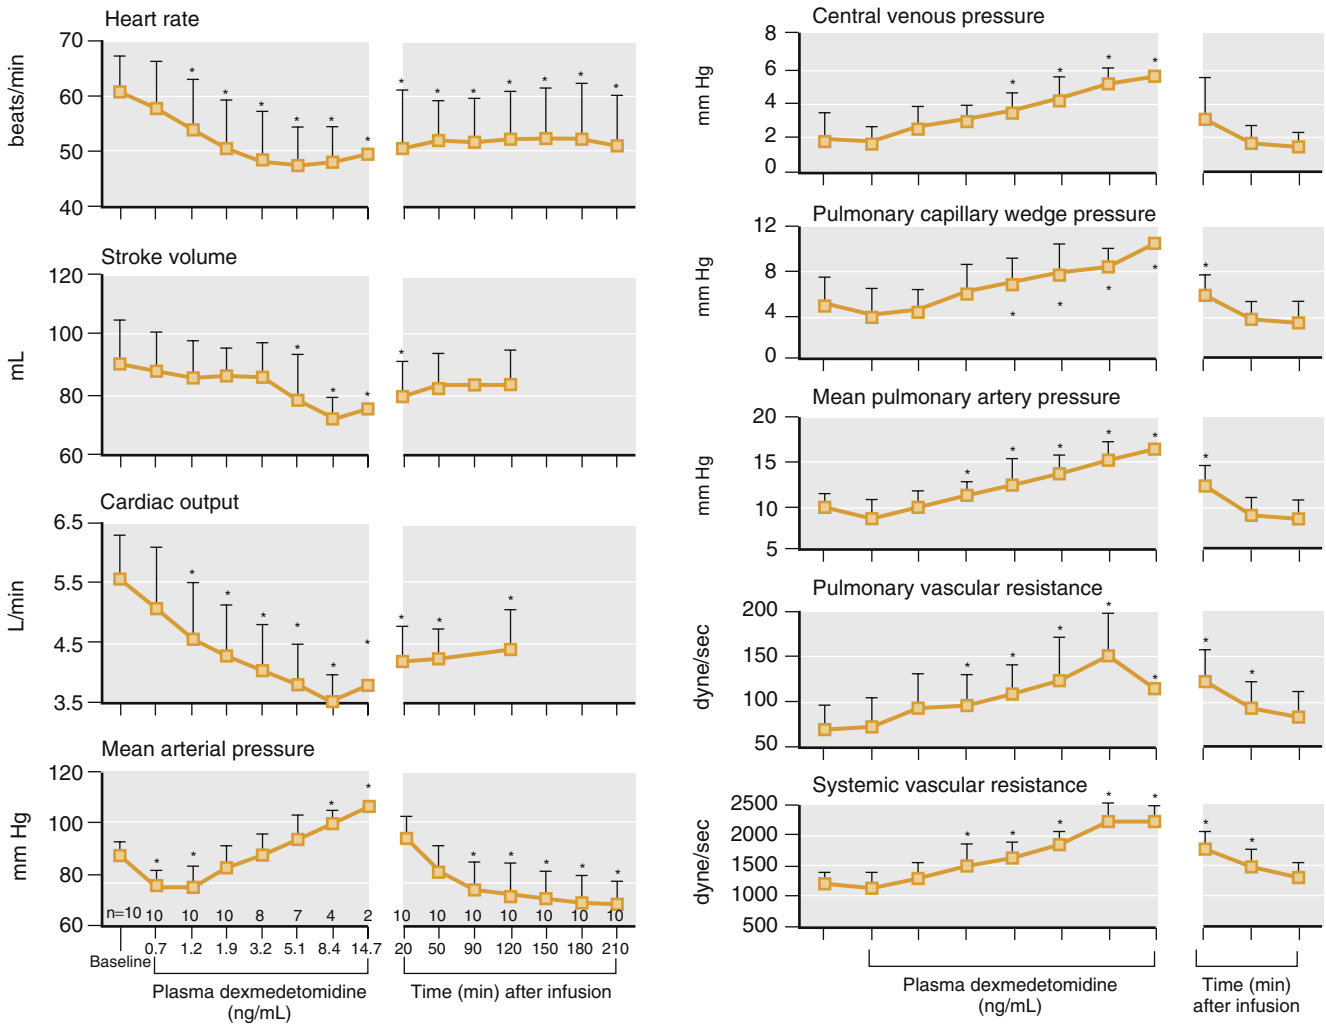

Figure 30-22. Effects of increasing plasma concentrations of dexmedetomidine. *(From Reves JG, Glass P, Lubarsky DA, et al: Intravenous anesthetics. In Miller RD, Eriksson LI, Fleischer LA, et al, editors:* Miller's anesthesia, *ed 7. Philadelphia, 2010, Churchill Livingstone, pp 719-768.)*

cerebral spinal fluid pressure.[395] In other studies, CBF velocity at the middle cerebral artery, as measured by transcranial Doppler imaging, decreased with increasing concentrations of dexmedetomidine but carbon dioxide responsiveness and autoregulation were preserved.[396,397] The decrease in CBF was not accompanied by a reduction in $CRMO_2$. More recently, in a study of six normal volunteers, the administration of dexmedetomidine to achieve serum levels of 0.6 ng/mL and 1.2 ng/mL (with and without hyperventilation) produced the predicted reduction of CBF with a concomitant reduction in $CRMO_2$.[398] This finding suggests that further work in injured brains must be done on the maintenance of the cerebral oxygen supply-to-demand relationship.

Dexmedetomidine has been used in neurosurgical procedures involving neurophysiologic monitoring (see also Chapter 70). Cortical evoked potential amplitudes and latencies were minimally affected when dexmedetomidine was used intraoperatively. It may also be suitable as an anesthetic adjunct during surgical treatment of seizures because the epileptiform activity of seizure foci was not reduced by dexmedotomidine.[399]

Effects on the Respiratory System

In spontaneously breathing volunteers, dexmedetomidine at concentrations producing significant sedation reduced minute ventilation, but with no change in arterial oxygenation, pH, or the slope in the carbon dioxide ventilatory response curve.[332] In a study comparing the effects of remifentanil and dexmedetomidine on respiratory parameters in normal volunteers, the hypercapnic ventilatory response was unaffected even at doses that produced unresponsiveness to vigorous stimulation.[400] Dexmedetomidine-treated patients exhibited a hypercarbic arousal phenomenon, which has been described during normal sleep.

Effects on the Cardiovascular System

Ebert and colleagues performed a study in volunteers by using a target-controlled infusion system to provide increasing concentrations (0.7 to 15 ng/mL) of dexmedetomidine (Fig. 30-22).[332] The lowest two concentrations produced a decrease in MAP (13%) followed by progressive increase (12%). Increasing concentrations of dexmedetomidine also produced progressive decreases in heart rate (maximum 29%) and cardiac output (35%).[332]

The most commonly reported hemodynamic adverse reactions associated with dexmedetomidine in a phase III trial in 401 patients were hypotension (30%), hypertension (12%), and bradycardia (9%).[369] The initial increase in arterial blood pressure is probably caused by the vasoconstrictive effects of dexmedetomidine when stimulating peripheral α_2 receptors. The incidence of hypotension and bradycardia may be related to the administration of a large IV "loading" dose. Omitting the loading dose or not giving more than 0.4 μg/kg reduces the incidence of hypotension or makes it less pronounced. Giving the loading dose over 20 minutes also minimizes the transient hypertension.[401] In several studies after IM and IV administration, dexmedetomidine caused, in a small percentage of patients, profound bradycardia (<40 beats/minute) and occasionally sinus arrest or pause. Generally, these episodes resolved spontaneously or were readily treated without adverse outcome by anticholinergics. No rebound effects have been found when discontinuing a dexmedetomidine infusion, even when it was given for more than 24 hours.[402] Because clonidine and dexmedetomidine have shown to reduce perioperative oxygen consumption and blunt the sympathetic response to surgery, cardiac outcome may be improved.[403,404] However, more studies are needed to determine whether dexmedetomidine is beneficial in decreasing the risk of myocardial ischemia.

USES

Dexmedetomidine has been approved as a short-term sedative for adult intubated patients in the ICU. Given its well-documented beneficial effects of anxiolysis, sedation, analgesia, and sympatholysis with minimal respiratory depression, it also has been used in various other clinical situations. It is well used as a sedative during radiologic or invasive procedures, in adults as well as in children. Two studies, comprising 140 children 1 to 7 years old, reported successful sedation for MRI scans compared with midazolam or propofol.[405]

As a premedicant, dexmedetomidine, at IV doses of 0.33 to 0.67 μg/kg given 15 minutes before the surgical procedure, seems efficacious, while minimizing the cardiovascular side effects of hypotension and bradycardia.[389] Dexmedetomidine has high bioavailability when administered nasally or buccally. This improves better compliance and absorption in younger children. A dose of 3 to 4 μg/kg 1 hour preoperatively is safe and effective.

In a study comparing the efficacy of dexmedetomidine or propofol as a sedative agent in a group of 40 patients receiving local anesthesia or regional blocks, dexmedetomidine (1 μg/kg given over 10 minutes) when used for intraoperative sedation resulted in a slower onset than propofol (75 μg/kg/minute for 10 minutes), but had similar cardiorespiratory effects when titrated to equal sedation. The average infusion rate of dexmedetomidine intraoperatively to maintain a BIS value of 70 to 80 was 0.7 μg/kg/minute. Sedation was more prolonged after termination of the infusion, as was recovery of arterial blood pressure. Dexmedetomidine can also produce profound sedation, and it has been used as a total IV anesthetic when given at 10 times the normal sedation concentration range.[406] This characteristic, combined with the cooperative status of the patient at a lighter sedative level, and its analgesic effect with sparing of respiratory function, makes the drug suitable as hypnotic agent during surgical procedures such as awake craniotomy, deep brain stimulation, surgical procedures near speech areas, or awake carotid endarterectomies, with fewer fluctuations from the desired sedation level and more stable hemodynamics.[396] The opioid-sparing effects are advantageous in the performance of bariatric surgery in patients who are prone to postoperative respiratory depression.[387]

Dexmedetomidine can be employed for addiction treatment; it has been described for use in rapid opioid detoxification, cocaine withdrawal, and iatrogenically induced benzodiazepine and opioid tolerance after prolonged sedation.[407] The use of dexmedetomidine in opioid or benzodiazepine withdrawal therapy in pediatric patients during mechanical ventilation in intensive care areas has been described as well[408] (see also Chapter 95).

Dexmedetomidine may produce dry mouth secondary to a decrease in salivation. Combined with the sparing effect on respiratory function, this effect is beneficial for the facilitation of awake fiberoptic intubation, an application that is rapidly emerging.[409] Furthermore, dexmedetomidine decreases intraocular pressure and decreases the shivering threshold.[410]

Intensive Care Unit

Dexmedetomidine may have advantages over propofol for sedation in mechanically ventilated postoperative patients (see also Chapter 101). In one study, heart rate was slower in the dexmedetomidine group, whereas MAP was similar. The Pa_{O_2}/fraction of inspired oxygen (Fi_{O_2}) ratio was significantly higher in the dexmedetomidine group. Time to extubation of the trachea after discontinuation of the infusion was similar at 28 minutes. Patients receiving dexmedetomidine had greater recall of their stay in the ICU, but all described this as pleasant overall.[411] Several other studies confirmed the decreased requirement for opioids (>50%) when dexmedetomidine is used for sedation compared with propofol or benzodiazepines. Hemodynamics during weaning are more stable, and this benefits patients who are at high risk for myocardial ischemia.[412] For sedation in the ICU, loading doses of 0.5 to 1 μg/kg have been used. Omitting the bolus dose or giving the lower dose has been associated with fewer episodes of severe bradycardia and other hemodynamic perturbations. Infusion rates of 0.1 to 1 μg/kg/hour are generally needed to maintain adequate sedation.

Delirium in the ICU is a risk factor for increased length of stay and increased mortality.[413] In a double-blind, randomized controlled trial of sedation in ventilated patients with dexmedetomidine versus lorazepam, investigators found that dexmedetomidine infusions provided more days alive without delirium or coma and a greater amount of time spent at the appropriate sedation level compared with lorazepam.[383] Dexmedetomidine also improved the patient's ability to communicate pain, compared with midazolam or propofol in two trials.[381]

The unique characteristics of dexmedetomidine (i.e., providing adequate sedation with minimal respiratory depression) make this selective α_2-adrenoceptor agonist

very useful when weaning patients from the ventilator.[414] Although the FDA approved the use of dexmedetomidine infusions for 24 hours or less, multiple studies have shown the safety of using this agent for longer periods, even up to 30 days.[384]

DROPERIDOL

HISTORY

Janssen and Schnabel and their associates synthesized haloperidol, the first member of the butyrophenones, which became the primary neuroleptic component in neuroleptanesthesia.[295,298] In 1959, DeCastro and Mundeleer combined haloperidol with phenoperidine (a meperidine derivative also synthesized by Janssen) in the forerunner to the practice of neuroleptanesthesia.[414a] Droperidol, a derivative of haloperidol, and fentanyl (a phenoperidine congener), both synthesized by Janssen, were used by DeCastro and Mundeleer in a combination they reported to be superior to haloperidol and phenoperidine. This neuroleptanesthesia combination produced more rapid onset of analgesia, less respiratory depression, and fewer extrapyramidal side effects. The fixed combination of droperidol and fentanyl, marketed as Innovar in the United States, was the drug primarily used for neuroleptanesthesia. The use of neuroleptanesthesia has largely disappeared in modern anesthetic practice. The primary use of droperidol in anesthesia has been as an antiemetic and, to a lesser extent, as a sedative and antipruritic.

In 2001, the FDA issued a black box warning regarding the use of droperidol and its potential for fatal arrhythmias and recommended that it be administered only during continuous electrocardiogram monitoring. With the withdrawal of droperidol in certain countries and more stringent labeling regarding potentially lethal dysrhythmias in others, the use of droperidol has decreased markedly. The validity of the risk of low-dose droperidol in causing QT prolongation, dysrhythmias, and death has been challenged by numerous editorials, articles, and letters reviewing the cases that prompted this action.[295,415-419] In Europe, 19 of 25 countries with council members in the European Society of Anaesthesiologists reported that droperidol is regularly used in a dose of 0.5 to 2.5 mg for the prevention of PONV. Furthermore, in 2007, an international consensus panel recommended droperidol as a first-line antiemetic despite the FDA warning.[295,420]

Droperidol is a butyrophenone, a fluorinated derivative of phenothiazines (Fig. 30-23). Butyrophenones produce CNS depression, characterized by marked apparent tranquility and cataleptic immobility, and are potent antiemetics. Droperidol is a potent butyrophenone, and, similar to the others, it produces its action centrally at sites where dopamine, norepinephrine, and serotonin act.[295] Investigators have postulated that butyrophenones may occupy GABA receptors on the postsynaptic membrane, thereby reducing synaptic transmission and resulting in a buildup of dopamine in the synaptic cleft. In particular, droperidol results in submaximal inhibition of the $GABA_A$ α_1-, β_1-, and γ_2-acetylcholine receptors and full inhibition of α_2-acetylcholine receptors. This submaximal inhibition of GABA receptors by droperidol may explain the anxiety, dysphoria, and restlessness that may occur with its administration.[295,421] An imbalance in dopamine and acetylcholine is thought to occur with subsequent alteration in normal transmission of signals in the CNS. The chemoreceptor trigger zone is the emetic center, and "red" astrocytes transport neurolept molecules from the capillary to dopaminergic synapses in the chemoreceptor trigger zone, where they occupy GABA receptors. This is thought to be the mechanism by which droperidol exerts its antiemetic effect.

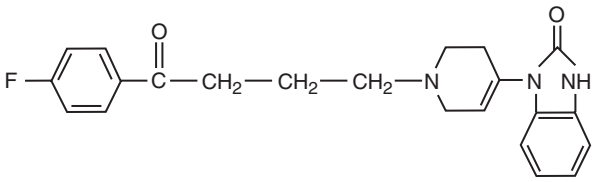

Figure 30-23. Structure of droperidol, a butyrophenone derivative. *(From Reves JG, Glass P, Lubarsky DA, et al: Intravenous anesthetics. In Miller RD, Eriksson LI, Fleischer LA, et al, editors:* Miller's anesthesia, *ed 7. Philadelphia, 2010, Churchill Livingstone, pp 719-768.)*

PHARMACOKINETICS

Droperidol is biotransformed in the liver into two primary metabolites. Its plasma decay can be described by a two-compartment model. The pharmacokinetics[295,422] is shown in Table 30-1.

PHARMACODYNAMICS

Effects on the Central Nervous System

The effects of neurolept anesthetics on human CBF and $CMRO_2$ have not been studied. In dogs, droperidol causes potent cerebral vasoconstriction, thus producing a 40% reduction in CBF. No significant change in $CMRO_2$ occurs during droperidol administration. The EEG in conscious patients shows some reduction in frequency, with occasional slowing. Low-dose droperidol also has been shown to cause balance disturbances at the time of discharge after doses used for antiemetic prophylaxis. Droperidol may produce extrapyramidal signs and worsens the symptoms of Parkinson disease. For this reason, the drug should be used with great caution in patients with this degenerative disorder. It also rarely may precipitate malignant neuroleptic syndrome.

Effects on the Respiratory System

When used alone, droperidol has little effect on the respiratory system. Droperidol (0.044 mg/kg) given to surgical patients produced a slight reduction in respiratory rate, and IV droperidol (3 mg) had no significant effect on tidal volume in volunteers. More detailed respiratory studies are unavailable.

Effects on the Cardiovascular System

Similar to most antipsychotics, droperidol may prolong the QT interval by delaying myocardial repolarization and precipitating torsades de pointes.[295,423] This effect

seems to be dose dependent and may be of clinical significance when other causes of QT prolongation also are present. Droperidol also may have some antiarrhythmic effects that are similar to those of quinidine. Droperidol produces vasodilation, with a decrease in blood pressure (see Table 30-3). This effect is considered to be a result of moderate α-adrenergic blockade. The dopamine-induced increase in renal blood flow (renal artery flowmeter methodology) is not significantly impaired by administration of droperidol. Droperidol has little effect on myocardial contractility.

USES

The use of droperidol today in the perioperative period is largely restricted to its antiemetic and sedative effects. It is an effective antiemetic; the dose for this use ranges from 10 to 20 μg/kg IV (typically 0.6 to 1.25 mg for a 70-kg individual).[295,424] Because droperidol in doses lower than 1 mg produce antiemetic effects and because the cardiac side effects may be dose dependent, an IV dose lower than 1 mg for prevention of PONV is advisable.[425] These doses of droperidol, given at the start of anesthesia for operations lasting 1 hour, reduce the incidence of nausea and vomiting by approximately 30%. These doses given at induction have little effect on wake-up time, but should they be given at the end of the surgical procedure, they could have some residual hypnotic effect. Overall, the antiemetic efficacy of droperidol alone is equal to that of ondansetron and results in an equal number of side effects, but droperidol is more cost effective. The efficacy of droperidol as an antiemetic is enhanced when it is used in combination with serotonin antagonists or dexamethasone, or both. Droperidol also has been shown to be effective in the treatment and prevention of pruritus secondary to opioid administration. It has been given by the IV route and into the epidural space for this purpose. When used in this fashion, droperidol also effectively reduces nausea, but it increases sedation. The safety of droperidol administration into the epidural space has not been fully evaluated, however, and it is not approved for administration by this route.

SUMMARY

Many different IV drugs are available for use in the care of patients requiring general anesthesia or sedation. The selection of a particular drug, but more often of a combination of drugs, must be based on the individual patient's need for hypnosis, amnesia, and analgesia. Drug selection must match the physiology or pathophysiology of the individual patient with the pharmacology of the particular drug or drugs. In addition, based on the pharmacokinetic and pharmacodynamic interactions now described, the optimal dosage of hypnotic-analgesic combinations may be selected. A patient in shock who requires induction of anesthesia should receive the drug that has a rapid onset of effect without causing further hemodynamic compromise. The knowledge of the clinical pharmacology of each of the IV anesthetic drugs enables the clinician to induce and maintain sedation or general anesthesia safely and effectively. No single perfect drug exists for any particular patient, but rather the informed practitioner wisely employs the appropriate drug or drugs in the practice of good anesthesia care.

Chapter 31

Opioid Analgesics

KAZUHIKO FUKUDA

Key Points

- An increased understanding of the molecular pharmacology of opioid receptors and opioid-induced cellular responses allows utilization of new innovative techniques for analgesia.
- Opioids suppress pain by their action in the brain, spinal cord, and peripheral nervous system.
- Opioids affect multiple organ systems, including the respiratory and cardiovascular systems, and can cause a variety of adverse effects. Proper dosing and monitoring allow these adverse effects to be minimized.
- Pharmacokinetic and pharmacodynamic properties of opioids are affected by a variety of factors, such as age, body weight, organ failure, and shock. To use opioids appropriately, these factors should be taken into consideration.
- Opioids are a vital part of providing the analgesic component of anesthesia, especially total intravenous anesthesia. Short-acting opioids, such as remifentanil, allow even more rapid dissipation of total intravenous anesthetics/RDM than that of inhaled anesthetics.
- Newer opioid delivery systems, such as transdermal fentanyl patches, allow more flexibility in providing analgesia for perioperative patient care.
- Opioids can pharmacokinetically or pharmacodynamically interact with drugs used perioperatively. Drug interactions should be understood for proper management of patients receiving opioids.

The term *opioid* refers broadly to all compounds related to opium. The word *opium* is derived from *opos*, the Greek word for juice, because the drug is derived from the juice of the opium poppy, *Papaver somniferum*. Opiates are drugs derived from opium and include the natural products morphine, codeine, and thebaine, as well as many semisynthetic congeners derived from them.

The first undisputed reference to opium is found in the writings of Theophrastus in the third century B.C. During the Middle Ages, many of the uses of opium were appreciated. Opium contains more than 20 distinct alkaloids. In 1806, Sertürner reported the isolation of a pure substance in opium that he named morphine, after Morpheus, the Greek god of dreams. By the middle of the nineteenth century, the use of pure alkaloids, rather than crude opium preparations, began to spread throughout the medical world.

In addition to the remarkable beneficial effects of opioids, the toxic side effects and addictive potential of these drugs also have been known for centuries. Synthetic opioid analgesics without side effects were explored, but many of the synthetic opioids share the side effects of natural opioids. The search for newer opioid agonists led to the synthesis of opioid antagonists and compounds with mixed agonist-antagonist properties, which expanded the therapeutic options and provided important tools for exploring mechanisms of opioid actions. Furthermore, newer methods of opioid administration, including patient-controlled analgesia (PCA) and computer-based infusion techniques, were developed.

PHARMACOLOGY OF OPIOIDS

CLASSIFICATION OF OPIOID COMPOUNDS

Opioids can be classified as naturally occurring, semisynthetic, and synthetic (Box 31-1). The naturally occurring opioids can be divided into two chemical classes: phenanthrenes (morphine and codeine) and benzylisoquinolines (papaverine). The semisynthetic opioids are morphine derivatives in which one of several changes has been made. Synthetic opioids are classified into four groups: the morphinan derivatives (levorphanol), the diphenyl or methadone derivatives (methadone, *d*-propoxyphene), the benzomorphans (phenazocine, pentazocine), and the phenylpiperidine derivatives (meperidine, fentanyl, alfentanil, sufentanil, and remifentanil). Structures of opioid compounds are shown in Figure 31-1[1] and Table 31-1.[1]

Opioids can be classified as agonists, partial agonists, mixed agonist-antagonists, and antagonists on the basis of their interaction with the opioid receptors.

OPIOID RECEPTORS

In 1973, three independent teams of investigators described the presence of opioid binding sites in the nervous system from the radioligand binding assays. From pharmacologic experiments, three types of opioid receptors were postulated. They were named μ for the morphine type, κ for the ketocyclazocine type, and σ for the SKF10047 (*N*-allylnormetazocine) type. In addition, a high-affinity receptor for enkephalins was found in the mouse vas deferens and was named the δ receptor. Furthermore, an ε receptor was proposed as the binding site for β-endorphin in the rat vas deferens. Pharmacologic actions of opioids and the involved receptors have been analyzed (Table 31-2).

Biochemical studies were performed to purify the opioid receptor protein but were not successful. Since the early 1990s, molecular biologic studies have elucidated the molecular structures and signal transduction mechanisms of the opioid receptors. Four different complementary DNAs (cDNAs) have been isolated as members of the opioid receptor family.[2] Investigators demonstrated that three of them correspond to the pharmacologically defined μ-, δ-, and κ-opioid receptors. The fourth receptor did not bind with opioid ligands with high affinities. Later, a novel peptide, nociceptin or orphanin FQ, was identified as an endogenous agonist of the fourth member of the opioid receptor family.[3,4] The μ-, δ-, and κ-opioid receptors and the nociceptin receptor share approximately 50% amino acid sequence homology with each other. Characteristics of the three opioid receptors and the nociceptin or orphanin FQ receptor are listed in Table 31-3. Hydropathy analysis of the primary structures of the opioid receptors predicted that the

*The numbers 3, 6, and 17 refer to positions in the morphine molecule, as shown above the table.

†Other changes in the morphine molecule are as follows:
(1)Single instead of double bond between C7 and C8
(2)OH added to C14
(3)No oxygen between C4 and C5
(4)Endoetheno bridge between C6 and C14; 1-hydroxy-1,2,2-trimethylpropyl substitution on C7

opioid receptors possess seven transmembrane domains (Fig. 31-2). This is a characteristic structural feature of the G-protein–coupled receptor. Crystallographic analysis revealed that the μ-opioid receptor actually possesses seven transmembrane domains and the morphinan ligand binds deeply within a large pocket.[5]

Further pharmacologic classification of the μ receptor as the μ_1, μ_2, and μ_3 subtypes has been proposed, but the molecular identity of these receptor subtypes remains to be clarified. Several possible molecular bases of the opioid receptor subtypes exist, including alternate splicing of a common gene product, receptor dimerization, and interaction of a common gene product with another receptor or signaling molecules.[6] Multiple μ-opioid receptor species can be produced from a gene product of the μ-opioid receptor gene by alternate splicing (Fig. 31-3).[7] Analysis of the alternate splicing products reveals differences in ligand binding and G-protein activation. Further research is necessary to clarify physiologic implications of the multiple alternate splicing products.

Several single nucleotide polymorphisms (SNPs) have been identified in the human μ-opioid receptor gene.[8] The A118G mutation, the most common of these SNPs, leads to a change in the gene product in the human μ-opioid receptors, which is an A-to-G substitution in exon 1 that results in an amino acid exchange at position 40 from asparagine to aspartate (N40D). Patients with cancer who are homozygous for the A118G variant require higher doses of oral morphine for long-term treatment of their pain.[9] A118G mutation of the human μ-opioid receptor gene reduces analgesic responses to morphine-6-glucuronide (M6G), but it does not significantly affect the respiratory depression induced by M6G.[10] Furthermore, morphine consumption with intravenous PCA after total abdominal hysterectomy is significantly greater in women homozygous for the A118G variant than in other patients.[11] Some studies have explored the relationship between gene-gene interactions and opioid responses. Kolesnikov and associates demonstrated that the heterozygous patients with μ-opioid receptor A118G and the catechol-*O*-methyltransferase G1974A mutation consumed significantly less morphine compared with homozygous patients of A118G.[12]

ENDOGENOUS OPIOID PEPTIDES

Enkephalin, β-endorphin, and dynorphin were identified as endogenous agonists for the δ-, μ-, and κ-opioid receptors, respectively. Following purification of these peptides from mammalian tissues, cDNAs for the precursors of these peptides were cloned. cDNA cloning and amino acid determination of preproopiomelanocortin demonstrated that cleavage of this precursor protein produces not only β-endorphin but also several other neuropeptides, including methionine-enkephalin, adrenocorticotropic hormone (ACTH), and α-melanocyte stimulating hormone. Amino acid sequence of preproenkephalin indicates that four methionine enkephalins and one leucine-enkephalin are cleaved from this precursor. Furthermore, the primary structure of preprodynorphin, the precursor of dynorphin, was determined by cDNA cloning.

A novel endogenous opioid peptide with a significant sequence homology to dynorphin was isolated in 1995.[3,4] This peptide was called orphanin FQ, or nociceptin,

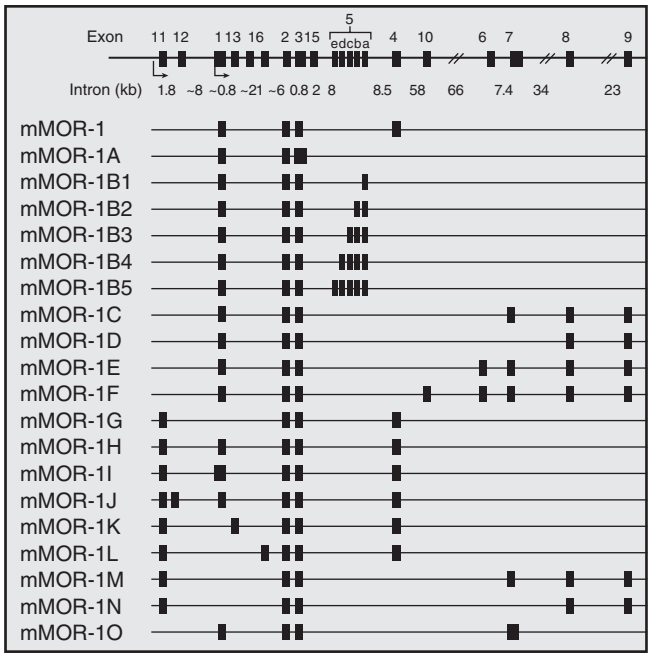

Figure 31-3. Alternate mRNA splicing of the mouse μ-opioid receptor gene leads to a combinatorial diversity of the μ-opioid receptor proteins. *(From Pasternak GW: Molecular insights into mu opioid pharmacology: from the clinic to the bench,* Clin J Pain *26[Suppl 10]:S3-S9, 2010.)*

because it lowered pain thresholds under certain conditions, in contrast to the other endogenous opioid peptides. Pharmacologic and physiologic studies demonstrated that orphanin FQ/nociceptin has behavioral and pain modulatory properties distinct from those of the three classic opioid peptides.[13] Studies of the effect of orphanin FQ/nociceptin on pain sensitivity produced conflicting results that may suggest that the effects of orphanin FQ/nociceptin on pain sensitivity depend on the underlying behavioral state of the animal. Prepronociceptin, the precursor of orphanin FQ/nociceptin, was cloned, and its amino acid sequence suggested the existence of prepronociceptin-derived neuropeptides other than orphanin FQ/nociception.[14]

The search for an endogenous ligand that binds with the μ receptor with high affinity and high selectivity led to the discovery of a class of novel endogenous opioids termed endomorphin-1 and endomorphin-2.[15] These peptides are tetrapeptides with the sequence Tyr-Pro-Trp-Phe and Tyr-Pro-Phe-Phe, respectively. An endomorphin gene has yet to be cloned, and much remains to be learned about the anatomic distribution, mode of interaction with the opioid receptors, function in vivo, and potential existence of other related peptides that are highly selective for each of the opioid receptors.

INTRACELLULAR SIGNAL TRANSDUCTION MECHANISM

The opioid receptors belong to the G-protein–coupled receptor family. Activation of the opioid receptors leads

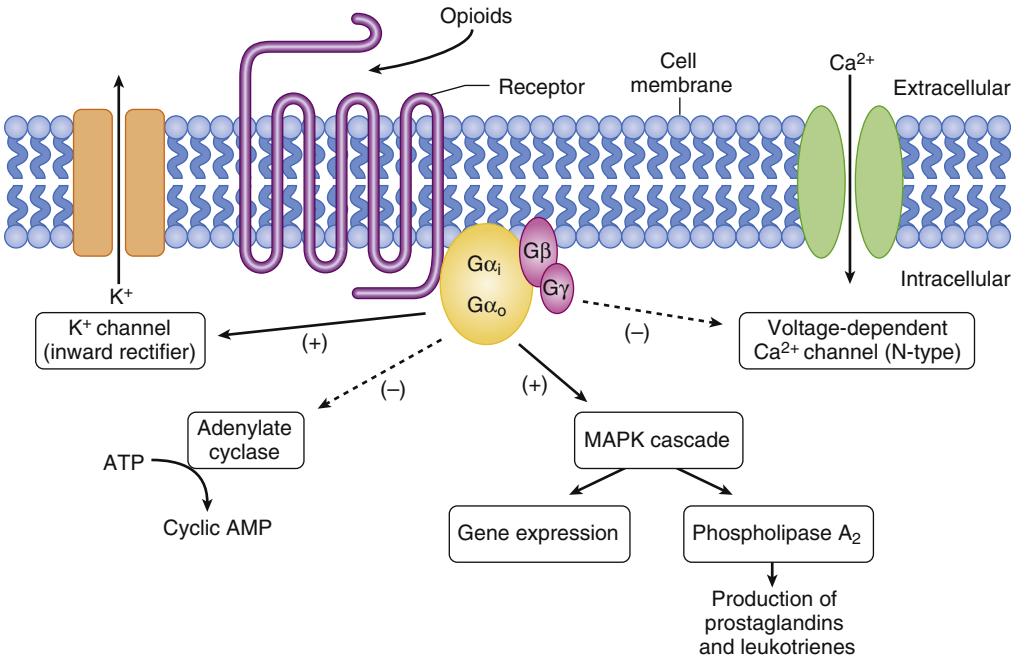

Figure 31-4. Intracellular signal transduction mechanisms linked with the opioid receptors. Opioid agonists bind with the opioid receptors, thus leading to activation of the G protein. Activity of adenylate cyclase and the voltage-dependent calcium (Ca^{2+}) channels is suppressed. Conversely, the inward rectifier potassium (K^+) channels and mitogen-activated protein kinase (MAPK) cascade are activated. *AMP,* Adenosine monophosphate; *ATP,* adenosine triphosphate.

to activation of the pertussis toxin–sensitive G proteins (G_i or G_o or both). Expression of the cloned opioid receptors in cultured cells by transfection of the cloned cDNAs has facilitated analysis of the intracellular signal transduction mechanisms activated by the opioid receptors[2] (Fig. 31-4). Adenylate cyclase is inhibited by opioid receptor activation, with a resulting reduction of the cellular cyclic adenosine monophosphate (AMP) content. Electrophysiologically, the voltage-gated Ca^{2+} channel is inhibited and the inwardly rectifying potassium (K^+) channels are activated by the opioid receptors. As a result, neuronal excitability is reduced by activation of the opioid receptors. In contrast, investigators reported that opioids also stimulate Ca^{2+} influx in neuronal cultured cells.[16] Extracellular signal-related kinase, a class of mitogen-activated protein kinases, is activated by the opioid receptors.[17] Opioid-induced activation of extracellular signal-related kinase can lead to an increase in arachidonate release[17] and expression of the immediate early genes, c-*fos* and *junB*.[18]

Long-term exposure of the opioid receptors to agonists induces cellular adaptation mechanisms, which may be involved in opioid tolerance, dependence, and withdrawal symptoms. Several investigators showed that short-term desensitization probably involves phosphorylation of the opioid receptors through protein kinase C.[19] Several other kinases also have been implicated, including protein kinase A and β-adrenergic receptor kinase (βARK), a member of the G-protein–coupled receptor kinase (GRK).[20] βARKs selectively phosphorylate agonist-bound receptors and thereby promote interactions with β-arrestins, which interfere with G-protein coupling and promote receptor internalization. β-Arrestin 2 functions as a scaffolding protein that interacts with signal transducers, and the recruitment of β-arrestin 2 induced by opioid receptor activation is involved in the regulation of activity of c-Src, Akt, and mitogen-activated protein kinases[21] (Fig.31-5). Acute morphine-induced analgesia was enhanced in mice lacking β-arrestin 2, a finding suggesting that this protein contributes to regulation of responsivity to opioids in vivo.[22]

Like other G-protein–coupled receptors, the opioid receptors can undergo rapid agonist-mediated internalization by a classic endocytic pathway.[23,24] These processes may be induced differentially as a function of the class of the ligand. For example, certain agonists, such as etorphine and enkephalins, cause rapid internalization of the μ receptor, whereas morphine, which decreases adenylyl cyclase activity equally well, does not cause μ-receptor internalization.[25] These findings may suggest that different ligands induce different conformational changes in the receptor that lead to divergent intracellular events. Furthermore, these observations may provide an explanation for differences in the efficacy and abuse potential of various opioids.[26]

Long-term tolerance to opioids is associated with superactivation of adenylyl cyclase activity, which is a counterregulatory response to the decrease in cyclic AMP levels seen after short-term opioid administration.[27] That this effect is prevented by pretreatment of cells with pertussis toxin demonstrates the involvement of G proteins (G_i or G_o or both).

MECHANISM OF ANALGESIA

Pain control by opioids must be considered in the context of brain circuits modulating analgesia and the functions of the various types of receptors in these circuits.[28] The analgesic effects of opioids arise from their ability to inhibit directly the ascending transmission of nociceptive information from the spinal cord dorsal horn and to activate pain control circuits that descend from the midbrain, through the rostral ventromedial medulla (RVM), to the spinal cord dorsal horn. Petrovic and associates used an experimental pain model and positron emission

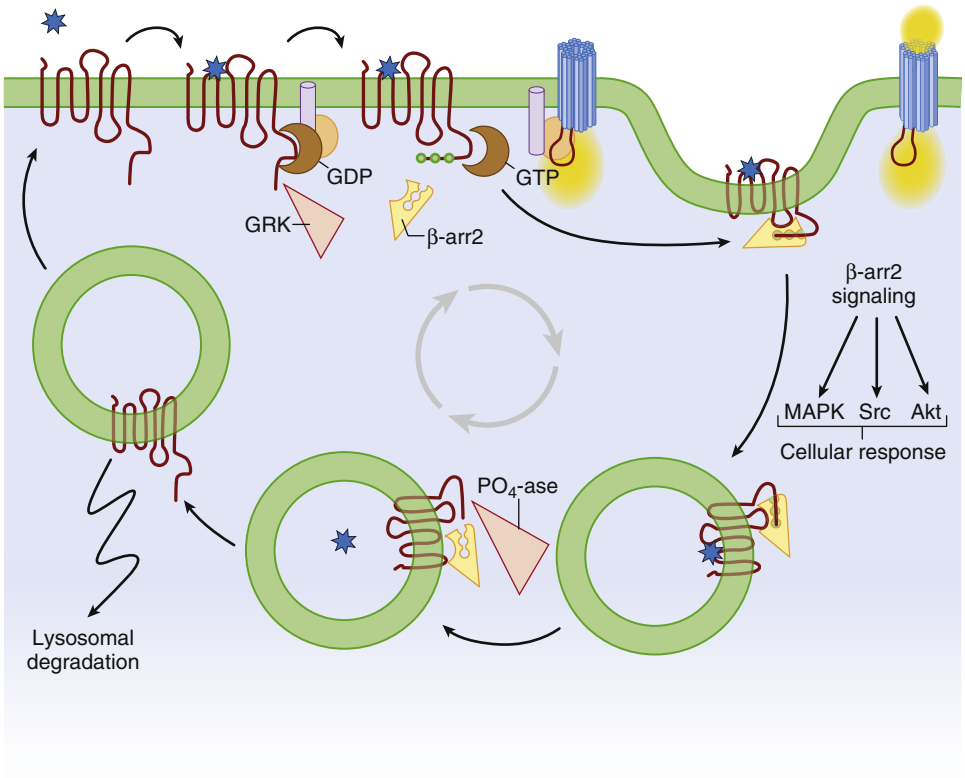

Figure 31-5. β-Arrestin 2 (β-arr2) and G protein in μ-opioid receptor recycling, signaling, and degradation. The *blue star* represents an opioid agonist and the trimeric membrane-associated complex in *brown, green,* and *blue* represents G protein α, β, and γ subunits, respectively. The α subunit is shown associated with guanosine diphosphate (GDP; resting state) or guanosine triphosphate (GTP; activated state). The βγ dimer interacts directly with the voltage-activated calcium (Ca^{2+}) channel to inhibit Ca^{2+} influx (indicated in *yellow*). *GRK,* G-protein–coupled receptor kinase; *MAPK,* mitogen-activated protein kinase; *PO_4-ase,* phosphatase. *(From Hales TG: Arresting the development of morphine tolerance and dependence,* Br J Anaesth *107:653-655, 2011.)*

tomography (PET) to study mechanisms of action of the short-acting μ-opioid agonist remifentanil and found drug-induced activation of the rostral anterior cingulate cortex, insula, orbitofrontal cortex, and brainstem areas.[29] The brainstem overlapped with brain areas that have been implicated in pain modulation, such as the periaqueductal gray (PAG). Surprisingly, placebo analgesia acts similarly on the activity of these brain areas, presumably by endogenous opioid release.[30]

Immunohistochemical studies and in situ hybridization analysis have demonstrated that opioid receptors are expressed in various areas in the central nervous system (CNS).[31] These areas include the amygdala, the mesencephalic reticular formation, the PAG, and the RVM. However, the role of the opioid receptors in all these areas has not been completely clarified.

Microinjection of morphine into the PAG or direct electrical stimulation of this area produces analgesia that can be blocked by naloxone. Opioid actions at the PAG influence the RVM, which in turn modulates nociceptive transmission in the dorsal horn of the spinal cord through the action of the descending inhibition pathway. Thus, opioids produce analgesia by direct actions on the spinal cord, as well as by neurally mediated action in the region separated from the site of opioid administration. Spinal serotonin type 7 ($5\text{-}HT_7$) receptors also play an important role on the antinociceptive effects of systemic morphine.[32]

The distribution of opioid receptors in descending pain control circuits indicates substantial overlap between μ and κ receptors. Interactions between the κ receptor and the μ receptor may be important for modulating nociceptive transmission from higher nociceptive centers, as well as in the spinal cord dorsal horn. The μ receptor produces analgesia within descending pain control circuits, at least in part, by the removal of γ-aminobutyric acidergic (GABAergic) inhibition of RVM-projecting neurons in the PAG and spinally projecting neurons in the RVM.[28] The actions of μ-receptor agonists are invariably analgesic, whereas those of κ-receptor agonists can be either analgesic or antianalgesic. The pain-modulating effects of the κ-receptor agonists in the brainstem appear to oppose those of μ-receptor agonists.[33]

Local spinal mechanisms, in addition to descending inhibition, underlie the analgesic action of opioids. In the spinal cord, opioids act at synapses either presynaptically or postsynaptically. Opioid receptors are abundantly expressed in the substantia gelatinosa, where substance P release from the primary sensory neuron is inhibited by opioids.

Although opioid receptor ligand binding is significant and little detectable receptor mRNA expression occurs in the spinal cord dorsal horn, high levels of opioid receptor mRNA are present in the dorsal root ganglia. This distribution may suggest that the actions of opioid receptor agonists relevant to analgesia at the spinal level are predominantly presynaptic. That opioids decrease the pain-evoked release of tachykinins from primary afferent nociceptors is well known. However, investigators demonstrated that at least 80% of tachykinin signaling in response to noxious stimulation remains intact after the intrathecal administration of large doses of opioids.[34] These results suggest that although opioid administration may reduce tachykinin release from primary afferent nociceptors, this reduction has little functional impact on the actions of tachykinins on postsynaptic pain-transmitting neurons.

The actions of opioids in bulbospinal pathways are critical to their analgesic efficacy. Opioid actions in the forebrain contribute to analgesia. Decerebration prevents analgesia when rats are tested for pain sensitivity using the formalin test,[35] and microinjection of opioids into several forebrain regions is analgesic in this test.[36] Analgesia induced by systemic administration of morphine in both the tail flick and formalin tests was disrupted either by lesioning or reversibly inactivating the central nucleus of the amygdala, thereby demonstrating that opioid actions in the forebrain contribute to analgesia after tissue damage, as well as after acute phasic nociception.[37,38]

Opioids may also produce analgesia through the peripheral mechanism.[39] Immune cells infiltrating the inflammation site may release endogenous opioid-like substances, which act on the opioid receptors located on the primary sensory neuron.[39] However, other findings do not support this conclusion.[40,41]

MECHANISM OF MOOD ALTERATIONS AND REWARDING PROPERTIES

The mechanisms by which opioids produce euphoria, tranquility, and other alterations of mood (including rewarding properties) are not entirely clear. Behavioral and pharmacologic evidence points to the role of dopaminergic pathways, particularly involving the nucleus accumbens (NAcc), in drug-induced reward. A functional magnetic resonance imaging study demonstrated that a small intravenous dose (4 mg) of morphine induces positive signal changes in reward structures, including the NAcc, sublenticular extended amygdala, orbitofrontal cortex, and hippocampus, and decreases signal in cortical areas similar to the action of sedative-hypnotics such as propofol and midazolam.[42] These observations are consistent with results of pharmacologic studies.

The shell of the NAcc is the site that may be involved directly in the emotional and motivational aspects of drug-induced reward. All three opioid receptor types are present on the NAcc and are thought to mediate, at least in part, the motivational effects of opiate drugs.[31] Selective μ- and δ-receptor agonists are rewarding when defined by place preference and intracranial self-administration paradigms. Conversely, selective κ-receptor agonists produce aversive effects. Positive motivational effects of opioids are partially mediated by dopamine release at the level of the NAcc.

The locus ceruleus contains both noradrenergic neurons and high concentrations of opioid receptors and is postulated to play a critical role in feelings of alarm, panic, fear, and anxiety. Neural activity in the locus ceruleus is inhibited by both exogenous opioids and endogenous opioid peptides.

ANALYSIS OF KNOCKOUT MICE

The physiologic roles of the opioid receptors and endogenous opioid peptides have been investigated mainly by pharmacologic and physiologic methods. However, analysis of the functional roles of these proteins has been difficult. More recently, knockout mice, in which a specific gene is inactivated by molecular biologic methods, have been produced. By analysis of knockout mice, the physiologic significance of the respective opioid receptors and endogenous opioid peptide precursors can be determined.[43]

In μ-receptor knockout mice, analgesia, the reward effect, and the withdrawal effect of morphine were lost.[44] Morphine-induced respiratory depression was not observed in μ-receptor knockout mice.[45] Therefore, the μ receptor is a mandatory component of the opioid system for morphine action. In μ-receptor knockout mice, ketamine-induced respiratory depression and antinociception were diminished,[46] a finding suggesting that ketamine interacts with the μ receptor to lead to these phenomena. Furthermore, minimum alveolar concentration (MAC) of sevoflurane was significantly higher in μ-receptor knockout mice than in wild-type mice, an observation suggesting the involvement of the μ receptor in the anesthetic potency of sevoflurane.[45] δ-Receptor knockout mice displayed a markedly reduced analgesic effect of opioids selective for δ receptors at the spinal cord level.[47] However, at the supraspinal level, analgesia could be induced by δ-receptor agonists in δ-receptor knockout mice, a finding suggesting the existence of a second δ-like analgesic system. Disruption of the κ receptor abolished the analgesic, hypolocomotor, and aversive actions of the κ-receptor agonists and induces hyperreactivity in the abdominal constriction test; this finding indicates that the κ receptor is involved in the perception of visceral chemical pain.[48]

In the mice lacking β-endorphin, morphine induced normal analgesia, but naloxone-reversible stress-induced analgesia could not be observed.[49] The preproenkephalin knockout mice were more anxious than wild-type mice, and males displayed increased offensive aggressiveness.[50] The mutant mice showed marked difference from controls in supraspinal, but not spinal, responses to painful stimuli.

Thus, the functional roles of individual components of the opioid system have been elucidated by analysis of knockout mice. However, many points remain to be clarified.

ACTIONS OF OPIOIDS ON TARGETS OTHER THAN OPIOID RECEPTORS

Opioids can interact with molecules other than the opioid receptors. In cardiac myocytes, morphine can inhibit voltage-dependent sodium (Na^+) current in a naloxone-insensitive manner, a finding suggesting the existence of a signal transduction mechanism that is not dependent on the opioid receptors.[51] Buprenorphine, a partial μ-opioid receptor agonist, also has a local anesthetic property and blocks voltage-gated Na^+ channels through the local anesthetic binding site.[52] Meperidine is an agonist of both μ and κ receptors. In addition, meperidine can block voltage-dependent Na^+ channels in amphibian peripheral nerves,[53] as well as in the *Xenopus* oocyte expression system (Fig. 31-6).[54] Furthermore, meperidine exerts agonist activity at the α_{2B}-adrenoreceptor subtype.[55] High concentrations of opioids, including meperidine, morphine, fentanyl, codeine, and naloxone, directly inhibit the *N*-methyl-D-aspartate (NMDA) receptor expressed in *Xenopus* oocytes.[56] Methadone is clinically used as a racemic

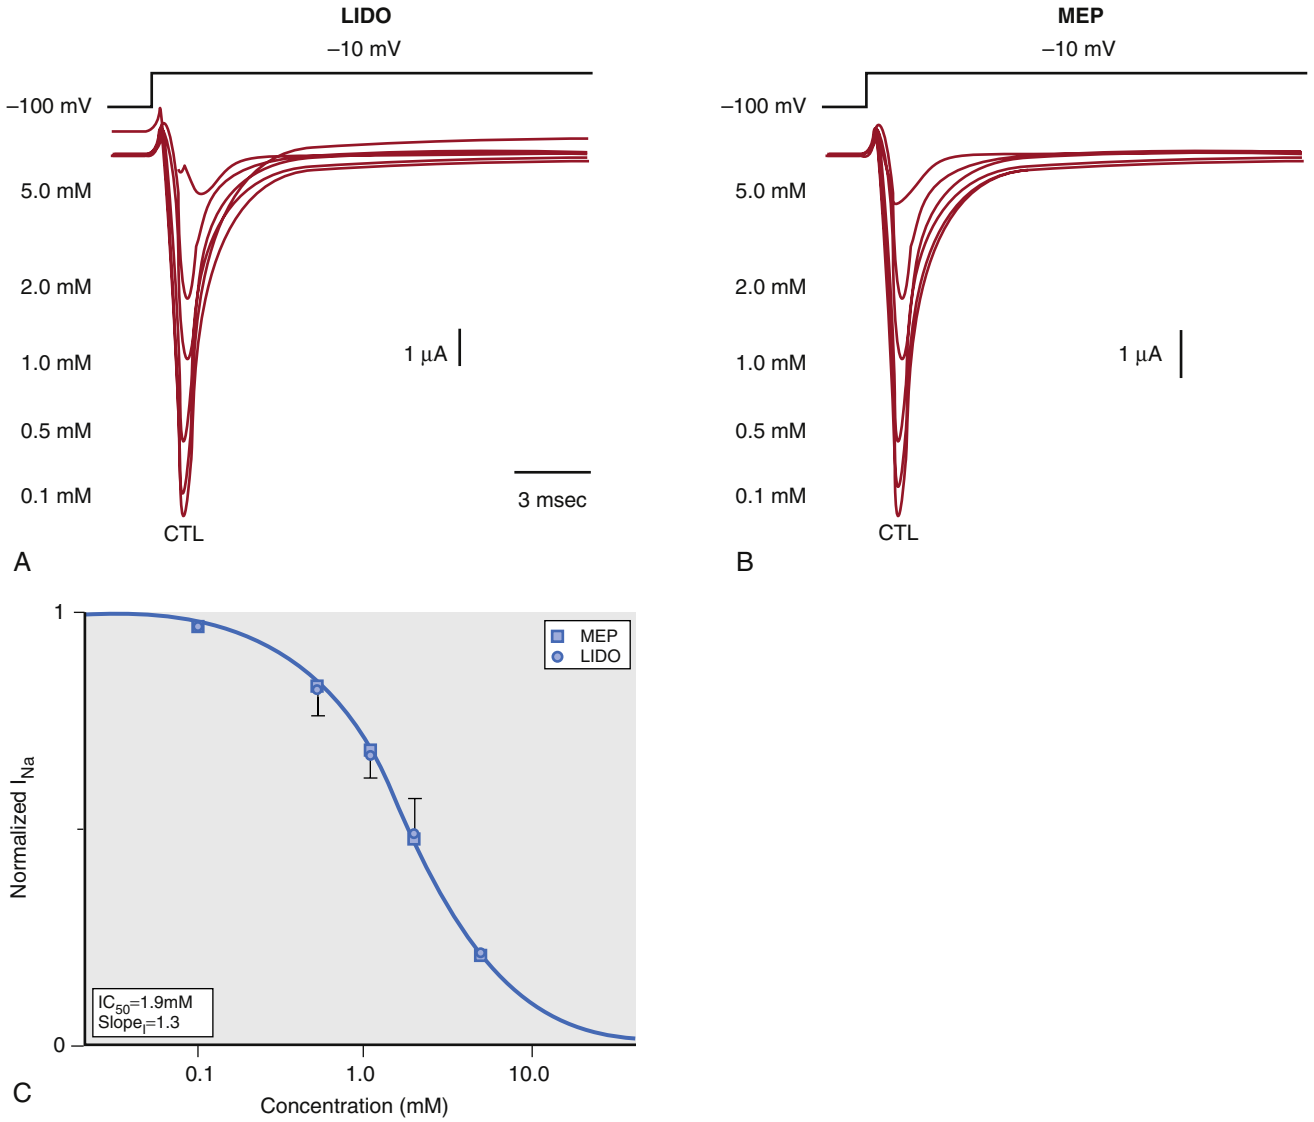

Figure 31-6. A to **C,** Meperidine blocks the sodium (Na^+) channels similarly to lidocaine. Na^+ currents induced by voltage jump were recorded from *Xenopus* oocytes expressing the Na^+ channels. Lidocaine (LIDO; **A**) and meperidine (MEP; **B**) dose dependently inhibited the current. *CTL,* Control. *(From Wagner LE 2nd, Eaton M, Sabnis SS, Gingrich KJ: Meperidine and lidocaine block of recombinant voltage-dependent Na^+ channels: evidence that meperidine is a local anesthetic,* Anesthesiology *91:1481-1490, 1999.)*

mixture of the *l* and *d* isomers. The opioid-like activity of the racemate seems to be almost entirely the result of *l*-methadone, whereas *d*-methadone acts as an NMDA antagonist.[57] The commercially available remifentanil solution (Ultiva), which contains glycine, directly activates the NMDA receptor expressed in *Xenopus* oocytes.[58] Furthermore, an electrophysiologic study in rat spinal cord showed that remifentanil hydrochloride does not directly activate NMDA receptors, the NMDA current recorded after application of Ultiva is related to the presence of glycine, and the glycine-induced NMDA current is potentiated by application of remifentanil hydrochloride through a pathway involving the μ-opioid receptor.[59] The serotonin type 3A (5-HT_{3A}) receptor, which is directly and indirectly linked to gastrointestinal motility, visceral pain, nausea, and vomiting, is competitively inhibited by morphine and hydromorphone, as well as by naloxone; however, investigators found that fentanyl-like opioids did not significantly affect activity of the 5-HT_{3A} receptor.[60,61] Tramadol acts as an agonist of transient receptor potential vanilloid-1 (TRPV1) heterologously expressed in cultured cells.[62] Tramadol may activate TRPV1 in sensory neurons, followed by local release of vasoactive neuropeptides and marked desensitization of the afferent fibers.

PHYSIOLOGIC ROLE OF NOCICEPTIN OR ORPHANIN FQ

Nociceptin or orphanin FQ is a 17-amino-acid peptide, the sequence of which resembles those of opioid peptides. Nociceptin or orphanin FQ precursor mRNA and peptide are present throughout the descending pain control circuits. In the spinal cord, nociceptin or orphanin FQ-receptor mRNA expression is stronger in the ventral horn than in the dorsal horn, but higher levels of ligand binding occur in the dorsal horn. Targeted disruption of the

nociceptin or orphanin FQ receptor in mice had little effect on basal pain sensitivity in several measures, whereas targeted disruption of the N nociceptin or orphanin FQ precursor consistently elevated basal responses in the tail flick test, findings suggesting an important role for nociceptin or orphanin FQ in regulating basal pain sensitivity.[63,64] Intrathecal injections of nociceptin or orphanin FQ have been shown to be analgesic[65]; however, supraspinal administration has produced hyperalgesia, antiopioid effects, or a biphasic hyperalgesic-analgesic response.[66] Nociceptin or orphanin FQ inhibits both pain-facilitating and analgesia-facilitating neurons in the RVM.[67] The effects of nociceptin or orphanin FQ on pain responses appear to depend on the preexisting state of pain in the animal. Physiologic implications of nociceptin or orphanin FQ remain to be elucidated.

Expression of opioid receptors on peripheral blood mononuclear cells is controversial. Williams and associates reported that human peripheral blood mononuclear cells express the nociceptin receptor, but not μ-, δ- or κ-opioid receptors.[68] Nociceptin, produced by the peripheral blood mononuclear cells, may be involved in the control of immune functions.

NEUROPHYSIOLOGIC EFFECTS OF OPIOIDS

ANALGESIC ACTION OF OPIOIDS

In human beings, morphine-like drugs produce analgesia, drowsiness, changes in mood, and mental clouding. A significant feature of opioid analgesia is that it is not associated with loss of consciousness. When morphine in the same dose is given to a normal, pain-free individual, the experience may be unpleasant. The relief of pain by morphine-like opioids is relatively selective in that other sensory modalities are not affected. Patients frequently report that the pain is still present, but they feel more comfortable. It is also important to distinguish between pain caused by stimulation of nociceptive receptors and transmitted over intact neural pathways (nociceptive pain) and pain that is caused by damage to neural structures, often involving neural supersensitivity (neuropathic pain). Although nociceptive pain usually is responsive to opioid analgesics, neuropathic pain typically responds poorly to opioid analgesics and may require larger doses. Not only is the sensation of pain altered by opioid analgesics, but also the affective response is changed.

The analgesic effects, as well as the side effects, of opioids vary among individuals. A pharmacogenomic twin study showed that the interindividual variations in opioid effects are likely the result of genetic and environmental factors.[69,70]

Animal and human studies indicated the existence of sex-related differences in opioid-mediated behavior.[71] Sarton and associates examined the influence of morphine on experimentally induced pain in healthy volunteers and demonstrated the gender differences in morphine analgesia, with greater morphine potency but slower speed of onset and offset in women.[72] In contrast, in a study examining interindividual variability in alfentanil analgesic sensitivity in experimental pain models in humans, no gender differences were detected.[73] The mechanism of the gender difference remains to be clarified.

The pharmacokinetic and pharmacodynamic characteristics of opioids often vary throughout the day, as demonstrated for oral morphine in chronic pain.[74] The duration of intrathecal sufentanil analgesia exhibited a temporal pattern, with 30% variation throughout the day in women in the first stage of labor.[75] The time of day of administration does not seem to influence the duration of labor analgesia with spinal-epidural administration of fentanyl or with systemic hydromorphone administration.[76] The potential impact of chronobiology on clinical practice is not clear, and research on the influence of circadian rhythms on the actions of opioids is warranted.

Some controversy remains regarding analgesia produced by the peripheral actions of opioids. One review concluded from meta-analysis that intraarticularly administered morphine has a definite but mild analgesic effect.[77] It may be dose dependent, and a systemic effect cannot be completely excluded. The addition of opioids in brachial plexus block improves the success rate and postoperative analgesia.[78,79] In contrast, the addition of sufentanil may not prolong the duration of brachial plexus block.[80]

EFFECTS OF OPIOIDS ON CONSCIOUSNESS

Cortical acetylcholine originates in the basal forebrain and is essential for maintaining normal cognition and arousal. Injection of morphine to the substantia innominata or intravenous morphine administration significantly decreased acetylcholine release within the prefrontal cortex in the rat, and this effect may be the neurochemical basis of opioid-induced change in consciousness.[81] Although unconsciousness in humans can be produced with high doses of opioids alone, opioid-based anesthesia can be unpredictable and inconsistent.[82] Therefore, opioids cannot induce anesthesia by themselves.[83] The anesthetic potential of opioids was tested by measurement of MAC.[84] Fentanyl can reduce the MAC of isoflurane at skin incision in patients by at least 80%.[85] The relationship between the plasma fentanyl concentration and reduction in MAC is not linear, and fentanyl has a sub-MAC ceiling effect on reduction of the MAC of isoflurane. The MAC of sevoflurane was also dose dependently reduced by fentanyl, with 3 ng/mL resulting in a 61% reduction in MAC[86] (see also Chapter 33). A ceiling effect was observed for MAC; 6 ng/mL fentanyl provided only an additional 13% reduction in the MAC of sevoflurane. Even potency ratios have been established for the "reduction of volatile anesthetic MAC" for most opioids such as sufentanil, fentanyl, alfentanil, and remifentanil. However, the MAC-reducing capabilites of the opioids are not complete; that is, these are not complete anesthetics. The opioids must be combined with other anesthetics to produce a "complete anesthetic."[85,87-89] Esmolol, a short-acting β_1-receptor antagonist, significantly decreased the MAC of isoflurane in the presence of alfentanil, although it did not significantly affect this parameter in the absence of alfentanil.[90] The mechanism of the interaction is unknown. Epidural fentanyl infusion reduces the awakening concentration of isoflurane more than does intravenous fentanyl infusion despite the lower plasma concentration, possibly by modulating the afferent nociceptive inputs in the spinal cord.[91]

The MAC that prevents movement in response to laryngoscopy and tracheal intubation in 50% of patients (MAC-TI) is higher than the MAC that prevents movement in response to surgical incision (MAC). The MAC-TI of sevoflurane was 3.55% and was reduced markedly to 2.07%, 1.45%, and 1.37% by the addition of fentanyl 1, 2, and 4 μg/kg, respectively, with no significant difference in the reduction between 2 and 4 μg/kg, thus showing a ceiling effect.[92] The MAC that prevents sympathetic responses to surgical incision in 50% of patients (MAC-BAR) decreased with increasing concentrations of fentanyl in plasma, and the initial steep reduction was followed by a ceiling effect.[86]

The bispectral index (BIS) was proposed as a measure of the effects of anesthetic agents on the brain (see also Chapter 50). In the presence of fentanyl, alfentanil, remifentanil, or sufentanil, loss of consciousness occurred at a lower effect-site concentration of propofol and at a higher BIS value than with propofol alone.[93] Furthermore, Wang and colleagues reported that infusion of remifentanil (0.1 to 0.4 μg/kg/minute) did not significantly change the median effective concentration (EC_{50}) of propofol necessary to lower the BIS value to 50 or less.[94] These results suggest that the hypnotic effect of propofol is enhanced by analgesic concentrations of opioids without changes in the BIS value. Conversely, infusion of remifentanil (effect-site target concentrations of 0.25, 2.5, and 10 ng/mL), combined with propofol infusion adjusted to a BIS of approximately 60, dose dependently decreased the BIS, thus suggesting a sedative or hypnotic effect of remifentanil.[95] Response surface analysis showed considerable synergy between opioids and hypnotics for sedation and suppression of responses to various noxious stimuli (see also Chapter 33).[96]

Opioids administered as a mainstay of surgical pain management can inhibit sleep on the first postoperative night. However, the effects of opioids on sleep and circadian rhythm are not clearly understood. A human study demonstrated that an overnight constant infusion of remifentanil inhibited rapid eye movement sleep without suppressing the nocturnal melatonin surge, findings that may suggest a minimal effect of opioids on the circadian pacemaker.[97]

ELECTROENCEPHALOGRAPHY

Increasing concentrations of inhaled anesthetic agents produce a continuum of electroencephalogram (EEG) changes and eventually result in burst suppression and a flat EEG. In contrast, a ceiling effect is reached with opioids. Once this ceiling has been obtained, increasing opioid dosage does not further affect the EEG.[98]

Although the potency and rate of equilibrium between plasma and brain are different among opioids, the effects of fentanyl, alfentanil, sufentanil, and remifentanil are consistent[99] (Fig. 31-7). Small doses of fentanyl (200 μg) produce minimal EEG changes, whereas higher doses (30 to 70 μg/kg) result in high-voltage slow (delta) waves suggesting a state consistent with anesthesia. Although transient isolated (usually frontotemporal) sharp wave activity can be observed after large doses of fentanyl and other opioids, it is not generalized (see also Chapter 49).

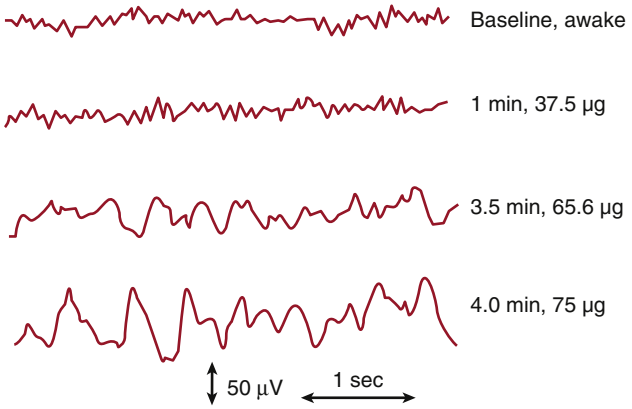

Figure 31-7. Representative 4-second electroencephalogram (EEG) tracings during infusion of sufentanil (total dose shown in the *right column*). The awake baseline EEG consists of mixed beta and alpha activity. At 1 minute, the EEG showed loss of beta activity and the presence of primarily alpha waves (8 to 13 Hz). At 3.5 minutes, the EEG consisted of mixed theta (4 to 7 Hz) and delta (<4 Hz) waves, and at 4.0 minutes, it consisted of delta waves of high amplitude. *(From Scott JC, Cooke JE, Stanski DR: Electroencephalographic quantitation of opioid effect: comparative pharmacodynamics of fentanyl and sufentanil,* Anesthesiology *74:34-42, 1991.)*

As an effect-site measure, the EEG can be employed to assess onset of drug action and drug potency ratios. The spectral edge and serum concentration are closely parallel for remifentanil,[100] whereas a significant time lag is found for recovery of the spectral edge for fentanyl and sufentanil[101] (Fig. 31-8). In healthy volunteers, approximate entropy derived from a parietal montage showed significant correlation with remifentanil concentration, and it was shown to be appropriate for the assessment of the remifentanil effect on the EEG.[102] Potency ratios based on EEG studies are similar to those obtained from studies determining the plasma drug levels of each opioid necessary to reduce the MAC of isoflurane by 50%.

EVOKED RESPONSES

Because opioids do not appreciably alter sensory-evoked potentials elicited at the posterior tibial or median nerve, sensory-evoked potentials can be used for spinal cord function monitoring during anesthesia with opioids.[103] Remifentanil produced dose-dependent reduction in auditory-evoked potentials.[104] Investigators also reported that remifentanil infusion (target plasma concentrations of 1, 2, and 3 ng/mL) did not affect evoked potential amplitudes and latencies.[105] In healthy human volunteers receiving 3 μg/kg fentanyl, amplitude and latency of motor-evoked responses to transcranial stimulation were not significantly affected.[106] Kawaguchi and associates reported that intraoperative myogenic motor-evoked potential monitoring is feasible during isoflurane or sevoflurane anesthesia with fentanyl.[107]

Middle latency auditory-evoked potentials (MLAEPs) and their derivatives are increasingly used as a surrogate measure of the level of anesthesia. Changes in MLAEPs following the administration of opioids occur and may result from either a direct depressant effect of opioids on MLAEPs itself or an indirect effect reflecting the action of

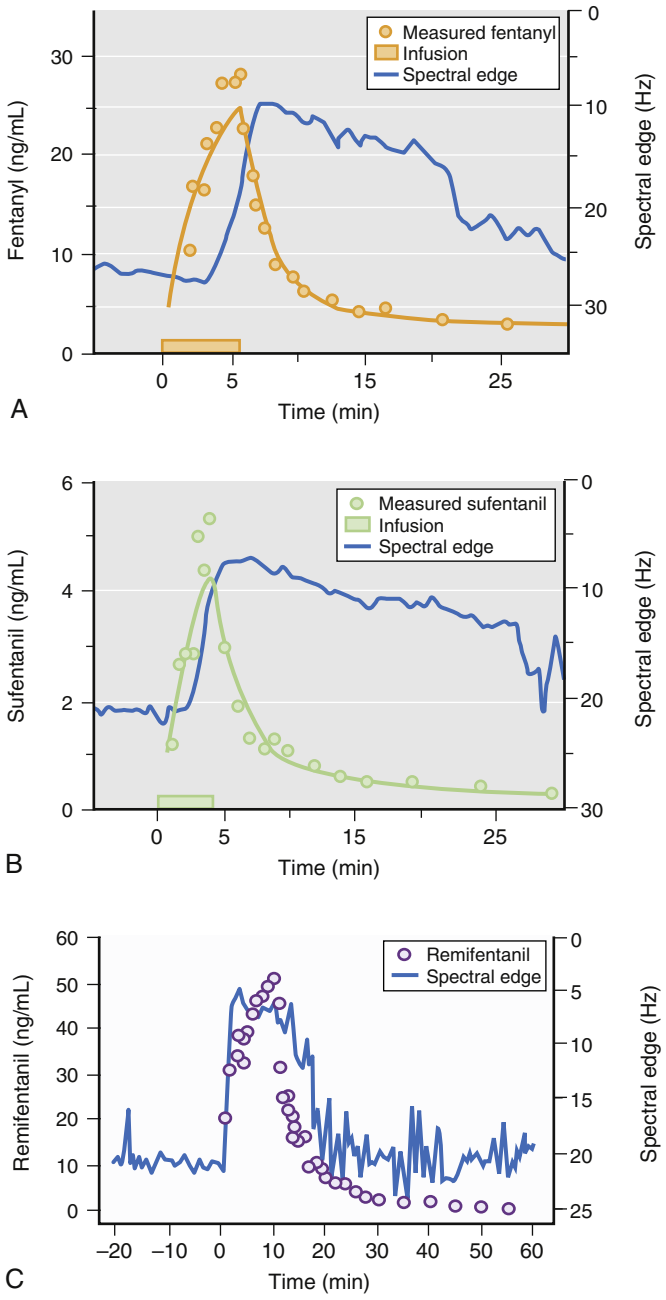

Figure 31-8. Time course of spectral edge and serum opioid concentration. Fentanyl (**A**) and sufentanil (**B**) were infused at 150 and 18.75 μg/minute, respectively. Remifentanil (**C**) was administered at 3 mg/kg/minute for 10 minutes. The spectral edge changes lag behind the serum concentration changes in the case of fentanyl and sufentanil, whereas the spectral edge and serum concentration closely parallel each other in the cases of remifentanil administration. *(From Scott JC, Ponganis KV, Stanski DR: EEG quantitation of narcotic effect: the comparative pharmacodynamics of fentanyl and alfentanil,* Anesthesiology *62:234-241, 1985; and Egan TD, Minto CF, Hermann DJ, et al: Remifentanil versus alfentanil: comparative pharmacokinetics and pharmacodynamics in healthy adult male volunteers,* Anesthesiology *84:821-833, 1996.)*

opioids in attenuating CNS arousal associated with noxious stimuli. Wright and colleagues examined the effect of remifentanil (1 or 3 μg/kg/minute) on MLAEPs in tracheally intubated and nonintubated patients and showed that remifentanil has an effect on MLAEPs in attenuating the arousal associated with intubation of the trachea but has no effect in the absence of a stimulus.[108] Similarly, Schraag and associates found no significant contribution of remifentanil alone on MLAEPs, whereas increasing the concentration of remifentanil led to a significant decrease of the calculated propofol effect-site concentrations necessary for unconsciousness.[109]

CEREBRAL BLOOD FLOW AND CEREBRAL METABOLIC RATE

Opioids generally produce modest decreases in cerebral metabolic rate and intracranial pressure (ICP), although the changes are influenced by the concomitant administration of other agents and anesthetic drugs, as well as by patients' conditions (see also Chapters 49 and 70). When vasodilation is produced by coadministered anesthetic agents, opioids are more likely to cause cerebral vasoconstriction. Opioids also decrease cerebral blood flow (CBF) when they are combined with nitrous oxide (N_2O). When opioids are administered alone or when the coadministered anesthetic agents cause cerebral vasoconstriction, opioids usually have no influence or result in a small increase in CBF.

Endogenous opioid activity is present in the cerebral arteries, although exogenously administered opioids were found to exert little effect on pial artery diameter in several animal models.[110] In the piglet, fentanyl, alfentanil, and sufentanil decreased arteriolar diameter in a dose-dependent naloxone-reversible manner.[111] In human volunteers, PET demonstrated that CBF changes induced by fentanyl are regionally heterogenous.[112]

In healthy volunteers, sufentanil (0.5 μg/kg intravenously [IV]) produces no significant effect on CBF.[113] Alfentanil (25 to 50 μg/kg IV), administered to patients receiving isoflurane (0.4 to 0.6%)–N_2O anesthesia, produces minimal reductions in middle cerebral artery flow velocity.[114] A PET study in human volunteers showed that remifentanil induced dose-dependent changes in relative regional CBF in areas involved in pain processing, such as the lateral prefrontal cortex, inferior parietal cortex, and supplementary motor area.[115] In patients scheduled to undergo a supratentorial tumor surgical procedure and receiving N_2O, remifentanil (1 μg/kg/minute), similar to fentanyl (2 μg/kg/minute), reduced CBF and did not significantly affect cerebrovascular carbon dioxide (CO_2) reactivity.[116]

Opioid-induced neuroexcitation and focal seizure activity can cause regional increases in brain metabolism. Regional increases in glucose use induced by high doses of alfentanil in the rat were associated not only with epileptiform activity but also with neuropathic lesions.[117] In humans, PET evaluation demonstrated that a 1 to 3 μg/kg/minute infusion of remifentanil induces a significant increase in the cerebral metabolic rate for glucose.[118]

INTRACRANIAL PRESSURE

Opioids are generally thought to affect ICP minimally. During isoflurane-N_2O–based anesthesia, opioids do not cause significant increases in ICP in patients undergoing craniotomy for supratentorial space-occupying lesions (see also Chapters 17 and 70).[119,120] Opioid sedation does not alter ICP in patients with head injuries.[121] Light

sedation with remifentanil (4.2 ± 1.8 μg/kg/hour) does not result in higher ICP than that observed with propofol (4.3 ± 2.5 mg/kg/hour) in patients undergoing stereotactic brain tumor biopsy, and cerebral perfusion pressure may be better preserved with remifentanil.[122]

Opioids may produce increases in ICP in patients undergoing craniotomy for excision of supratentorial space-occupying lesions, especially if intracranial compliance is compromised (see also Chapter 70). In a study of patients with severe head injury who have preserved and impaired autoregulation, morphine (0.2 mg/kg) and fentanyl (2 μg/kg) moderately increased ICP, a finding suggesting that mechanisms other than vasodilation could be implicated in the opioid-induced ICP elevation.[123] Investigators also demonstrated no change in ICP in hydrocephalic children after alfentanil (70 μg/kg) administration.[124] Whether these discrepancies of the opioid effects on ICP reflect pressure assessment methods or the effects of other drugs is not clear.

NEUROPROTECTION

Although certain early studies suggested potentially adverse effects of μ-opioid agonists on ischemic brain, other studies documented that certain opioid agents, such as the κ-opioid agonists, can be neuroprotective, at least in animal models of focal ischemia (see also Chapter 70). Investigators also showed that activation of δ-opioid receptors increases the survival time of mice during lethal hypoxia. An in vitro study involving rat cerebellar brain slices demonstrated that pretreatment with morphine at clinically relevant concentrations induced acute neuroprotection mediated by activation of the δ_1-opioid receptors, activation of adenosine triphosphate (ATP)–sensitive K^+ channels, and free radical production in mitochondria.[125]

In contrast, Charchaflieh and associates demonstrated, using the rat hippocampal slice model, that fentanyl is neither neurotoxic nor protective against anoxic injury to neurons when used in concentrations comparable to those produced in clinical practice.[126]

In the rat focal ischemia model, in contrast to isoflurane, fentanyl neither increased nor decreased brain injury compared with awake unanesthetized rats.[127]

MUSCLE RIGIDITY

Opioids can increase muscle tone and may cause muscle rigidity. The incidence of rigidity noted with opioid anesthetic techniques varies greatly because of differences in dose and speed of opioid administration, the concomitant use of N_2O, the presence or absence of muscle relaxants, and the patient's age. Opioid-induced rigidity is characterized by increased muscle tone that sometimes progresses to severe stiffness with the potential for serious problems (Table 31-4). Clinically significant opioid-induced rigidity usually begins just as or after a patient loses consciousness. Mild manifestations of rigidity, such as hoarseness, can occur in conscious patients. Vocal cord closure is primarily responsible for the difficult ventilation with bag and mask that follows the administration of opioids. Delayed or postoperative rigidity is probably related to second peaks that can occur in plasma opioid concentrations, similar to the recurrence of respiratory depression.

TABLE 31-4 POTENTIAL PROBLEMS ASSOCIATED WITH OPIOID-INDUCED RIGIDITY

System	Problem
Hemodynamic	↑CVP, ↑ PAP, ↑ PVR
Respiratory	↓ Compliance, ↓ FRC, ↓ ventilation Hypercarbia, hypoxemia
Miscellaneous	↑ Oxygen consumption, ↑ intracranial pressure, ↑ fentanyl plasma levels

CVP, Central venous pressure; *FRC,* functional residual capacity; *PAP,* pulmonary artery pressure; *PVR,* pulmonary vascular resistance.

The precise mechanism by which opioids cause muscle rigidity is not clearly understood. Muscle rigidity is not the result of a direct action on muscle fibers because it can be decreased or prevented by pretreatment with muscle relaxants. Mechanisms of opioid-induced muscle rigidity involving the CNS have been postulated. Pharmacologic investigation using selective agonists and antagonists suggest that systemic opioid-induced muscle rigidity is primarily caused by activation of central μ receptors, whereas supraspinal δ_1 and κ_1 receptors may attenuate this effect.[128] Some aspects of opioid-induced catatonia and rigidity (increased incidence with age, muscle movements resembling extrapyramidal side effects) are similar to Parkinson disease and suggest similarities in neurochemical mechanisms. Patients with Parkinson disease, particularly if they are inadequately treated, may experience reactions such as dystonia following opioid administration.[129]

Pretreatment with or concomitant use of nondepolarizing muscle relaxants can decrease the incidence and severity of rigidity (see also Chapter 34). Induction doses of sodium thiopental and subanesthetic doses of diazepam and midazolam can prevent, attenuate, or successfully treat rigidity.

NEUROEXCITATORY PHENOMENA

Fentanyl causes seizure activity seen on the EEG in animals, but EEG evidence of seizure activity after fentanyl, alfentanil, and sufentanil is generally lacking in humans. Remifentanil induced generalized tonic-clonic seizure-like activity in an otherwise healthy adult.[130] Morphine produces tonic-clonic activity after epidural and intrathecal administration.[131] Focal neuroexcitation on the EEG (e.g., sharp and spike wave activity) occasionally occurs in humans after large doses of fentanyl, sufentanil, and alfentanil.

The mechanisms underlying opioid-induced neuroexcitatory phenomena are not completely clear. Excitatory opioid actions may be related to coupling to mitogen-activated protein kinase cascades.[132] Local increases in CBF and metabolism are also of theoretic concern because prolonged seizure activity, even if focal, could lead to neuronal injury or cellular death. Fentanyl, alfentanil, and sufentanil in large doses also induced hypermetabolism

and histopathologic alterations of the limbic system in rats.[133] Experimental study using excised mouse hippocampus showed that the proseizure effect of morphine is mediated by selective stimulation of the μ- and κ-opioid receptors but not the activation of the δ-opioid receptor.[134] In rats, midazolam, naloxone, and phenytoin prevented EEG seizure activity and histologically evident brain damage induced by large doses of fentanyl.[135]

Measurement of CBF by magnetic resonance imaging in human volunteers indicated that the cingulate cortex is the most susceptible to activation by remifentanil (0.05 to 0.2 μg/kg/minute), and susceptibility is affected by the apolipoprotein E genotype.[136] These findings support the notion that neuroactivation of limbic areas by the perioperative use of opioids may have a role in the genesis of postoperative cognitive dysfunction.

PUPIL SIZE

Morphine and most μ- and κ-agonists cause constriction of the pupil by an excitatory action on the parasympathetic nerve innervating the pupil. Opioids release cortical inhibition of the Edinger-Westphal nucleus, with resulting papillary constriction. After intravenous administration of morphine (0.125 mg/kg) in one report, a 26% decrease in pupil diameter occurred at 1 hour, and a period of more than 6 hours was necessary for complete recovery of pupil diameter.[137] The changes in pupil size associated with opioid action may be too slight to be of clinical utility in assessing the degree of opioid effect. The pupillary dilatation reflex has been successfully used to assess the analgesic component of a balanced anesthetic regimen. The pupillometer may be a valuable tool to guide morphine administration in the immediate postoperative period.[138]

PRURITUS

Histamine release is not causative because non–histamine-releasing opioids also produce pruritus. Intrathecal morphine-induced itching in monkeys was suggested to be mediated by the μ receptor.[139] Activation of a μ-opioid receptor isoform MOR1D by morphine induced activation of the gastrin-releasing peptide receptor that heterodimerized with MOR1D, thus resulting in activation of phospholipase β_3 and intracellular Ca^{2+} increase in neurons leading to itch sensation in mice.[140] Naloxone reverses opioid-induced itching, but opioid antagonists are not ideal therapeutic agents against pruritus because opioid analgesia is also reversed by these agents. A meta-analysis demonstrated that prophylactic use of serotonin type 3 ($5\text{-}HT_3$) antagonists significantly reduced the severity and the need for treatment of pruritus.[141] Activation of the κ-opioid receptor inhibits pruritus evoked by subcutaneous and intrathecal morphine in animal models.[142] Tamdee and colleagues reported that 15 mg of pentazocine, an agonist of the κ-opioid receptor and partial agonist of the μ-opioid receptor, is superior to 4 mg of ondansetron for the treatment of pruritus induced by intrathecal morphine in parturients undergoing cesarean delivery.[143] Tenoxicam, a nonsteroidal antiinflammatory drug (NSAID), was reported to be effective for pruritus induced by epidural fentanyl.[144] Intravenous administration of droperidol (1.25 mg), propofol (20 mg), or alizapride (100 mg) reduced the incidence of pruritus induced by the use of morphine 0.2 mg intrathecally in patients undergoing cesarean section with spinal anesthesia.[145] Preoperative gabapentin prevents pruritus induced by intrathecal morphine in patients undergoing lower limb operations with spinal anesthesia.[146]

Facial itching may not necessarily be a manifestation of direct opioid action at the level of the trigeminal nucleus, but rather, it may reflect opioid-triggered neural transmission at a distant site. Why the face is prone to pruritus even after spinal opioid administration is not known. Pruritus resulting from cholestasis is ameliorated by opioid antagonists.[147]

RESPIRATORY EFFECTS OF OPIOIDS

The respiratory depressant actions of opioids represent their most serious adverse effects (see also Chapter 51). Although some early studies indicated involvement of both μ- and δ-opioid receptors, a more recent report demonstrated that activation of the μ-opioid receptor in the caudal medullary raphe region, which is important for regulating pain and respiratory modulation, inhibits the ventilatory response to hypercapnia in anesthetized rats.[148] Furthermore, administration of morphine or M6G did not produce significant respiratory depression in the μ-opioid receptor knockout mice.[149] Polymorphism of the μ-opioid receptor at nucleotide position 118, which is known to affect M6G-induced analgesia, does not significantly change the susceptibility of respiratory depressive effect of M6G.[10] This result suggests that analgesia and respiratory depression may be mediated by different signal transduction mechanisms activated by the μ-opioid receptor.

Morphine depresses respiratory mucous transport, which is one of the most important defenses against respiratory tract infections. However, morphine had no effect on the beating frequency of nasal cilia in vitro.[150]

THERAPEUTIC EFFECTS

By decreasing pain and central ventilatory drive, opioids are effective agents in preventing hyperventilation induced by pain or anxiety. Because the lack of adequate pain relief can also cause postoperative respiratory dysfunction, opioids can be used as postoperative analgesics to prevent respiratory dysfunction. The antitussive actions of opioids are well known and central in origin. Investigators reported that an effect-site concentration of 2 ng/mL of remifentanil can suppress coughing induced by extubation after propofol or sevoflurane anesthesia.[151] In contrast, fentanyl, sufentanil, and alfentanil curiously elicit a brief cough in up to 50% of patients when the drug is injected by intravenous bolus. Fentanyl, administered through a peripheral intravenous cannula, provoked cough when it was injected rapidly, but the incidence of cough decreased significantly as the injection time was increased,[152] as well as by the administration of 1.5 mg/kg lidocaine 1 minute before fentanyl administration.[153] Investigators reported that preemptive use of 25 μg, administered 1 minute before bolus injection of

fentanyl (125 or 150 μg), can effectively suppress fentanyl-induced cough.[154] A prospective randomized controlled study demonstrated that a huffing maneuver, consisting of a forced expiration against an open glottis, just before intravenous fentanyl administration significantly reduced the incidence and severity of fentanyl-induced coughing in the majority of the patients.[155]

Opioids are also excellent agents for depressing upper airway, tracheal, and lower respiratory tract reflexes, but the mechanism is not clear. Although opioids can affect the contractile responses of airway smooth muscles, the clinical significance and relevance of opioid-induced effects on airway resistance remain controversial.[156] Opioids blunt or eliminate somatic and autonomic responses to tracheal intubation. They allow patients to tolerate endotracheal tubes without coughing or "bucking." Conversely, two successive dose of 1.5 μg/kg fentanyl did not effectively prevent laryngospasm in children 2 to 6 years old who were anesthetized with sevoflurane.[157] Opioids can also help avoid increases in bronchomotor tone in asthma. In addition, fentanyl also has antimuscarinic, antihistaminergic, and antiserotoninergic actions and may be more effective than morphine in patients with asthma or other bronchospastic diseases.

RESPIRATORY DEPRESSION

Opioids activating the μ receptor cause dose-dependent depression of respiration, primarily through a direct action on brainstem respiratory centers.[158] The stimulatory effect of CO_2 on ventilation is significantly reduced by opioids. Hypercapnic responses can be separated into central and peripheral components. In one report, morphine-induced changes in the central component were equal in men and women, whereas changes in the peripheral component were larger in women.[159] In addition, the apneic threshold and resting end-tidal partial pressure of CO_2 are increased by opioids (Fig. 31-9). Opioids also decrease hypoxic ventilatory drive.

Respiratory rate is usually drastically decreased in opioid overdose, although a hypoxic CNS insult can counter this effect. The prolonged expiratory time in the respiratory cycle induced by opioids frequently results in greater reductions in respiratory rate than in tidal volume. Monitoring of breath intervals can sensitively detect fentanyl-induced respiratory depression and can be used as a measure of dynamic opioid effect.[160] High doses of opioids usually eliminate spontaneous respirations without necessarily producing unconsciousness. Patients receiving high doses of opioids may still be responsive to verbal command and often breathe when they are directed to do so.

Peak onset of respiratory depression after an analgesic dose of morphine is slower than after comparable doses of fentanyl, and respiratory depression induced by small doses of morphine usually lasts longer than after equipotent doses of fentanyl. Sufentanil (0.1 to 0.4 μg/kg) produces shorter-lasting respiratory depression and longer-lasting analgesia than does fentanyl (1.0 to 4.0 μg/kg).[161] Plasma fentanyl concentrations of 1.5 to 3.0 ng/mL are associated with significant decreases in CO_2 responsiveness. With higher doses of fentanyl (50 to 100 μg/kg),

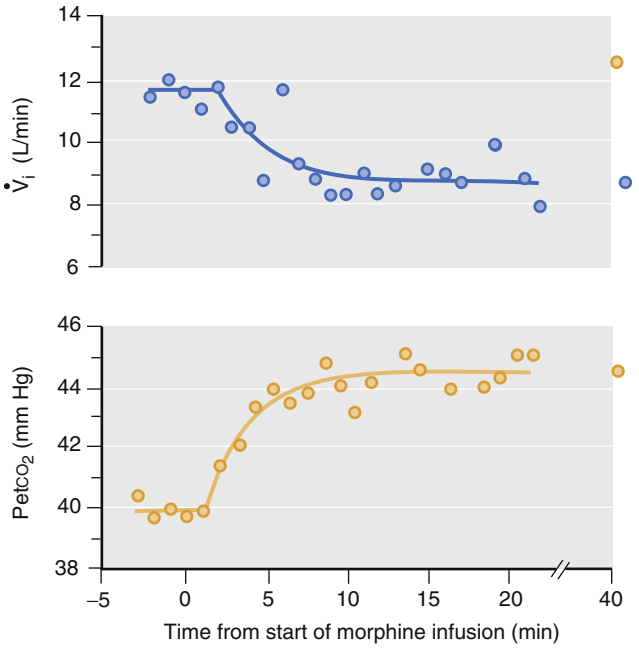

Figure 31-9. Influence of morphine administration (bolus dose of 100 μg/kg given at the start of the infusion [0 minute], followed by a continuous infusion of 30 μg/kg/hour) on resting inspired minute ventilation ($\dot{V}_i$) and resting pressure of end-tidal carbon dioxide ($Petco_2$) in a single subject. A one-component exponential was fitted to the data. The estimated time constant for the $\dot{V}_i$ data is 3.0 minutes and for $Petco_2$ data is 2.6 minutes. The time delays are between 1 and 2 minutes. *(From Sarton E, Teppema L, Dahan A: Sex differences in morphine-induced ventilatory depression reside within the peripheral chemoreflex loop,* Anesthesiology *90:1329-1338, 1999.)*

respiratory depression can persist for many hours. When moderately large doses (20 to 50 μg/kg or greater) of fentanyl are used, the potential need for postoperative mechanical ventilation should be anticipated. The effects of remifentanil, no matter what the dose, are attenuated rapidly and completely within 5 to 15 minutes following termination of its administration. In healthy humans, the EC_{50} for depression of minute ventilation with remifentanil and alfentanil was 1.17 ng/mL and 49.4 ng/mL, respectively.[162] In healthy volunteers, fentanyl 1 μg/kg and remifentanil 0.5 μg/kg had similar maximum decreases in minute ventilation (≈50%), but the onset of and recovery from ventilatory depression were faster with remifentanil.[163]

Naloxone has been accepted as a standard therapy for opioid-induced respiratory depression. However, reports have noted naloxone-resistant respiratory depression after intrathecal morphine administration.[164] Although serotonin agonists, ampakines, and the antibiotic minocycline may be considered newer treatments to prevent opioid-induced respiratory depression, more study is necessary before these treatments are used in humans.[158]

FACTORS AFFECTING OPIOID-INDUCED RESPIRATORY DEPRESSION

Many factors affect the magnitude and duration of opioid-induced respiratory depression (Box 31-2).

BOX 31-2 ***Factors Increasing the Magnitude and/or Duration of Opioid-Induced Respiratory Depression***

High dose
Sleep
Old age
Central nervous system depressant
  Inhaled anesthetics, alcohol, barbiturates, benzodiazepines
Renal insufficiency
Hyperventilation, hypocapnia
Respiratory acidosis
Decreased clearance
  Reduction of hepatic blood flow
Secondary peaks in plasma opioid levels
  Reuptake of opioids from muscle, lung, fat, and intestine
Pain

Older patients are more sensitive to the anesthetic and respiratory depressant effects of opioids (see also Chapter 80). Older patients also experience higher plasma concentrations of opioids administered on a weight basis. Morphine can produce greater respiratory depression on a weight basis in neonates than in adults because morphine easily penetrates the brain in neonates and infants with incomplete blood-brain barriers.

The respiratory depressant effects of opioids are increased or prolonged (or both) when these drugs are administered with other CNS depressants, including potent inhaled anesthetic agents, alcohol, barbiturates, benzodiazepines, most intravenous sedatives, and hypnotics. However, droperidol, scopolamine, and clonidine do not enhance the respiratory depressant effects of fentanyl or other opioids.

Although opioid action is usually dissipated by redistribution and hepatic metabolism, rather than by urinary excretion, the adequacy of renal function may influence the duration of opioid activity. In renal insufficiency, the respiratory depressant properties of the morphine metabolite M6G would become evident as it accumulated.

Hypocapnic hyperventilation enhances and prolongs postoperative respiratory depression after fentanyl (10 and 25 μg/kg). Intraoperative hypercarbia produces the opposite effects. Possible explanations for these findings include increased brain opioid penetration (increased un-ionized fentanyl with hypocarbia) and removal (decreased CBF with hypocarbia). In patients who hyperventilate because of anxiety or pain, even small doses of intravenous opioids can result in transient apnea because of acute shifts in apneic thresholds.

Delayed or recurring respiratory depression has been reported with most opioids. Mechanisms for this phenomenon may include augmented release of fentanyl or other opioids from skeletal muscle into the systemic circulation on rewarming, shivering, motion, or any other condition that enhances muscle perfusion.

CARDIOVASCULAR EFFECTS OF OPIOIDS

Numerous reports have demonstrated that large doses of opioid, administered as the sole or primary anesthetic agent, result in hemodynamic stability throughout the operative period.

NEUROLOGIC MECHANISMS

Key areas of the brainstem that integrate cardiovascular responses and maintain cardiovascular homeostasis are the nucleus solitarius, the dorsal vagal nucleus, the nucleus ambiguus, and the parabrachial nucleus. The nucleus solitarius and parabrachial nucleus play an important role in the hemodynamic control of vasopressin secretion. Enkephalin-containing neurons and opioid receptors are distributed in these regions. The direct administration of μ-agonists into the CNS of animals most commonly, but not always, produces hypotension and bradycardia.[165] The ventrolateral PAG region, a key central site mediating opioid analgesia, also affects hemodynamic control.[166] In addition, opioids can modulate the stress response through receptor-mediated actions on the hypothalamic-pituitary-adrenal axis. Most opioids reduce sympathetic and enhance vagal and parasympathetic tone. Patients who are volume depleted, or individuals depending on high sympathetic tone or exogenous catecholamines to maintain cardiovascular function, are predisposed to hypotension after opioid administration.

The predominant and usual effect of opioids on heart rate is bradycardia resulting from stimulation of the central vagal nucleus. Blockade of sympathetic actions may also play a role in opioid-induced bradycardia. Meperidine, in contrast to other opioids, rarely results in bradycardia, but it can cause tachycardia.

CARDIAC MECHANISMS

The direct cardiac actions of opioids, in particular the effects on myocardial contractile mechanisms, are significantly less pronounced than are those of many other intravenous and inhaled anesthetics. However, opioid receptors exist in cardiac myocytes of several species.

Contractility

Morphine decreases Ca^{2+} transients but not cardiac contraction and enhances myofilament Ca^{2+} sensitivity through the action on the δ_1-opioid receptor expressed in the heart.[167] In rabbit ventricular myocytes, morphine prolonged action potential duration by increasing L-type Ca^{2+} current, an effect mediated by δ- and κ-opioid receptors, and hyperpolarized cardiac resting membrane potential by increasing the inwardly rectifying K^+ current, which is not mediated by opioid receptors.[168] Conversely, investigators demonstrated that morphine decreased the isometric force of contraction in atrial muscles from nonfailing and failing human hearts through a naloxone-insensitive mechanism.[169] Fentanyl produces little or no change in myocardial contractility.[170] Usually, most hemodynamic variables remain unchanged after large doses of fentanyl. However, fentanyl has positive inotropic effects. Possible mechanisms of the dose-dependent positive inotropic effects of fentanyl, as well as those of sufentanil, include catecholamine release or direct myocardial adrenergic activation. Alfentanil, at concentrations achieved in clinical practice, increases contraction

in ventricular cells by a mechanism involving an increase in the sensitivity of the contractile apparatus to Ca^{2+}.[171] The negative inotropic effect of tumor necrosis factor-α (TNF-α) and interleukin-1β (IL-1β) on ventricular myocytes caused by disruption of sarcoplasmic reticulum Ca^{2+} handling and the Ca^{2+} transient was reported to be ameliorated by alfentanil, but this response may not be mediated by opioid receptors.[172] Studies in dogs demonstrated little change in hemodynamics with moderate doses (160 μg/kg) of alfentanil and transient cardiac stimulation (increases in left ventricular contractility, aortic blood flow velocity, and acceleration) with very large doses (5 mg/kg). In dogs, remifentanil produced hemodynamic effects that include decreases in contractility and cardiac output, as well as reductions in heart rate and blood pressure.[173] However, a study using transthoracic echocardiography demonstrated that continuous target-controlled infusion of remifentanil (target effect-site concentration 2 ng/mL, infusion rate 0.08 to 0.09 μg/kg/minute) did not affect systolic and diastolic left ventricular function in young healthy subjects during spontaneous breathing.[174]

Cardiac Rhythm Conduction

Opioid-induced bradycardia is primarily mediated by the CNS (see also Chapter 45). However, some reports have noted direct effects of opioids on cardiac pacemaker cells. Alfentanil significantly decreased the frequency of contractions of the right atrial-sinoatrial node in a dose-related manner in isolated cardiac tissues from young adult rabbits.[175] Premedication with or concomitant administration of β-adrenergic or Ca^{2+} channel entry blockers can exacerbate the bradycardia and may result in asystole after the administration of opioids. Periods of asystole, 10 to 12 seconds in duration, may resolve spontaneously, but they usually respond to atropine (0.4 to 0.8 mg IV).

Fentanyl may depress cardiac conduction by a mechanism mediated by direct membrane actions, as opposed to opioid receptor interactions.[176] During induction of anesthesia in patients undergoing coronary artery bypass graft surgery, the QT interval increased significantly after the injection of fentanyl[177] (see also Chapter 67). However, pretreatment with fentanyl (2 μg/kg) or remifentanil (1 μg/kg) significantly attenuated QTc prolongation associated with laryngoscopy and tracheal intubation during propofol or sevoflurane induction.[178,179] Both sufentanil and alfentanil have been demonstrated to be devoid of electrophysiologic effects on the normal or accessory pathways in patients with Wolff-Parkinson-White syndrome.[180,181] Clinically, cardiac conduction disturbances attributable to opioids are rare, but they may be more likely to occur in the presence of Ca^{2+} channel or β-adrenergic blockers.

The overall effect of opioid anesthesia is antiarrhythmogenic. Naloxone, morphine, and levorphanol protected against arrhythmia induced by coronary artery occlusion in rats.[182] A direct effect on ionic currents in cardiac muscle was suggested as the mechanism of the antiarrhythmogenic activity of opioids. Opioid antagonists were more antiarrhythmogenic than were agonists in rats.[183] Some of the electrophysiologic actions of opioids resemble those of class III antiarrhythmogenic drugs.

Myocardial Ischemia

Determining the effects and consequences of opioid action on myocardial ischemia is complex because the results can depend on such factors as the species studied and experimental design (see also Chapter 67). In an experimental model of myocardial ischemia in rabbits, fentanyl had antiarrhythmic and antiischemic action with central and peripheral opioid receptor involvement.[184] Opioids can mimic ischemic preconditioning. Opioid receptor stimulation results in a reduction in infarct size similar to that produced by ischemic preconditioning.[185] Although the preconditioning effect of opioids is mediated mainly by the cardiac κ- and δ-opioid receptors,[186] part of the protective effect of remifentanil may be produced by μ-agonist activity outside the heart.[187] Preconditioning with small doses of intrathecal morphine can provide comparable cardioprotection to myocardial ischemic preconditioning and preconditioning with intravenous morphine, and the effect seems to involve δ-, κ- and μ-opioid receptors.[188] Late preconditioning, in which cardioprotective effects can be observed 24 hours after drug administration, was also produced by morphine-induced activation of the opioid receptor in rat hearts.[189] Remote preconditioning by brief ischemia of other distant organs, such as the intestine, kidney, and limb, similarly provides cardioprotection that is as effective as classic ischemic preconditioning. The myocardial κ-opioid receptors were demonstrated to mediate cardioprotection by remote preconditioning.[190] Brief cycles of ischemia and reperfusion during the early phase of reperfusion protect the heart from infarction. This phenomenon, termed *postconditioning*, was shown to be induced by activation of the κ-opioid receptor in the heart.[191] Volatile anesthetic agents may also be capable of producing protection against ischemic injury when these drugs are administered solely on reperfusion. This anesthetic-induced postconditioning can be enhanced by morphine through the activation of phosphatidyl-3-kinase and opioid receptors.[192]

Stimulation of δ_1-opioid receptor generates oxygen (O_2) radicals through mitochondrial ATP-sensitive K^+ channels, with resulting attenuation of oxidant stress and cell death in cardiomyocytes.[193] Involvement of adenosine A1 receptor and protein kinase C in the cardioprotective effect of opioids was also suggested.[194,195] Whether the experimental results showing protective effects of opioid against myocardial ischemia will translate into reductions in morbidity and mortality in patients with coronary artery disease has yet to be established by clinical trials.[196] Clinically, large doses of opioids can maintain myocardial perfusion and the O_2 supply-demand ratio as well as or better than can inhalation-based techniques.

Coronary Circulation

Opioids appear to have no significant effect on coronary vasomotion or myocardial metabolism; they do not produce steal phenomena, and they do not diminish the ability of large coronary arterioles to respond to vasoactive agents.[197] Coronary conductance is regulated by arterial baroreflex control, and a vasodilator response is induced by a rise in aortic pressure. This baroreflex control is enhanced by low plasma concentrations of

fentanyl (1 to 2 ng/mL), but it appears to be depressed with increasing plasma concentrations of fentanyl.[198] In a study of the effects of opioids and neuroendocrine modulators on porcine coronary arteries, fentanyl, but not sufentanil or morphine, antagonized acetylcholine-induced contractions.[199] The effect of fentanyl was not reversible by naloxone and thus was thought to represent a direct smooth muscle effect.

Circulatory Reflexes

In an experiment examining baroreceptor reflex responses induced by perfusion of the carotid sinus at predetermined levels, baroreceptor reflexes were well preserved with moderate doses of fentanyl, whereas high doses of fentanyl depressed the baroreceptor reflexes.[200] The oculocardiac reflex, which is caused by traction on the extraocular muscles during surgical procedures for strabismus, was significantly augmented by fentanyl, sufentanil, and remifentanil.[201] Among pediatric patients undergoing surgical procedures for strabismus and anesthetized with propofol (12 mg/kg/hour) and alfentanil (0.04 mg/kg/hour), virtually all patients developed oculocardiac reflex, and atrioventricular rhythm disorders were frequent.[202]

HISTAMINE RELEASE

Morphine causes histamine release and sympathoadrenal activation. Codeine and meperidine induce mast cell activation with the release of histamine, probably by a mechanism other than the μ-opioid receptors.[203]

Increases in plasma histamine after morphine administration cause dilatation of terminal arterioles and direct positive cardiac chronotropic and inotropic actions. In patients pretreated with both H_1- and H_2-antagonists, the cardiovascular responses are significantly attenuated despite comparable increases in plasma histamine concentrations. Meperidine also causes histamine release more frequently than do most other opioids. Unlike morphine or meperidine, fentanyl, alfentanil, and remifentanil do not produce increases in plasma histamine, and hypotension is less frequent with these opioids.

VASCULAR MECHANISMS

A more recent pharmacologically defined opioid receptor subtype, designated μ_3, is opiate alkaloid sensitive and insensntive to opioid peptides including peptides previously shown to have affinities for the μ-opioid receptors. This receptor is expressed in human endothelial cells and is coupled to vasodilation through nitric oxide production. Morphine-induced vasodilation may be partially caused by activation of the μ_3 receptor.[204] Pharmacologic studies evaluating alfentanil, fentanyl, and sufentanil in dogs demonstrated direct peripheral vessel smooth muscle relaxation.[205] Measurement of forearm blood flow after infusion of sufentanil into the brachial artery indicated that sufentanil has a direct vasodilatory effect on human vascular tissue that is probably independent of a neurogenic or systemic mechanism.[206] A supraclinical dose of alfentanil attenuated the phenylephrine-induced contraction through an inhibitory effect on calcium (Ca^{2+}) influx by blocking the L-type Ca^{2+} channels in rat aortic vascular smooth muscle.[207] Remifentanil can cause transient instability in hemodynamic variables. However, this change may not solely be the result of autonomic nervous system or CNS inhibition or centrally mediated vagal stimulation. A pharmacologic study using rat thoracic aortic rings indicated that remifentanil vasodilates by an endothelium-dependent mechanism involving prostacyclin and nitric oxide released from the endothelium and by an endothelium-independent vasodilation probably mediated by the suppression of voltage-sensitive Ca^{2+} channels.[208] In patients with total artificial hearts in which cardiac output is preload independent, remifentanil induces a dose-dependent and significant systemic vasodilation without significant effects on capacitance vessels.[209]

Opioids may affect the pulmonary vasculature, as well as the systemic circulation. Phenylephrine-induced contraction of the canine pulmonary artery was primarily mediated by α_{1B}-adrenergic receptor activation, and it was attenuated by fentanyl by binding to and directly inhibiting the α_{1B}-adrenergic receptor.[210] Pharmacologic studies in cats demonstrated that sufentanil and remifentanil have potent vasodepressor activity in the pulmonary vascular bed and that these responses may be mediated by the histamine and opioid receptor–sensitive pathway.[211,212]

Activation of muscarinic acetylcholine receptors expressed on endothelial cells results in the activation of nitric oxide synthase and release of nitric oxide, which relaxes vascular smooth muscle by activation of 3,5-cyclic guanosine monophosphate. Investigators showed that fentanyl attenuated acetylcholine-induced relaxation of rat aorta precontracted with phenylephrine by an inhibitory effect at a level proximal to nitric oxide synthase activation on the pathway involving endothelial M_3 muscarinic receptor activation.[213]

Opioids are often administered to patients requiring surgical intervention for the control of hemorrhage. An animal study demonstrated that pretreatment with morphine before inducing the shock state decreased leukocyte adhesion and vascular permeability in the microcirculation of the mesenteric venule, a finding suggesting the survival benefit for use of morphine during acute resuscitation[214] (see also Chapter 108).

ENDOCRINOLOGIC EFFECTS OF OPIOIDS

The main components of the neuroendocrine stress response are the corticotropin-releasing hormone brain centers (e.g., paraventricular hypothalamic nucleus) and the locus ceruleus–norepinephrine/autonomic nervous system. Increased levels of stress hormones are considered undesirable because they promote hemodynamic instability and intraoperative and postoperative metabolic catabolism. In some circumstances, the hormonal and metabolic responses to surgery are extreme and are thought to contribute to operative mortality.

Opioids are capable of reducing the stress response by modulating nociception at several different levels of the neuraxis, as well as by influencing centrally mediated neuroendocrine responses. Opioids are potent inhibitors

of the pituitary-adrenal axis.[215] Endogenous opioid peptides may serve as stress hormones themselves and not just as modulators of the secretion of other hormones. This activity is suggested by the finding that β-endorphin and ACTH are derived from the same precursor proopiomelanocortin and are cosecreted during stress.

Morphine modifies hormonal responses to surgical trauma in a dose-related fashion. Morphine can prevent ACTH release, suppress surgically induced increases in plasma cortisol, and attenuate the pituitary-adrenal response to surgical stress. Morphine can increase some stress-responding hormones by increasing plasma histamine release, adrenal medullary release mechanisms, and release of catecholamine from sympathetic nerve endings.

Fentanyl and its congeners are more effective than morphine in modifying hormonal responses to surgery. The efficacy of fentanyl in controlling the hormonal manifestations of the stress response can be dose dependent. Fentanyl doses of 50 μg/kg or larger can help reduce the hyperglycemic response to cardiac surgical procedures in pediatric patients to less than 200 mg/dL throughout the operation.[216] In contrast, neither fentanyl nor sufentanil alone can completely block the sympathetic and hormonal stress responses, and perhaps no dose-response relationship exists for opioid-associated control of the stress response.[217] The stress response to cardiopulmonary bypass (CPB) is difficult to suppress with sufentanil or fentanyl. Alfentanil can suppress increases in plasma cortisol and catecholamines before but not during CPB and may prevent increases in antidiuretic hormone (ADH) and growth hormone throughout coronary artery bypass surgery. A randomized controlled trial showed that remifentanil (0.85 μg/kg/minute), when compared with fentanyl (total doses of 15 and 28 μg/kg), blunts the hypertensive responses and cortisol excretion associated with cardiac surgery but is associated with more hypotension.[218]

STRESS REDUCTION AND OUTCOME

Anesthetic techniques or drugs that minimize the stress response may reduce morbidity and mortality in a variety of circumstances. Anand and colleagues evaluated the impact of sufentanil versus morphine-halothane anesthesia on hormonal and metabolic responses and morbidity and mortality in neonates undergoing cardiac surgical procedures.[219] Most strikingly, a statistically significant difference in postoperative mortality was observed (0 of 30 infants given sufentanil versus 4 of 15 infants given halothane plus morphine). Mangano and associates also reported that, after myocardial revascularization, patients receiving intense postoperative analgesia with sufentanil (1 μg/kg/hour) experienced a lower incidence and severity of electrocardiographically documented ischemia compared with patients receiving intermittent intravenous morphine (2.2 ± 2.1 mg/hour) for postoperative analgesia.[220] High-dose opioids (remifentanil 0.85 μg/kg/minute or fentanyl 28 μg/kg) are associated with a decreased rate of myocardial infarction after cardiac surgical procedures.[218]

Many different hormonal changes induced by surgery have been described. However, the concomitant neural, cellular, immune, and biochemical changes have been less well defined, and little is understood or proven with regard to how modifying hormonal responses alters outcome.[221] Additional studies are necessary for complete elucidation of the relationship between control of surgically induced hormonal responses and outcome.

OPIOID TOLERANCE AND OPIOID-INDUCED HYPERALGESIA

The mechanisms of dependence and tolerance involve genetic, molecular, cellular, physiologic, and functional factors. In the locus ceruleus, the major noradrenergic nucleus in the brain, long-term opioid exposure results in inhibition of adenylyl cyclase, reduced activity of protein kinase A, and up-regulation of the cyclic AMP pathway.[222] The changes in μ-receptor density that occur before or during the development of tolerance do not appear to be essential for the development of opioid tolerance.[223] Possible mechanisms involve protein kinase signal transduction cascades that link extracellular signals to cellular changes by regulating target gene expression. Central glucocorticoid receptors (GRs) have been implicated in the cellular mechanism of neuronal plasticity, which has many cellular steps in common with the mechanism of opioid tolerance. Investigators showed that the development of tolerance to the antinociceptive effect of morphine was substantially attenuated when a GR antagonist was coadministered with morphine, but the GR agonist dexamethasone facilitated the development of morphine tolerance; these findings suggest an important role of spinal GRs in the cellular mechanisms of morphine tolerance in rats.[224] Morphine tolerance occurs more rapidly in younger rats than in older rats and is unlikely to be the result of differences in drug metabolism or clearance, an observation suggesting that aging may have an impact on the molecular processes involved in the development of tolerance.[225] Activation of glial cells, including astrocytes and microglia, at the level of the spinal cord may play an important role in the development of opioid tolerance.[226,227]

Short-term administration of opioids results in analgesia and side effects, whereas tolerance and dependence were thought to occur only after long-term administration. However, tolerance can also develop rapidly after short-term opioid exposure in animals and humans. Intraoperative remifentanil infusion (0.3 μg/kg/minute) in patients undergoing major abdominal surgical procedures performed using desflurane anesthesia increased postoperative pain and morphine requirements when compared with low-dose remifentanil (0.1 μg/kg/minute); these findings suggest the development of acute remifentanil tolerance.[228] In contrast, there is a report that target-controlled infusion of alfentanil and remifentanil for postoperative analgesia does not lead to opioid tolerance.[229] In human volunteers, continuous infusion of remifentanil (0.08 μg/kg/minute) for 3 hours did not decrease the pain threshold.[230] Thus, the development of acute opioid tolerance in humans remains controversial.

Opioids can elicit hyperalgesia in experimental models after repeated opioid administration or continuous delivery.[231] This phenomenon seems to be related to opioid tolerance.[232] In rats, thermal hyperalgesia and mechanical

allodynia were observed for several days after cessation of morphine administration (40 mg/kg/day for 6 days).[233] The opioid-induced hyperalgesia resulted from spinal sensitization to glutamate and substance P.[234] Furthermore, cholecystokinin and the NMDA–nitric oxide system are responsible for the development of acute tolerance to opioids,[235] which is also affected by spinal serotonin activity.[236] Opioid-induced hyperalgesia and subsequent acute opioid tolerance can be prevented by ketamine, a finding suggesting involvement of the NMDA receptor.[237,238] Methadone is unique in possessing both μ-opioid and NMDA-antagonist properties. Opioid-induced hyperalgesia resulted from the presence of *l*-methadone (μ-opioid agonist) in the racemate and was antagonized by the presence of *d*-methadone (NMDA antagonist).[239] N_2O is an effective NMDA antagonist. Intraoperatively, 70% N_2O administration significantly reduced postoperative opioid-induced hyperalgesia in patients receiving propofol (≈120 μg/kg/minute) and remifentanil (0.3 μg/kg/minute).[240]

Spinal cyclooxygenase-2 (COX-2) protein was upregulated and release of prostaglandin E_2 in the spinal cord was increased after morphine withdrawal in rats.[241] In humans, hyperalgesia after 30-minute intravenous infusion of remifentanil (0.1 μg/kg/minute) could be prevented by the administration of parecoxib, a COX-2 inhibitor, before remifentanil infusion,[242] thereby suggesting the involvement of COX-2 in opioid-induced hyperalgesia.

Genetic analysis in mice suggested that genetic variants of the β_2-adrenergic receptor gene seem to explain some of the differences among various strains of mice in the development of opioid-induced hyperalgesia, and the selective β_2-adrenergic receptor antagonist butoxamine was shown to reverse opioid-induced hyperalgesia in a dose-dependent manner.[243] In mice, systemic or intrathecal injection of the 5-HT_3 receptor antagonist, ondansetron, was shown to prevent or reverse opioid-induced tolerance or hyperalgesia.[244]

The occurrence of opioid-induced hyperalgesia may possibly be affected by general anesthetic agents coadministered with opioids. When women undergoing surgical treatment of breast cancer were anesthetized with sevoflurane or propofol to keep the BIS value at 40 to 50, postoperative hyperalgesia induced by intraoperative remifentanil infusion (effect-site target of 4 ng/mL) was significant with sevoflurane anesthesia but not apparent with propofol anesthesia.[245] Human data generally support the existence of opioid-induced hyperalgesia in a few specific settings. The conditions under which opioid-induced hyperalgesia is expressed should be clarified, and its clinical significance remains to be elucidated.[246]

MANAGEMENT OF OPIOID-DEPENDENT PATIENTS

A variety of problems should be taken into consideration for anesthetic management of opioid-dependent patients.[247] Complications in opioid-addicted patients include cardiopulmonary problems, renal problems, and anemia. Long-term morphine administration causes adrenal hypertrophy and impairs corticosteroid secretion. Viral and nonviral hepatitis, acquired immunodeficiency syndrome, osteomyelitis, muscle weakness, and neurologic complications may be found in addicted patients. Because underestimation and undertreatment of pain are common in opioid-dependent patients, it is important to identify the goals of short-term pain management in these patients (Box 31-3).[248] Anesthetic management of the opiate-dependent or addicted patient should include adequate premedication with opioids, administration of supplemental intraoperative and postoperative opioids, and provision of nonopioid analgesics and neural blockade. No ideal anesthetic approach exists for a patient with a chronic addiction or a patient with an acute opiate overdose. One treatment for opioid addiction is rapid detoxification with a high dose of naloxone or naltrexone. For this treatment, general anesthesia is induced before the start of opioid antagonism and is maintained for several hours to prevent perception of withdrawal symptoms by the patient.[249,250] Blockade of μ-opioid receptors by naloxone (total dose of 12.4 mg) in opioid-addicted patients induces sympathetic neural activation, including an increase in plasma catecholamine concentration and cardiovascular stimulation, which is abolished by α_2-agonists.[251]

BOX 31-3 ***Goals of Acute Pain Management in Opioid-Dependent Patients***

1. Identification of the population of at-risk patients receiving long-term opioid therapy for various chronic pain situations (musculoskeletal disease, neuropathic conditions, sickle cell disease, HIV-related disease, palliative care), drug abusers, recovering addicts in opioid maintenance programs
2. Prevention of withdrawal symptoms and complications
3. Symptomatic treatment of psychological affective disorders such as anxiety
4. Effective analgesic treatment in the acute phase
5. Rehabilitation to acceptable and suitable maintenance opioid therapy

HIV, Human immunodeficiency virus.

RENAL AND URODYNAMIC EFFECTS OF OPIOIDS

μ-Receptor activation causes antidiuresis and decreases electrolyte excretion. κ-Receptor stimulation predominantly produces diuresis with little change in electrolyte excretion. Indirect actions may involve inhibiting or altering the secretion of ADH and atrial natriuretic peptide. The absence of increases in plasma ADH, renin, and aldosterone indicates that fentanyl, sufentanil, alfentanil, and probably remifentanil most likely preserve or minimally alter renal function in humans. If renal function does change during opioid anesthesia and surgery, this is probably the result of secondary changes in systemic and renal hemodynamics.

The mechanism by which opioids cause urinary retention is incompletely understood. Effects of opioids on the lower urinary tract include disturbances of micturition characterized by urinary retention, especially after intrathecal opioid administration. Intrathecal administration

of morphine and sufentanil caused dose-dependent suppression of detrusor contractility and decreased sensation of urge.[252] Mean times to recovery of normal lower urinary tract function were 5 and 8 hours after 10 or 30 μg sufentanil and 14 and 20 hours after 0.1 or 0.3 mg morphine, respectively. Not all opioid agonists behave similarly, and morphine appears to be particularly potent with regard to producing urodynamic problems. Malinovsky and associates compared the urodynamic effects of intravenous morphine (10 mg), buprenorphine (0.3 mg), fentanyl (0.35 mg), and nalbuphine (20 mg).[253] All the opioids altered bladder sensations, but detrusor contraction decreased only after the administration of fentanyl and buprenorphine. Urinary retention induced by intravenous infusion of remifentanil (0.15 μg/kg/minute) could be reversed by a single intravenous dose of methylnaltrexone (0.3 mg/kg) or naloxone (0.01 mg/kg).[254] Reversal of urinary retention by methylnaltrexone indicates that peripheral mechanisms may play a role in opioid-induced bladder dysfunction.

GASTROINTESTINAL EFFECTS OF OPIOIDS

Several opioid receptor types can be demonstrated on myenteric neurons, and both κ- and μ-receptor agonists regulate cholinergic transmission in the myenteric plexus. κ-Agonists appear to modulate release of acetylcholine more potently than do μ-agonists by inhibition of N-type voltage-sensitive Ca^{2+} channels through a pertussis toxin–sensitive G protein in guinea pig ileum.[255] The adverse gastrointestinal effects of exogenous opioid treatment include nausea, vomiting, altered fluid dynamics, inhibited gastric emptying, inhibited intestinal coordinated propulsive activity, and increased transit time, all of which may contribute to postoperative ileus (Box 31-4).[256]

The effect of morphine on esophageal motility has been extensively explored. Morphine (80 μg/kg) increased the velocity but did not alter the amplitude or duration of primary peristalsis of the esophagus, and it decreased the duration and magnitude of swallow-induced relaxation of the lower esophageal sphincter.[257] Gastric emptying is delayed by opioids through supraspinal (vagus nerve–mediated) and spinal, as well as peripheral, mechanisms. Intrathecal morphine (0.4 mg) significantly decreased the gastroduodenal propagation velocity and acetaminophen absorption, and intramuscular morphine (4 mg) resulted in additional effects.[258] Tramadol (1.25 mg/kg IV) has a measurable but smaller inhibitory effect on gastric emptying than does codeine (1 mg/kg IV) or morphine (0.125 mg/kg IV).[259] Opioids administered epidurally, as well as intrathecally, reduce gastrointestinal motility.[258] The translocation of enteric microorganisms from the intestinal tract to extraintestinal sites was promoted by reduction of gut propulsion after morphine treatment in rats.[260] Propofol (0.3 mg/kg bolus and 1.0 mg/kg/hour) abolished the decrease in gastric tone induced by morphine (0.1 mg/kg IV), but it did not abolish a morphine-induced delay of gastric emptying.[261]

Naloxone reverses opioid-induced delays in gastric emptying. Methylnaltrexone, a quaternary naloxone derivative that does not cross the blood-brain barrier, can attenuate morphine-induced delays in gastric emptying, thus suggesting a peripheral mechanism in the opioid effect on gastrointestinal tract.[262] Naloxone (0.7 mg/kg) significantly inhibited gastric emptying of saline and milk in rats.[263] This observation may suggest that opioids can affect the gastrointestinal tract by a mechanism independent of the opioid receptors. Intravenous, but not intramuscular, metoclopramide (10 mg) also can reverse morphine-induced delays in gastric emptying.[264]

Opioid effects on the intestine are complex. Transit time from mouth to ileum may not be significantly altered by morphine because morphine enhances ileal propulsion before decreasing motility. Opioids increase tone and decrease propulsive activity in most of the intestine. In rats, pretreatment with epidural or intraperitoneal morphine attenuated ischemia-induced inhibition of bowel motility.[265]

BOX 31-4 *Effects of Opioids on the Gastrointestinal Tract*

Pharmacologic Action	Clinical Effect
Decreased gastric motility and emptying	Decreased appetite; increased gastroesophageal reflux
Decreased pyloric tone	Nausea and vomiting
Decreased enzymatic secretion	Delayed digestion; hard, dry stools
Inhibition of small and large bowel propulsion	Delayed absorption of medication; straining; incomplete evacuation; bloating; abdominal distention; constipation
Increased fluid and electrolyte absorption	Hard, dry stools
Increased nonpropulsive segmental contractions	Spasms; abdominal cramps; pain
Increased anal sphincter tone	Incomplete evacuation

From Viscusi ER, Gan TJ, Leslie JB, et al: Peripherally acting mu-opioid receptor antagonists and postoperative ileus: mechanisms of action and clinical applicability, Anesth Analg *108:1811-1822, 2009.*

BILIARY AND HEPATIC EFFECTS

Opioid agonists increase biliary duct pressure and sphincter of Oddi (choledochoduodenal sphincter) tone in a dose- and drug-dependent manner through opioid receptor–mediated mechanisms. However, the clinical consequences of opioid-induced biliary tract actions are usually minimal. Although traditional teaching dictates that morphine induces "spasm" in the sphincter of Oddi and should not be used in patients with acute pancreatitis, no study or evidence indicates that morphine is contraindicated for use in acute pancreatitis.[266] Increases in biliary pressure caused by opioids are, with the exception of meperidine, reversible with naloxone. Oddi sphincter manometry through choledochoscopy demonstrated that the regular dose of morphine could increase common bile duct pressure, whereas pethidine had no effect, and tramadol inhibited motility of the sphincter of Oddi.[267] Fragen and associates studied the effect of remifentanil (0.1 mg/kg/minute) on the flow of dye from the gallbladder into

the duodenum and showed that remifentanil delays the drainage of dye from the gallbladder into the duodenum, but the delay is shorter than that reported after morphine or meperidine.[268]

Opioids have minimal effects on liver function during anesthesia and surgery. Remifentanil pretreatment can attenuate liver injury induced by ischemia and reperfusion. This effect is mediated by inducible nitric oxide synthase expression and exhausting reactive O_2 species but does not involve opioid receptors.[269]

NAUSEA AND VOMITING

Postoperative nausea and vomiting comprise a serious problem that often embarrasses patients and anesthesiologists[270,271] (see also Chapter 97). The etiology, treatment, and prevention of postoperative nausea and vomiting have been extensively investigated (Fig. 31-10).[272] Intraoperative use of opioids is a well-known risk factor for postoperative nausea and vomiting. Opioids stimulate the chemoreceptor trigger zone in the area postrema of the medulla, possibly through δ receptors, and thereby lead to nausea and vomiting. When compared with approximately equipotent doses of fentanyl and sufentanil, alfentanil is associated with a lower incidence of postoperative nausea and vomiting.[273]

The use of propofol in balanced anesthesia or total intravenous anesthesia (TIVA) significantly reduces the incidence of opioid-induced nausea and vomiting. When opioids are administered, antiemetic prophylaxis should be considered, including drugs with anticholinergic activity, butyrophenones, dopamine antagonists, serotonin antagonists, and acupressure. Ondansetron, a 5-HT_3 receptor antagonist, was found to be effective for postoperative opioid-induced nausea and vomiting.[274] A meta-analysis concluded that prophylactic use of 5-HT_3 receptor antagonists significantly reduced the incidence of postoperative nausea and vomiting and the need of rescue antiemetic therapy in parturient patients who received intrathecal morphine for cesarean delivery.[141] Nausea and vomiting after epidural morphine (3 mg) for postcesarean section analgesia could be prevented by dexamethasone (8 mg IV) as efficiently as droperidol (1.25 mg IV).[275] Cannabinoid receptor agonists are effective antiemetics in some clinical settings. Animal experiments showed that the cannabinoid agonist suppresses opioid-induced retching and vomiting by activation of the cannabinoid CB1 receptor.[276] A continuous low-dose naloxone infusion (0.25 μg/kg/hour) ameliorates some of the opioid-induced side effects, including nausea, vomiting, and pruritus, in many but not all patients without adversely affecting analgesia.[277] Transdermal scopolamine was shown to be effective for prophylactic use in parturient patients receiving intrathecal morphine while undergoing cesarean delivery, but it was associated with a higher incidence of side effects such as dry mouth and blurry vision.[278]

OTHER OPIOID EFFECTS

OBSTETRICS

Alfentanil and pethidine have been safely used as analgesics during the harvesting of human oocytes for subsequent in vitro fertilization[279] (see also Chapter 77). The teratogenic actions of opioids, including fentanyl, sufentanil, and alfentanil, at least in animal models, appear to be minimal. The parenteral administration of opioids before delivery remains a common method of analgesia. Nociception as a result of uterine cervical distention was able to be suppressed by μ- and κ-agonists in rats,[280] but the analgesic effect of μ-agonist but not κ-agonist was reduced by estrogen.[281] Aortocaval compression and associated hypotension may be exacerbated by parenteral opioids, especially following the use of morphine or meperidine. Fatal manifestations of maternal opioid administration include decreases in heart rate variability. Adverse neonatal effects can occur after administration of either morphine or meperidine to mothers. Fetal acidosis increases opioid transfer from the mother. Attempts to minimize neonatal effects of opioids include restricting opioid administration to the first stage of labor. In one report, the short-acting opioid alfentanil administered before cesarean delivery attenuated the maternal stress response but led to a slightly reduced Apgar score.[282] In a randomized double-blind controlled study, a single bolus of 1 μg/kg remifentanil administered to patients undergoing elective cesarean delivery effectively attenuated hemodynamic changes after induction of anesthesia and tracheal intubation, but remifentanil crosses the placenta and may cause mild neonatal depression.[283]

Because the fetus is capable of pain perception after the twenty-sixth week of gestation, adequate postoperative fetal pain management is essential after fetal surgery. Investigators showed that the sheep fetus absorbs sufentanil after intraamniotic instillation, and significantly greater plasma concentrations were achieved in the fetal lamb than in the ewe.[284]

Morphine and meperidine have been found in the breast milk of mothers receiving intravenous opioid analgesia.[285,286] Although both fentanyl and morphine are concentrated in breast milk in milk-to-plasma ratios of 2:1 to 3:1, newborn exposure is reported to be insignificant. Newborns of addicted mothers can exhibit opioid withdrawal and require observation and appropriate treatment.[287]

ANAPHYLACTOID REACTIONS

True allergic reactions and systemic anaphylactoid reactions to opioids are rare. More commonly, local reactions caused by preservatives or histamine may occur. In 32% of heroin addicts who died suddenly after heroin injection, the concentration of tryptase was elevated (>10 μg/L), but no correlation was found between the immunoglobulin E levels and tryptase, a finding supporting the hypothesis that mast cell degranulation was not mediated by allergic reactions.[288] This report suggests that many heroin fatalities are caused by an anaphylactoid reaction.

OCULAR EFFECTS

The use of fentanyl, sufentanil, and alfentanil during induction of anesthesia can help prevent increases in intraocular pressure. Fentanyl, alfentanil, and sufentanil doses as small as 2.5, 10, and 0.1 μg/kg, respectively, may be sufficient as long as appropriate anesthetic depth is achieved before tracheal intubation. Remifentanil (1 μg/kg) combined with propofol (2 mg/kg) or thiopental (5 mg/kg) was reported to be effective for prevention of intraocular pressure change after succinylcholine and tracheal intubation.[289,290]

IMMUNE EFFECTS

Opioids influence specific enzymatic degradation and regulation processes, as well as immune regulation through modulation of immune cell activity. Several immune cell populations, including T cells, macrophages, and natural killer (NK) cells, serve as targets for the effects of opioids. Investigators showed that the maximal suppression of NK cell activity, proliferation of splenic T and B cells, and interferon-γ production were observed 0.5 to 1 hour after the injection of 15 mg/kg of morphine in rats.[291] The time course was nearly concordant with the antinociceptive effect of morphine. Postoperative administration of morphine (10 mg intramuscularly [IM]) did not significantly affect NK cell activity, whereas tramadol (100 mg IM) enhanced NK cell activity.[292] Intravenous fentanyl causes a rapid increase in NK cell cytotoxicity, which is coincident with an increase in the percentage of $CD16^+$ and $CD8^+$ cells in peripheral blood.[293] When compared with fentanyl (1000 μg), administration of morphine (40 mg) as part of a balanced anesthetic technique suppressed several components of the inflammatory response (interleukin-6, CD11b, CD18, postoperative hyperthermia) to cardiac surgery and CPB.[294]

As a potential mechanism for the immunosuppressive effects of morphine, activation of nuclear factor NF-κB by an inflammatory stimulus was inhibited by morphine-induced activation of μ_3-opioid receptors in a nitric oxide–dependent manner.[295] Several investigators independently reported direct effects of morphine on apoptosis in cultured human peripheral blood lymphocytes that may result in compromised immune function.[296] However, another report noted that morphine has no effect on apoptosis-related molecules and does not promote apoptosis of human peripheral blood lymphocytes.[297]

CANCER PROGRESSION

Patients who receive general anesthesia with opioids have a greater rate of cancer recurrence than do patients who receive local or regional anesthetic agents.[298] Opioids may directly stimulate proliferation and invasion of tumor cells and inhibit apoptosis of tumor cells, or they may indirectly affect cancer recurrence by immunosuppression.[299] Overexpression of the μ-opioid receptor in human non–small cell lung cancer was suggested to promote tumor growth and progression.[300] Exploration of the opioid receptors in cancer cells could contribute to a diagnostic and therapeutic option of cancer. Furthermore, investigators reported that women with the A118G genotype of the μ-opioid receptor have decreased breast cancer–specific mortality, a finding suggesting that opioid pathways may be involved in tumor growth.[301]

WOUND HEALING

The topical application of opioids has been explored as a strategy for reducing pain associated with cutaneous wounds. Activation of peripheral opioid receptors on primary afferent neurons reduces the excitability of these neurons and suppresses the antidromic release of substance P and calcitonin gene–related peptide, which play an essential role in wound repair. Topical morphine application significantly reduced the number of myofibroblasts and macrophages in the closing wound.[302] These findings limit the topical application of opioids as an analgesic therapeutic strategy in the treatment of painful cutaneous wounds.

PHARMACOKINETICS AND PHARMACODYNAMICS OF OPIOIDS

Using modern drug assay technology and with the widespread availability of computers, investigators can analyze pharmacologic data with combined pharmacokinetic-pharmacodynamic models to separate drug responses into pharmacokinetic and pharmacodynamic components. Pharmacokinetic parameters govern the relationship between opioid dose and the opioid concentrations in blood (or other body fluid). Pharmacodynamic parameters describe the relationship between the

opioid concentration in blood (or other fluid) and opioid effect.

PHYSICOCHEMICAL PROPERTIES

Opioids are weak bases. When dissolved in solution, opioids are dissociated into protonated and free-base fractions, with the relative proportions depending on the pH and ion dissociation constant (pK_a). The free-base fraction is more lipid soluble than the protonated fraction. High lipid solubility facilitates transport of opioid into the biophase or site of action. Therefore, highly lipid-soluble opioids have a more rapid onset of action. However, because the opioid receptor "recognizes" an opioid molecule in the protonated form, the intensity of opioid effects is closely related to the ionized concentration of drug in the biophase.

All opioids are to some extent bound to plasma proteins, including albumin and α_1-acid glycoprotein. Only the un-ionized, unbound fraction constitutes the diffusible fraction and provides the concentration gradient that promotes diffusion of opioid from blood to the tissue of interest. Thus, the speed of onset of opioid effect is affected by both the lipid solubility and protein binding.

PHARMACOKINETIC FEATURES OF INDIVIDUAL DRUGS

Representative pharmacokinetic parameters for the opioids commonly used in anesthesia are displayed in Table 31-5.

Morphine

Morphine pharmacokinetics is notably different from that of the fentanyl congeners. This difference is in large part the result of morphine's comparatively low lipid solubility. Relatively little transient first-pass uptake of morphine by the lung occurs. The pK_a of morphine (8.0) is greater than physiologic pH, and thus after intravenous injection, only a small fraction (10% to 20%) of morphine is un-ionized. Penetration of morphine into and out of the brain is presumably slower than that of other opioids. Approximately 20% to 40% of morphine is bound to plasma proteins, mostly albumin.

Morphine is principally metabolized by conjugation in the liver, but the kidney plays a key role in the extrahepatic metabolism of morphine. Morphine-3-glucuronide (M3G) is the major metabolite of morphine, but it does not bind to opioid receptors and possesses little or no analgesic activity. M3G may actually antagonize morphine, and this effect may contribute to both variability in response and resistance to morphine analgesic therapy. M3G was reported to cause seizures in animals and allodynia in children.[303] M6G accounts for nearly 10% of morphine metabolite and is a more potent μ-receptor agonist than morphine, with a similar duration of action. Investigators reported that M6G contributes substantially to morphine's analgesic effects, even in patients with normal renal function.[304] Especially in patients with renal dysfunction, the accumulation of M6G can lead to an increased incidence of adverse effects, including respiratory depression. Except for renal function, M6G accumulation was shown to be affected by transmembrane transporters inhibited by probenecid.[305] M6G can induce respiratory depression in a manner similar to that of morphine, but the site of action in the ventilatory control system may be different between M6G and morphine.[306] Investigators suggested that SNP at the μ-opioid receptor affects the susceptibility to M6G-related opioid toxicity.[307] Because the hepatic extraction ratio of morphine is high, the bioavailability of orally administered morphine is significantly lower (20% to 30%) than after intramuscular or subcutaneous injection. M6G is in fact the primary active compound when morphine is administered orally (Fig. 31-11).[308] In contrast to the reports suggesting a high potency of M6G, other reports have shown that short-term intravenous administration of M6G does not provide effective analgesia.[309]

Fentanyl

A three-compartment model is typically used to describe decay of plasma fentanyl concentrations. The lungs exert a significant first-pass effect and transiently take up approximately 75% of an injected dose of fentanyl. Approximately 80% of fentanyl is bound to plasma

TABLE 31-5 PHYSICOCHEMICAL AND PHARMACOKINETIC DATA OF COMMONLY USED OPIOID AGONISTS

	Morphine	Fentanyl	Sufentanil	Alfentanil	Remifentanil

proteins, and significant amounts (40%) are taken up by red blood cells. Fentanyl is relatively long acting, in large part because of this widespread distribution in body tissues.

Fentanyl is primarily metabolized in the liver by *N*-dealkylation and hydroxylation. Metabolites begin to appear in plasma as early as 1.5 minutes after injection. Norfentanyl, the primary metabolite, is detectable in the urine for up to 48 hours after intravenous fentanyl administration in humans.

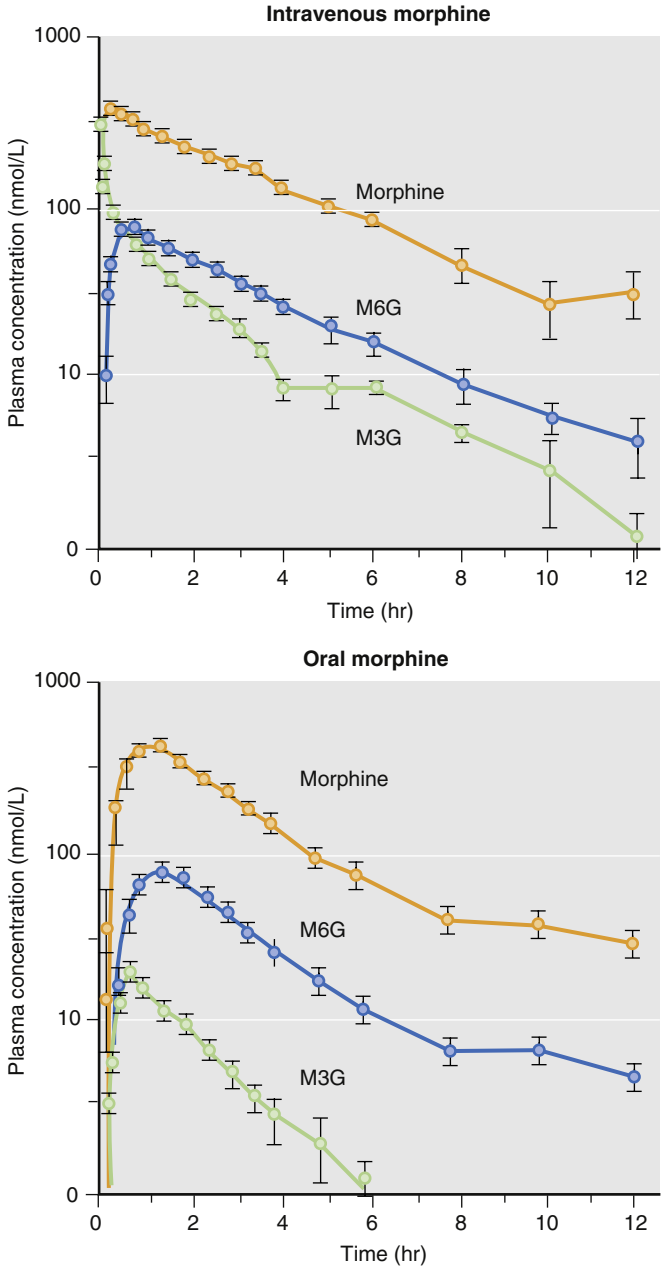

Figure 31-11. Mean plasma concentrations (± SEM) of morphine, morphine-6-glucuronide (M6G), and morphine-3-glucuronide (M3G) after intravenous and oral administration of morphine. *(From Osborne R, Joel S, Trew D, Slevin M: Morphine and metabolite behavior after different routes of morphine administration: demonstration of the importance of the active metabolite morphine-6-glucuronide,* Clin Pharmacol Ther *47:12-19, 1990.)*

Alfentanil

After intravenous injection, plasma concentrations of alfentanil are described by either a two-compartment or a three-compartment model. Alfentanil is bound to plasma proteins (mostly glycoproteins) in higher proportions (90%) than is fentanyl. At physiologic pH, alfentanil is mostly (90%) un-ionized because of its relatively low pK_a (6.5). Thus, despite more intense protein binding, the diffusible fraction of alfentanil is higher than is that of fentanyl. This explains, in part, the short latency to peak effect of alfentanil after intravenous injection.

The main metabolic pathways of alfentanil are similar to those of sufentanil and include oxidative *N*-dealkylation and *O*-demethylation, aromatic hydroxylation, and ether glucuronide formation. The degradation products of alfentanil have little, if any, opioid activity. Human alfentanil metabolism may be accomplished predominantly, if not exclusively, by cytochrome P450 3A3/4 (CYP3A3/4).[310] This enzyme is known to display at least an eightfold difference in activity in humans. Alfentanil is also metabolized by human liver microsomal CYP3A5, which shows more than a twentyfold pharmacogenetic variability in expression level and thus results in significant differences in human liver alfentanil metabolism.[311] An in vitro study demonstrated that propofol in clinically relevant concentrations interferes with oxidative metabolic degradation of alfentanil and sufentanil in the microsomal fraction of pig and human liver.[312]

Sufentanil

The pharmacokinetic property of sufentanil is adequately described by a three-compartment model. After intravenous injection of sufentanil, first-pass pulmonary extraction, retention, and release are similar to those of fentanyl.[313] The pK_a of sufentanil at physiologic pH is the same as that of morphine (8.0), and therefore only a small amount (20%) exists in the un-ionized form. Sufentanil is twice as lipid soluble as fentanyl and is highly bound (93%) to plasma proteins, including α_1-acid glycoprotein.

The major metabolic pathways of sufentanil include *N*-dealkylation, oxidative *O*-demethylation, and aromatic hydroxylation. Major metabolites include *N*-phenylpropanamide.

Remifentanil

Although chemically related to the fentanyl congeners, remifentanil is structurally unique because of its ester linkages. Remifentanil's ester structure renders it susceptible to hydrolysis by blood- and tissue-nonspecific esterases that results in rapid metabolism and rapid reduction of blood concentrations after cessation of infusion[314] (Fig. 31-12). Remifentanil thus constitutes the first "ultrashort"-acting opioid for use as a supplement to general anesthesia.

The pharmacokinetic properties of remifentanil are best described by a three-compartment model. Remifentanil clearance is several times more rapid than normal hepatic blood flow, consistent with widespread extrahepatic metabolism. However, remifentanil is not significantly metabolized or sequestered in the lungs.[315] It is a weak base with a pK_a of 7.07. It is highly lipid soluble, with an octanol-water partition coefficient of 19.9 at

pH 7.4. Remifentanil is highly bound (70%) to plasma proteins (mostly α_1-acid glycoprotein). The remifentanil free base is formulated with glycine. Because glycine has been shown to act as an inhibitory neurotransmitter that causes a reversible motor weakness when it is injected intrathecally in rodents, remifentanil is not approved for spinal or epidural use.[316]

The primary metabolic pathway of remifentanil is de-esterification to form a carboxylic acid metabolite, GI90291 (Fig. 31-13),[317] which is 0.003 to 0.001 times as potent as remifentanil. The low in vivo potency of GR90291 can be explained by a low affinity to the μ receptor in combination with poor brain penetration.[318] Excretion of GI90291 depends on renal clearance mechanisms. Evidence from dogs suggests that the remifentanil metabolites are, for practical purposes, completely inactive, even in patients with renal failure. The pharmacokinetics of remifentanil is not appreciably influenced by renal or hepatic failure. In blood, remifentanil is metabolized primarily by enzymes within erythrocytes. Remifentanil is not a good substrate for pseudocholinesterase and therefore is not influenced by pseudocholinesterase deficiency.[319]

SURROGATE MEASURES OF OPIOID POTENCY

Because a high-resolution measure of analgesia is not available, opioid potencies are usually estimated by some surrogate measures. Reduction of the MAC required to produce lack of movement to skin incision has been a frequently used surrogate measure for estimation of opioid potency (Fig. 31-14).[320] However, the MAC is not useful as a surrogate measure of opioid potency outside the operating room.

The EEG has been another widely used surrogate measure for estimating opioid potency. The EEG is advantageous because it is noninvasive and can be used as an effect

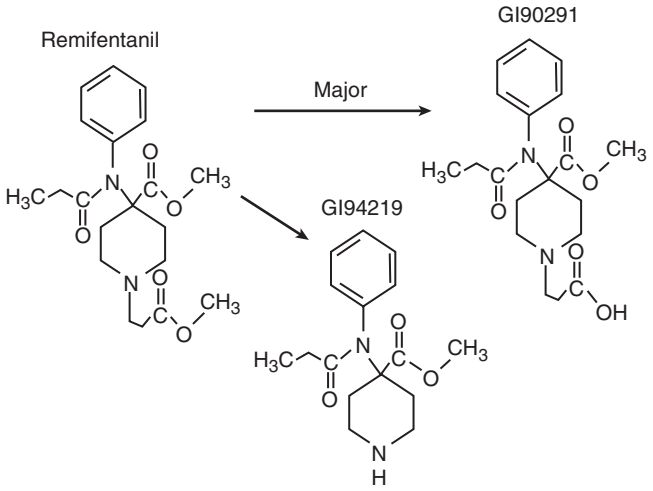

Figure 31-13. Metabolic pathway of remifentanil. De-esterification by nonspecific plasma and tissue esterases to form a carboxylic acid metabolite (GI90291) that has only 1/300 to 1/1000 the potency of the parent compound is the primary metabolic pathway. *N*-Dealkylation of remifentanil to G194219 is a minor metabolic pathway. *(From Egan TD, Lemmens HJ, Fiset P, et al: The pharmacokinetics of the new short-acting opioid remifentanil [GI87084B] in healthy adult male volunteers,* Anesthesiology *79:881-892, 1993.)*

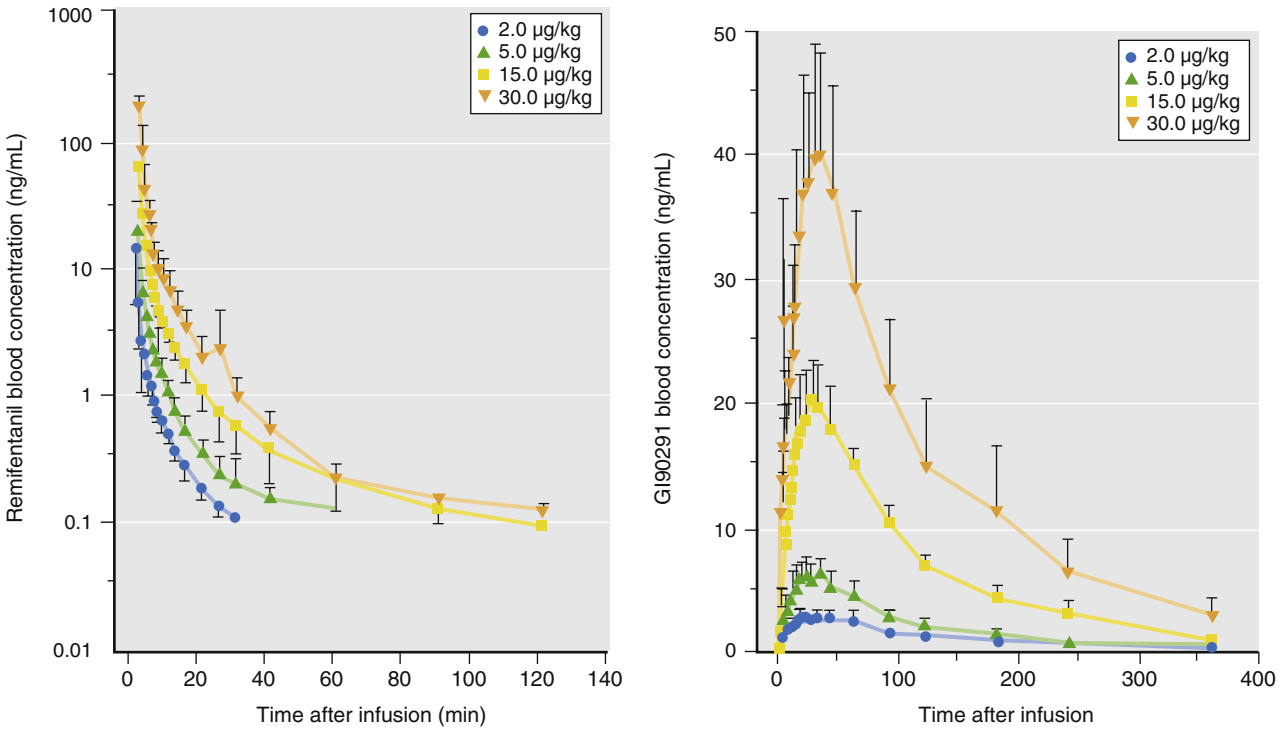

Figure 31-12. Mean (± standard deviation) blood concentration–time curves of remifentanil and its metabolite GI90291 after a 1-minute transfusion of remifentanil of 2, 5, 15, and 30 μg/kg (n = 6 for each dose). *(From Westmoreland CL, Hoke JF, Sebel PS, et al: Pharmacokinetics of remifentanil [GI87084B] and its major metabolite [GI90291] in patients undergoing elective inpatient surgery,* Anesthesiology *79:893-903, 1993.)*

measure when an experimental subject is unconscious or apneic. When processed by Fourier spectral analysis, the raw changes on the EEG translate into a significant decrease in the value of the spectral edge, a parameter that quantitates the frequency below which a given percentage (usually 95%) of the power in the signal of the EEG is found. Although the clinical meaning of the changes on the EEG produced by opioids is unclear, the opioid potencies estimated by using the EEG as a surrogate measure appear to be clinically reliable because they relate to clinically determined potencies in a proportional, reproducible fashion. However, because the surrogate measures do not always assess the drug effect of clinical interest (analgesia), estimations of potency based on surrogate measures must be interpreted with some caution.

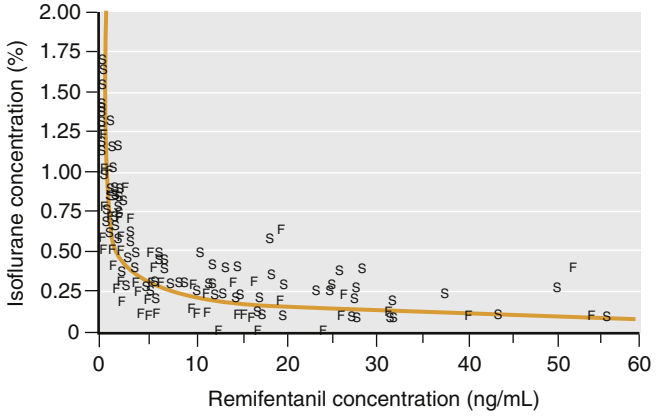

Figure 31-14. The reduction in isoflurane concentration to prevent movement at skin incision in 50% of patients by increasing measured remifentanil whole blood concentrations. *F* represents a patient who moved, and *S* represents a patient who did not move. The *solid line* is the logistic regression solution for a 40-year-old patient. *(From Lang E, Kapila A, Shlugman D, et al: Reduction of isoflurane minimal alveolar concentration by remifentanil,* Anesthesiology *85:721-728, 1996.)*

FACTORS AFFECTING PHARMACOKINETICS AND PHARMACODYNAMICS OF OPIOIDS

Age

The pharmacokinetics and pharmacodynamics of opioids can be influenced by age. Neonates clearly exhibit a reduced rate of elimination of essentially all opioids,[321] presumably because of immature metabolic mechanisms, including the cytochrome P450 system. The prolonged elimination of opioids observed in the neonatal period quickly normalizes toward adult values within the first year of life.[321]

Intraoperative requirements of opioids differ between adults and children. The infusion rate of remifentanil to block somatic and autonomic response to skin incision was almost twofold higher in children (2 to 11 years) than in adults (20 to 60 years).[322,323] With advanced age, although pharmacokinetic changes may play a minor role, pharmacodynamic differences are primarily responsible for the decreased dose requirement in older adults. In one report, age was inversely correlated with central volume of distribution, clearance, and potency of remifentanil[324] (Fig. 31-15). These combined pharmacokinetic

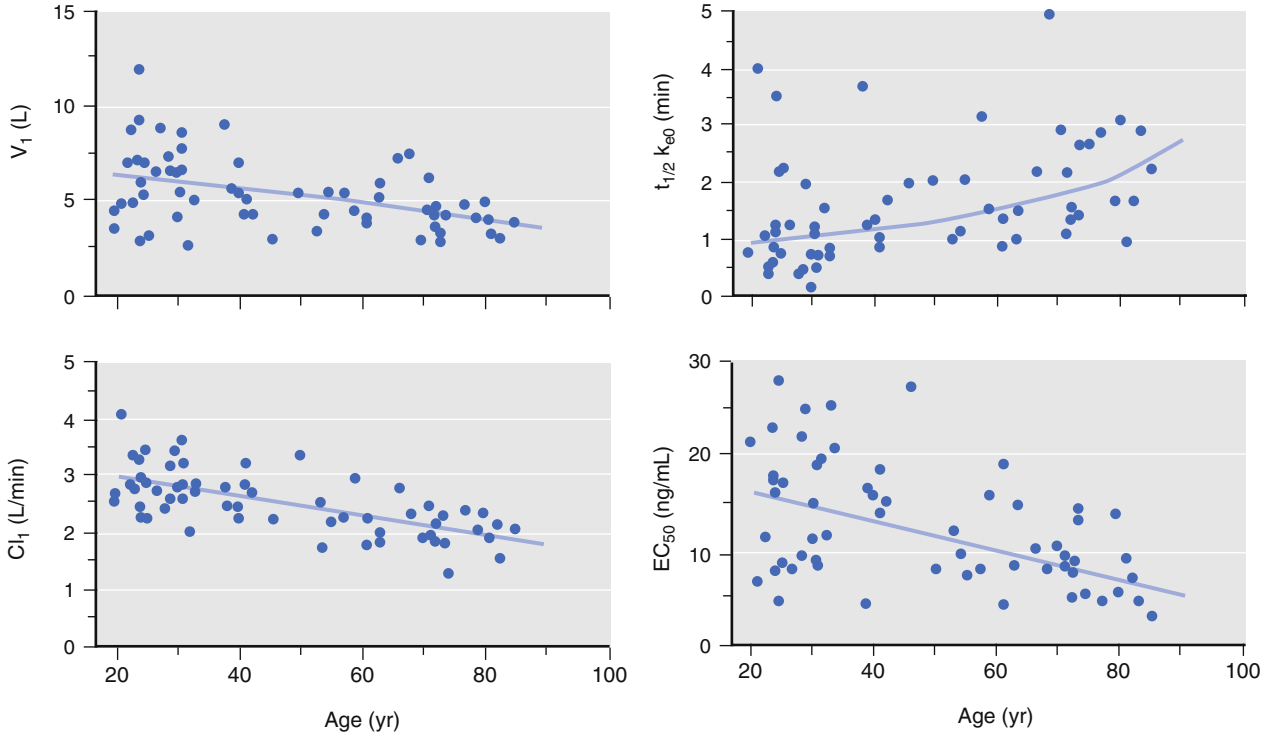

Figure 31-15. Relationship between pharmacokinetic and pharmacodynamic parameters and age for remifentanil. Volume of distribution (V_1) and clearance (Cl_1) are estimated using a three-compartment model. $t_{½}k_{e0}$ is a half-life corresponding to k_{e0}, a first-order rate constant for elimination of drug from the effect compartment. EC_{50}, Median effective concentration. *(From Minto CF, Schnider TW, Egan T et al: Influence of age and gender on the pharmacokinetics and pharmacodynamics of remifentanil. I. Model development. Anesthesiology. 86:10-23, 1997.)*

and pharmacodynamic changes mandate a reduction in remifentanil dosage by at least 50% or more in older patients (see also Chapter 80).

Body Weight

Many opioid pharmacokinetic parameters, especially clearance, appear to be more closely related to lean body mass (see also Chapter 71). This means that opioid dosage regimens may best be based on lean body mass and not on total body weight. Total body weight–based dosing in an obese patient results in much higher remifentanil effect-site concentrations than does lean body mass–based dosing.[325] In contrast, for lean patients, the concentrations that result from total body weight–based dosing are not much greater than are those based on body mass (Fig. 31-16). Clinically, context-sensitive half-times are not significantly different between obese and lean subjects (Fig. 31-17). Mounting evidence suggests that lean body mass is a better predictor of metabolic capacity than is total body weight. Ideal body weight, a parameter closely related to lean body mass and one that is perhaps more easily estimated by the clinician, is probably an acceptable alternative.

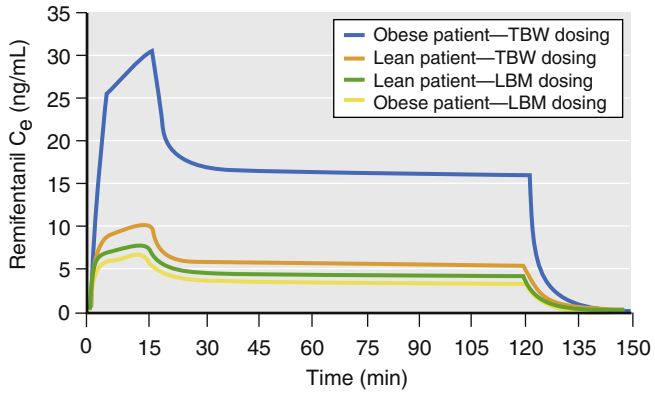

Figure 31-16. A computer simulation of the time course of remifentanil concentration change, when the dosage regimen is calculated based on lean body mass (LBM) or total body weight (TBW) for both obese and lean patients. TBW-based dosing in an obese patient results in dramatically higher drug concentrations. *(From Egan TD, Huizinga B, Gupta SK, et al: Remifentanil pharmacokinetics in obese versus lean patients,* Anesthesiology *89:562-573, 1998.)*

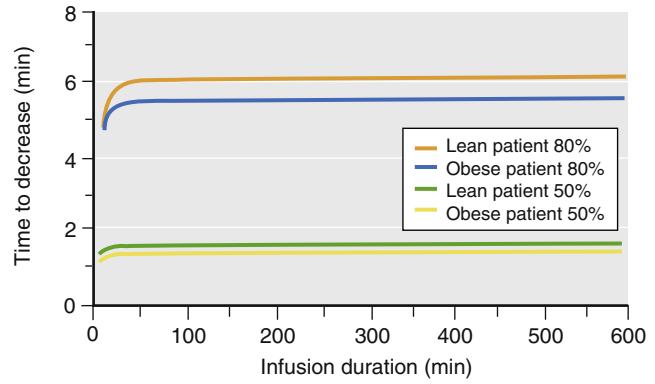

Figure 31-17. A computer simulation of the context-sensitive half-times (50% decrement times) and 80% decrement times of remifentanil in obese versus lean subjects. In clinical terms, the curves are not grossly different in obese and lean subjects. *(From Egan TD, Huizinga B, Gupta SK, et al: Remifentanil pharmacokinetics in obese versus lean patients,* Anesthesiology *89:562-573, 1998.)*

Renal Failure

Renal failure has implications of major clinical importance with respect to morphine and meperidine (see also Chapter 74). For the fentanyl congeners, the clinical importance of renal failure is less marked.

Morphine is an opioid with active metabolites that depend on renal clearance mechanisms for elimination. Morphine is principally metabolized by conjugation in the liver, and the water-soluble glucuronides (M3G and M6G) are excreted by the kidney. The kidney also plays a role in the conjugation of morphine and accounts for nearly 40% of the drug's metabolism.[326] Patients with renal failure can develop very high levels of M6G and life-threatening respiratory depression (Fig. 31-18).[327] In view of these changes induced by renal failure, morphine may not be a good choice in patients with severely altered renal clearance mechanisms.

The clinical pharmacology of meperidine is also significantly altered by renal failure. Normeperidine, the main metabolite, has analgesic and CNS excitatory effects. Because the active metabolites are subject to renal excretion, this potential CNS toxicity secondary to normeperidine accumulation is especially a concern in patients in renal failure.

The clinical pharmacology of the fentanyl congeners is not grossly altered by renal failure, although a decrease in plasma protein binding may potentially alter the free fraction of the fentanyl class of opioids. In the presence of renal impairment, fentanyl, alfentanil, sufentanil, and remifentanil do not deliver a high active metabolite load, and their clearance is not significantly prolonged.[328] Neither the pharmacokinetics nor the pharmacodynamics of remifentanil is altered by impaired renal function. Levels of GI90291 that develop during remifentanil infusion in patients with renal failure are not likely to produce any clinically significant effects.

Hepatic Failure

Even though the liver is the metabolic organ primarily responsible for opioid biotransformation, the degree of liver failure typically observed in perioperative patients, with the exception of patients undergoing liver transplantation, does not have a major impact on the pharmacokinetics of most opioids (see also Chapter 74). In addition to reduced metabolic capacity (i.e., cytochrome P450 system and conjugation), liver disease may also lead to reductions in hepatic blood flow, hepatocellular mass, and plasma protein binding. The increase in total body water and the edema of advanced liver disease may alter the distribution characteristics of a drug. Enzyme induction, such as that observed in early alcoholism, can actually increase the metabolic capacity of the liver.

Morphine pharmacokinetics is relatively unchanged by developing liver disease, such as liver cirrhosis and hepatic carcinoma, because of the substantial compensatory extrahepatic metabolism of morphine. A reduction in hepatic blood flow would be expected to slow the decline in morphine plasma concentrations. In one report, M6G-to-morphine and M3G-to-morphine ratios

were significantly reduced after liver resection, and the circulating morphine concentration was increased, mainly as a result of lower morphine clearance.[329] In patients with cirrhosis, the metabolism of meperidine is decreased, which leads to accumulation of the parent drug and possible CNS depressive effects similar to those observed in hepatic encephalopathy. Although the elimination of normeperidine is also decreased in these patients, the ratio of normeperidine to meperidine is generally low, and the narcotic effects of meperidine usually predominate.[330] The disposition of fentanyl and sufentanil appears to be unaffected by liver diseases.[331] The reductions in liver blood flow that result from either liver disease or some other disorder (e.g., shock) can affect the pharmacokinetic parameters of alfentanil, fentanyl, and sufentanil. A significant decrease in clearance of alfentanil was demonstrated in patients with mild to moderate cirrhosis when compared with volunteers from the historical control group.[332] Greater elimination half-lives ($t_{½}$; 3.7 ± 2.6 hours) have also been observed for alfentanil in patients undergoing abdominal aortic surgical procedures.[333] Remifentanil is an opioid whose pharmacokinetics is completely unchanged by liver disease (Fig. 31-19).[334] Its kinetics does not change during the anhepatic phase of orthotopic liver transplantation.[335] Investigators reported that 0.25 to 0.5 μg/kg/minute remifentanil could provide perioperative analgesia without neurologic deterioration in patients suffering from chronic hepatic failure with mild encephalopathy.[336]

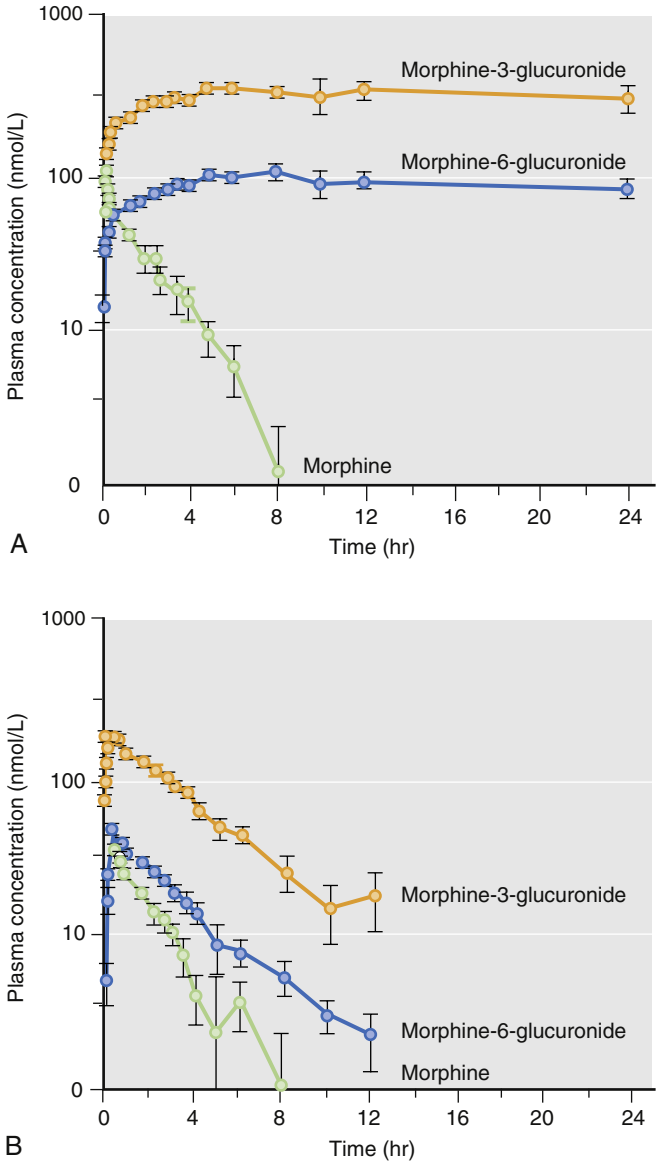

Figure 31-18. Effect of renal failure on the pharmacokinetics of morphine. The graphs show the time-dependent change of the serum concentration of morphine and its metabolites in patients with renal failure (**A**) and in patients with normal renal function (**B**) who received 0.1 mg/kg morphine intravenously. *(From Osborne R, Joel S, Grebenik K, et al: The pharmacokinetics of morphine and morphine glucuronides in kidney failure,* Clin Pharmacol Ther *54:158-167, 1993.)*

Cardiopulmonary Bypass

CPB produces significant alterations in the pharmacokinetics of most opioids (see also Chapter 67). These

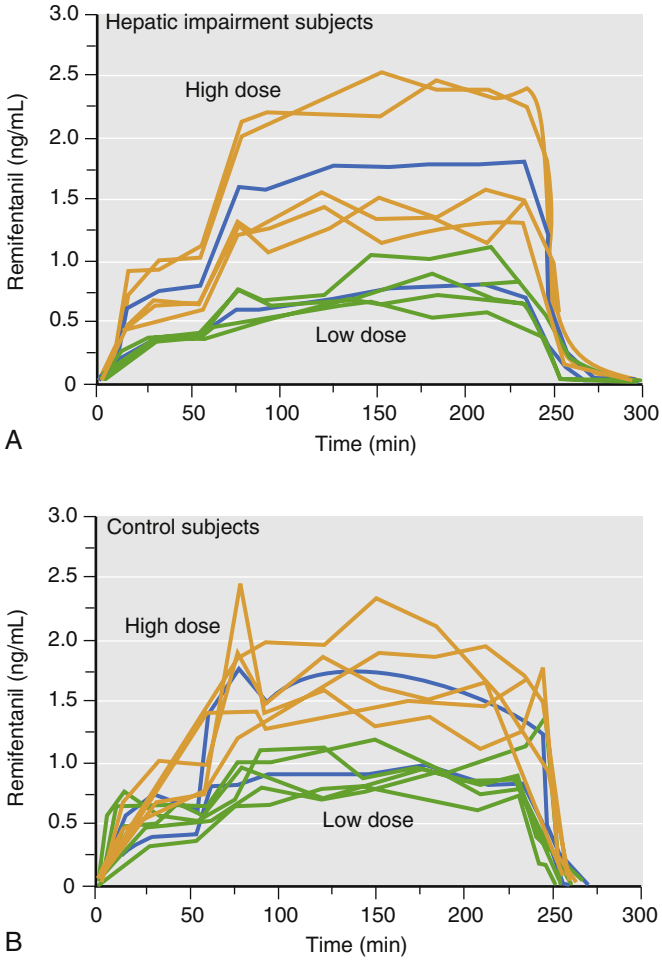

Figure 31-19. Time-dependent changes of blood concentration of remifentanil in patients with liver disease (**A**) and in control subjects (**B**). In the low-dose group, remifentanil was infused at 0.0125 μg/kg/minute for 1 hour and then at 0.025 μg/kg/minute for 3 hours. In the high-dose group, the infusion rate of remifentanil was 0.025 μg/kg/minute for 1 hour and then 0.05 μg/kg/minute for 3 hours. *(From Dershwitz M, Hoke JF, Rosow CE, et al: Pharmacokinetics and pharmacodynamics of remifentanil in volunteer subjects with severe liver disease,* Anesthesiology *84:812-820, 1996.)*

alterations are a result of CPB-induced modifications in distribution volumes (secondary to priming) and changes in acid-base balance, organ blood flow, plasma protein concentrations, and body temperature. Binding of drugs to components of the bypass circuit can also alter opioid pharmacokinetics.

When morphine is given as a premedication before cardiac anesthesia, its concentrations decline significantly on initiation of CPB. Miller and associates examined the effect of CPB on plasma fentanyl concentration and showed that the total concentration of fentanyl in plasma was significantly decreased and the unbound fraction of fentanyl rose on initiation of CPB.[337] The total fentanyl concentration remained relatively stable during bypass until near the end of CPB, at which time the mean total concentration increased, coincident with rewarming. Population pharmacokinetic modeling applied to concentration versus time data from patients undergoing coronary artery bypass grafting with CPB demonstrated that the effect of CPB on fentanyl pharmacokinetics is clinically insignificant and that a simple three-compartment model accurately predicts fentanyl concentrations throughout surgical procedures involving the use of CPB.[338] Elimination of alfentanil is prolonged by CPB primarily because of increased distribution. The volume of distribution in steady state (Vd_{ss}) and the volume of central compartment for alfentanil were significantly greater in the CPB groups than in the nonbypass group.[339] However, the elimination $t_{½\beta}$ of alfentanil did not differ significantly among the normothermic CPB, hypothermic CPB, and nonbypass groups. Between the normothermic and hypothermic CPB groups, no significant differences in Vd_{ss}, clearance, or $t_{½\beta}$ were found. The free fraction of alfentanil during CPB remains constant despite complex changes in binding protein concentrations.[340] In adult patients undergoing elective myocardial revascularization with hypothermic CPB who received continuous infusions of remifentanil 1.0 to 2.0 μg/kg/minute, no evidence of accumulation or sequestration was found.[315] Russell and colleagues reported that normothermic CPB did not significantly affect the clearance of remifentanil, but hypothermic CPB reduced it by an average of 20%, findings attributed to the effect of temperature on blood and tissue esterase activity.[341] In pediatric patients undergoing CPB for repair of atrial septal defects, no changes in the Vd_{ss}, volume of the central compartment, $t_{½\alpha}$, and $t_{½\beta}$ were noted, but clearance values increased 20% in the postbypass period.[342] In patients undergoing coronary artery bypass graft surgery with hypothermic CPB who received a continuous infusion of remifentanil, the volume of distribution increased by 86% with institution of CPB and remained increased after CPB, and elimination clearance decreased by 6.37% for each degree lower than 37°C.[343] Thus, although clearance of remifentanil reduced during CPB, remifentanil remains a very short-acting drug even during CPB.

Acid-Base Changes

Changes in pH influence the protein binding of fentanyl, sufentanil, and alfentanil. The results are an increase in protein binding with alkalosis and a decrease with acidosis (see also Chapter 60). These effects are more intense for fentanyl than for sufentanil and for sufentanil than for alfentanil. Relative changes in the free drug fraction with pH variation from 7.4 to 7.0 were much higher for fentanyl (52%) when compared with sufentanil (29%) and alfentanil (6%). The pH dependence of plasma protein binding of the opioids significantly correlates with their partition between an organic and aqueous phase, thus suggesting the hydrophobic character of the interaction between plasma proteins and opioids. Increased ionization decreases the amount of fentanyl available for hepatic metabolism or renal excretion. Intraoperative hyperventilation during surgical procedures can significantly influence the pharmacokinetics of sufentanil and can result in an increased distribution volume and prolonged elimination half-time.

Thus, both intraoperative respiratory alkalosis and respiratory acidosis, especially in the immediate postoperative period, can prolong and exacerbate opioid-induced respiratory depression.

Hemorrhagic Shock

Common practice is to administer reduced doses of opioids to patients in hemorrhagic shock to minimize adverse hemodynamic consequences and to prevent a prolonged opioid effect (see also Chapter 81). This prolonged drug effect is at least partially attributable to a pharmacokinetic mechanism. Analysis of pigs receiving fentanyl suggested that central clearance and central and second compartment distribution volumes were significantly reduced in hemorrhagic shock, with higher fentanyl concentrations for any given dosage and a prolonged context-sensitive half-time (Fig. 31-20).[344] Hemorrhagic shock also altered the pharmacokinetics of remifentanil, a finding suggesting that less remifentanil would be required to maintain a target plasma concentration (Fig. 31-21).[345] However, because of the rapid metabolism of remifentanil, changes in context-sensitive half-time are small. In a stepwise hemorrhagic model of pigs receiving TIVA with remifentanil (0.5 μg/kg/minute) and propofol (6 mg/kg/hour after 2 mg/kg bolus), the plasma remifentanil concentration showed a threefold greater increase than did

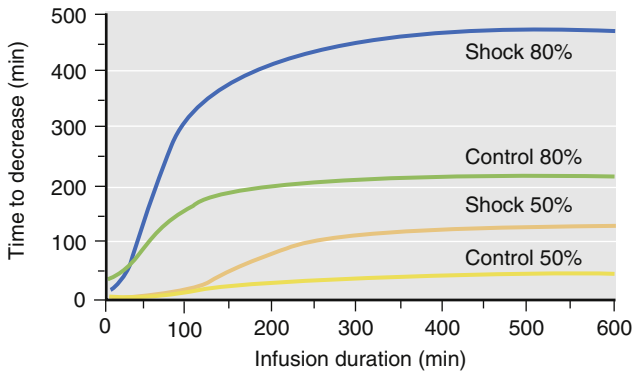

Figure 31-20. A computer simulation of the context-sensitive half-times (50% decrement times) and 80% decrement times of fentanyl in animals in shock versus control animals. *(From Egan TD, Kuramkote S, Gong G, et al: Fentanyl pharmacokinetics in hemorrhagic shock: a porcine model,* Anesthesiology *91:156-166, 1999.)*

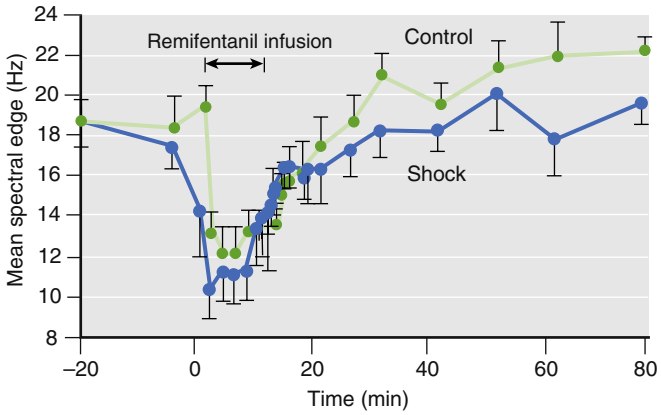

Figure 31-21. Mean spectral edge changes versus time during remifentanil infusion. The graph indicates spectral edge measurements for control animals and for animals in hemorrhagic shock, respectively. *(From Johnson KB, Kern SE, Hamber EA, et al: Influence of hemorrhagic shock on remifentanil: a pharmacokinetic and pharmacodynamic analysis,* Anesthesiology *94:322-332, 2001.)*

that of propofol.[346] Thus, the remifentanil dose should be reduced substantially compared with propofol during TIVA for patients with significant blood loss.

ANESTHETIC TECHNIQUES USING OPIOIDS

See also Chapters 56, 57, 64, 65, and 98.

ANALGESIA

Opioids are frequently used to relieve pain during monitored anesthesia care and regional anesthesia. A single bolus administration of opioids can provide significant pain relief. Morphine is slow in onset and does not allow rapid titration to effect. Meperidine (50 to 100 mg IV) produces variable degrees of pain relief and is not always effective in patients with severe pain. Intravenous boluses of fentanyl (1 to 3 μg/kg), alfentanil (10 to 20 μg/kg), or sufentanil (0.1 to 0.3 μg/kg) can produce potent and short-lasting analgesia. Infusion rates range from 0.01 to 0.05 μg/kg/minute for fentanyl, 0.0015 to 0.01 μg/kg/minute for sufentanil, 0.25 to 0.75 μg/kg/minute for alfentanil, and 0.05 to 0.25 μg/kg/minute for remifentanil. Plasma concentrations of opioids necessary for various purposes are listed in Table 31-6.

Changes in the excitability of central neurons play an important role in the establishment of pain. In rats, low doses of fentanyl blocked the synaptic form of central sensitization in the spinal cord in vivo, a finding suggesting the possibility of preemptive analgesia by fentanyl, but higher doses do not have this effect.[347] Reductions in postoperative pain and improved recovery have been attributed to preemptive analgesia with either epidural fentanyl or bupivacaine after radical prostatectomy.[348] In contrast, in patients undergoing transperitoneal tumor nephrectomy, preoperative intravenous administration of a combination of morphine, ketamine, and clonidine failed to exert a clinically relevant effect on postoperative pain.[349] Aida and colleagues reported that the effectiveness of preemptive analgesia varies according to the type of surgical procedure, and preemptive analgesia with epidural morphine was reliably effective in limb and breast operations but ineffective in abdominal surgical procedures.[350] A meta-analysis demonstrated that the results of preemptive analgesia with systemic administration of opioids are equivocal.[351] Thus, whether preemptive analgesia can be effectively achieved clinically by the early administration of opioids remains uncertain.

PCA with opioids is now a cornerstone of postoperative analgesia, but pharmacokinetic optimization of opioid treatment in acute pain is a complex matter. Without considering effect-site drug concentrations over time, the choice of opioid and the amount, method, and frequency of its administration cannot be optimal. Morphine remains a popular and rational choice for PCA therapy. A double-blind randomized study demonstrated that effect-compartment controlled remifentanil PCA with a slow and progressive adapted algorithm is feasible in young women undergoing uterine artery embolization.[352] The combination of opioids with other drugs may improve PCA. For thoracic surgical procedures, the addition of ketamine to opioids for intravenous PCA was superior to intravenous PCA opioids alone, whereas the effect of added ketamine was not significant for orthopedic or abdominal surgical procedures.[353]

BALANCED ANESTHESIA

The term *balanced anesthesia* was introduced by Lundy in 1926. Lundy suggested that a balance of anesthetic agents and techniques be used to produce the different components of anesthesia (i.e., analgesia, amnesia, muscle relaxation, and abolition of autonomic reflexes with maintenance of homeostasis). Anesthesia with a single agent can require doses that produce excessive hemodynamic depression. The inclusion of an opioid as a component of balanced anesthesia can reduce preoperative pain and anxiety, decrease somatic and autonomic responses to airway manipulations, improve hemodynamic stability, lower requirements for inhaled anesthetic agents, and provide immediate postoperative analgesia. Opioids interact synergistically and markedly reduce the dose of propofol and other sedative-hypnotics required for loss of consciousness and during noxious stimulation such as skin incision[354] (Fig. 31-22). Although the intent of combining opioids with sedative-hypnotics or volatile anesthetic agents is to produce anesthetic conditions with stable hemodynamics before and after noxious stimulation, this ideal is not always achieved.[355,356]

The timing, rate of administration, and dose of supplemental opioid should also be tailored to the specific condition of the patient and the expected duration of the operation, to avoid problems. Giving a large dose of any opioid shortly before the end of a surgical procedure is very likely to result in postoperative respiratory depression. However, analgesic concentrations of opioids have little effect on the MAC awake of inhaled anesthetic agents.[357]

The ideal opioid would permit rapid titration, successfully prevent unwanted responses to noxious stimuli, require little supplementation, not depress cardiovascular

TABLE 31-6 RANGE OF APPROXIMATE PLASMA (OR WHOLE BLOOD FOR REMIFENTANIL) OPIOID CONCENTRATION

	Fentanyl (ng/mL)	Sufentanil (ng/mL)	Alfentanil (ng/mL)	Remifentanil (ng/mL)
Predominant agent	15-30	5-10	400-800	—
Major surgery	4-10	1-3	200-400	2-4
Minor surgery	3-6	0.25-1	50-200	1-3
Spontaneous ventilation	1-3	<0.4	<200	0.3-0.6
Analgesia	1-2	0.2-0.4	50-150	0.2-0.4

From Bailey PL, Egan TD, Stanley TH: Intravenous opioid anesthetics. In Miller RD, editor: Anesthesia, *ed 7. Philadelphia, 2010, Churchill Livingstone, p 800.*

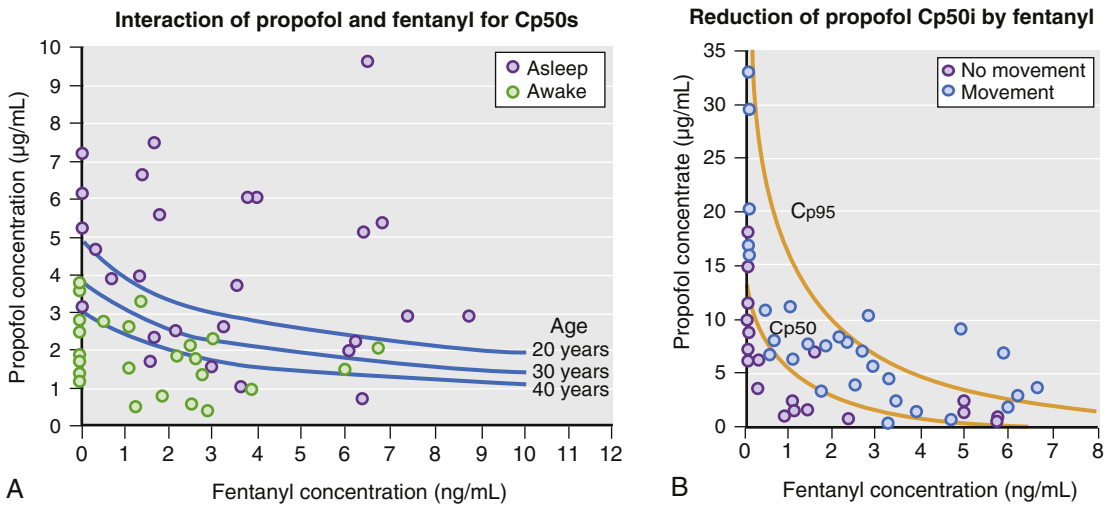

Figure 31-22. A, Measured arterial propofol and fentanyl concentrations at which patients did and did not respond to a verbal command at 10 minutes after the initiation of the infusion of these drugs. The *solid lines* represent the modeled concentration of propofol, according to decade of age when combined with the measured fentanyl concentrations, at which 50% of patients did not respond to verbal command (Cp50s). **B,** Reduction by increasing concentration of fentanyl of propofol concentration at which 50% or 95% of patients did not move at skin incision (Cp50i and CP95i, respectively). The *solid lines* represent the logistic regression solution. *(From Smith C, McEwan AI, Jhaveri R, et al: The interaction of fentanyl on the Cp50 of propofol for loss of consciousness and skin incision,* Anesthesiology *81:820-828, 1994.)*

function, permit the return of adequate spontaneous ventilation in a timely manner, and produce residual if not complete postoperative analgesia with minimal side effects. Alfentanil and remifentanil provide the greatest ability to titrate opioids rapidly because of their extremely rapid time to onset (1 to 2 minutes) of peak effect. Sufentanil, alfentanil, and remifentanil are arguably superior to fentanyl in most respects. Antagonism of opioid action with naloxone for troublesome respiratory depression is required less frequently after alfentanil and sufentanil compared with fentanyl. Pharmacologic antagonism is rarely required after remifentanil administration.

Fentanyl

Anesthetic induction is usually achieved by combining a loading dose of fentanyl (2 to 6 µg/kg) with a sedative-hypnotic, most commonly thiopental or propofol, and a muscle relaxant. Maintenance of anesthesia can be achieved with N_2O (60% to 70%) in O_2, low concentrations of potent inhaled anesthetic agents, and additional fentanyl (intermittent boluses of 25 to 50 µg every 15 to 30 minutes or a constant infusion of 0.5 to 5.0 µg/kg/hour).

The plasma concentration of fentanyl required for postoperative analgesia was approximately 1.5 ng/mL,[358] but levels of at least 2 to 3 ng/mL are usually required during surgery if the only inhaled agent is N_2O. In unpremedicated patients anesthetized with a fentanyl infusion and N_2O in O_2, the CP_{50} (minimal steady-state plasma concentration of an intravenous analgesic or anesthetic agent required to prevent a somatic response in 50% of patients following skin incision) and the CP_{50}- BAR (minimal plasma concentration of an intravenous analgesic or anesthetic agent required to prevent a somatic, hemodynamic, or autonomic response in 50% of patients following skin incision) for fentanyl at skin incision are 3.26 and 4.17 ng/mL, respectively.[359] The MAC of isoflurane at skin incision can be reduced by 50% and 63% with plasma fentanyl concentrations of 1.67 and 3.0 ng/mL, respectively.[85] Increasing plasma fentanyl concentrations from 3.0 to 10 ng/mL only further reduced the MAC of isoflurane from 63% to 82%. The intraoperative requirement of propofol is also reduced by fentanyl. In patients undergoing spine fusion, to keep the mean arterial pressure within 15% of the control value when fentanyl was infused to maintain the plasma concentration at 0, 1.5, 3.0, and 4.5 ng/mL, average propofol infusion rates were 10.1 ± 2.5 (mean ± SD), 7.5 ± 1.2, 5.7 ± 1.1, and 4.9 ± 1.2 mg/kg/hour, respectively.[360]

Opioid pharmacokinetics and pharmacodynamics vary considerably among patients. Investigators reported that fentanyl dose based on total body weight may cause overdosing in obese patients.[358] Nevertheless, a balanced technique with fentanyl, by titrating the opioid in anticipation of various stimuli and patients' responses with pharmacokinetic guidelines in mind, often results in a stable hemodynamic course and rapid awakening of a pain-free patient. Repeated doses or continuous infusions of fentanyl are most likely to result in significant depression of spontaneous ventilation.

Alfentanil

Because alfentanil penetrates the brain so rapidly, equilibration of alfentanil between the plasma and the CNS can be achieved while plasma alfentanil levels are relatively high compared with sufentanil and fentanyl. This property explains how low doses (10 to 30 μg/kg) of alfentanil, administered just before or simultaneously with a sedative-hypnotic, are effective.

Alfentanil (25 to 50 μg/kg IV), followed by small titrated sleep doses of any sedative-hypnotic (e.g., 50 to 100 mg sodium thiopental), is usually successful in preventing significant hemodynamic stimulation from laryngoscopy and intubation. In one report, the optimum dose of alfentanil, coadministered with 2.5 mg/kg propofol, when inserting a classic laryngeal mask airway was 10 μg/kg.[361] Further opioid supplementation can be achieved with an alfentanil infusion (0.5 to 2.0 μg/kg/minute) or intermittent boluses of alfentanil (5 to 10 μg/kg) for shorter procedures. In balanced anesthetic techniques in which potent inhaled anesthetic agents are also employed, relatively low plasma alfentanil concentrations (e.g., 29 ng/mL) can reduce the MAC of isoflurane by approximately 50%.[87] In one report, the EC_{50} of alfentanil during propofol anesthesia, in which the plasma concentrations of propofol are kept at target concentrations of 3 μg/mL, was 92 ng/mL for intubation, 55 ng/mL for skin incision, 84 ng/mL for the opening of the peritoneum, and 66 ± 38 ng/mL for the intraabdominal part of surgery.[362] The hemodynamic changes induced by propofol may have an important influence on the pharmacokinetics of alfentanil. Propofol (target concentration, 1.5 μg/mL) decreased the elimination clearance of alfentanil by 15%, rapid distribution clearance by 68%, slow distribution clearance by 51%, and lag time by 62% in one report.[363] Alfentanil infusions or repeated doses should be minimized 15 to 30 minutes before the end of the surgical procedure, to avoid problematic residual respiratory depression.

Sufentanil

The mean plasma sufentanil concentration reported to be the CP_{50} for prevention of hemodynamic responses to laryngoscopy and tracheal intubation was 1.08 ng/mL with a range of 0.73 to 2.55 ng/mL. In combination with propofol for induction of anesthesia in children, bolus administration of sufentanil 0.3 μg/kg can completely abolish the cardiovascular response to tracheal intubation.[364] Maintenance of anesthesia can be achieved with N_2O (60% to 70%) in O_2 and further sufentanil (intermittent boluses, 0.1 to 0.25 μg/kg, or constant infusion, 0.5 to 1.5 μg/kg/hour). The CP_{50} for sufentanil during skin incision (2.08 ± 0.62 ng/mL) is twice as great as that for intubation in unpremedicated patients.[365] CP_{50} value ratios at skin incision for sufentanil, fentanyl, and alfentanil in N_2O-O_2 anesthesia are approximately 1:2:150 and represent different and probably more accurate potency ratios than those traditionally published based on drug dose. In patients undergoing coronary artery bypass grafting, sufentanil doses larger than 1.25 ± 0.21 ng/mL reduced isoflurane requirements to less than 0.5% through the operation.[366]

Remifentanil

Very short duration of action of remifentanil mandates that an infusion (0.1 to 1.0 μg/kg/minute) be started before or soon after the bolus dose to ensure a sustained opioid effect. Maintenance infusion rates of remifentanil range from 0.1 to 1.0 μg/kg/minute for balanced anesthesia. Remifentanil can reliably suppress automatic, hemodynamic, and somatic responses to noxious stimulation.

The use of remifentanil allows rapid (5 to 15 minute) emergence. Infusion rates of 0.1 ± 0.05 μg/kg/minute should permit the return of spontaneous ventilation and responsiveness with maintenance of analgesia. A randomized double-blind placebo-controlled study demonstrated that the combination of 0.05 to 0.1 μg/kg/minute remifentanil and 2 mg midazolam provided effective sedation and analgesia during outpatient surgical procedures performed using local anesthesia.[367] Administration of remifentanil 1 μg/kg followed by 0.5 μg/kg/minute with propofol and 66% N_2O provided sufficient anesthesia for craniotomy with stable hemodynamics and rapid tracheal extubation.[368] Associated with emergence from remifentanil anesthesia, the need for alternative analgesic therapies should be anticipated, and these medications should be administered in a timely fashion. Perioperative administration of morphine (0.15 or 0.25 mg/kg IV) or fentanyl (0.15 mg) did not provide entirely adequate immediate postoperative pain control after remifentanil-based anesthesia in patients undergoing major abdominal operations.[369,370] Administration of ketamine (0.15 mg/kg followed by 2 μg/kg/minute) decreased intraoperative remifentanil use during abdominal surgical procedures and reduced postoperative morphine consumption without increasing the incidence of side effects.[371] In children undergoing surgical correction of strabismus, a combination of sevoflurane (2.5%) and remifentanil (1 μg/kg followed by 0.1 to 0.2 μg/kg/minute) caused less frequent postoperative vomiting but higher postoperative pain scores, compared with fentanyl (2 μg/kg followed by 1 μg/kg every 45 minute).[372]

Postoperative pain relief with low-dose remifentanil infusion was also reported. After general anesthesia with propofol (75 μg/kg/minute) and remifentanil (0.5 to 1.0 μg/kg/minute) for abdominal or thoracic surgical procedures, continuous infusion of remifentanil (0.05 or 0.1 μg/kg/minute) provided adequate analgesia.[373]

NEUROLEPTANALGESIA-ANESTHESIA

In 1959, De Castro and Mundeleer derived the concept of *neuroleptanalgesia,* which involved the combination of a major tranquilizer (usually the butyrophenone

droperidol) and a potent opioid analgesic (fentanyl) to produce a detached, pain-free state of immobilization and insensitivity to pain. Neuroleptanalgesia is characterized by analgesia, absence of clinically apparent motor activity, suppression of autonomic reflexes, maintenance of cardiovascular stability, and amnesia in most patients. The addition of an inhaled anesthetic, usually N_2O, improves amnesia and has been called neuroleptanesthesia. Because of the frequent and serious postoperative adverse effects of the neurolept component, droperidol, this technique is rarely used today.

"Neuroleptic" drugs traditionally include the phenothiazines (e.g., chlorpromazine) and the butyrophenones (e.g., haloperidol and droperidol). Butyrophenones cause sedation, tranquility, immobility, antiemesis, an extrapyramidal syndrome with face and neck dyskinesia, oculogyric crises, torticollis, agitation, and hallucinations. Administering droperidol alone, without analgesics or other sedatives, often produces feelings of discomfort or dysphoria in patients. The cardiovascular effects of droperidol are most often limited to mild hypotension, probably mediated through α-adrenergic blockade. Little respiratory depression is induced by droperidol, although significant variability exists, and occasional respiratory depression may be noted. Droperidol and other butyrophenones may enhance hypoxia-induced increases in ventilation in humans because of their antidopaminergic effects at the carotid body. Droperidol was previously used as a premedication (0.025 to 0.075 mg/kg IM), as an antiemetic (0.01 to 0.02 mg/kg IV), as an adjunct for awake endotracheal intubations (0.025 to 0.1 mg/kg IV), and as treatment for agitated, belligerent, or psychotic patients (0.05 to 0.2 mg/kg IV or IM).

Neuroleptanalgesia or neuroleptanesthesia is contraindicated in patients receiving monoamine oxidase inhibitors (MAOIs), in patients who abuse drugs or alcohol, or in those with Parkinson disease.

TOTAL INTRAVENOUS ANESTHESIA

Many different intravenous compounds can be employed in numerous combinations to provide TIVA. Most commonly, an opioid is combined with another drug more likely to provide hypnosis and amnesia. For example, the combination of alfentanil and propofol produces excellent TIVA. Alfentanil provides analgesia and hemodynamic stability while blunting responses to noxious stimuli. Conversely, propofol provides hypnosis and amnesia and is antiemetic. Profound synergism also exists when more than two agents, such as propofol, alfentanil, and midazolam, are combined. Anesthetic induction with alfentanil (25 to 50 μg/kg) and propofol (0.5 to 1.5 mg/kg), followed by infusions of 0.5 to 1.5 μg/kg/minute of alfentanil and 80 to 120 μg/kg/minute of propofol, produce complete anesthesia in patients ventilated with air and O_2 with or without N_2O for a variety of procedures. Investigators proposed that alfentanil concentrations as low as 85 ng/mL, when combined with a blood propofol concentration of 3.5 μg/mL, can produce both optimal anesthetic conditions and speed of recovery.[374] Stanski and Shafer suggested that bolus doses and initial infusion rates would be 30 μg/kg and 0.35 μg/kg/minute for alfentanil and 0.7 mg/kg and 180 μg/kg/minute for propofol.[375] Recognizing that these calculations were based on EC_{50} data in patients undergoing only moderately painful procedures, anesthesiologists should adjust these doses accordingly. In patients undergoing ear, nose, throat surgical procedures, TIVA with remifentanil and propofol provided a more rapid respiratory recovery after brief surgical procedures, compared with TIVA with alfentanil and propofol.[376]

The optimal propofol-opioid concentrations that ensure adequate anesthesia and rapid emergence were determined by computer modeling. The optimal propofol concentration decreases in the order of fentanyl > alfentanil > sufentanil >> remifentanil. A shorter context-sensitive half-time allows the administration of greater amounts of opioid (and less propofol) during anesthesia without creating prolonged opioid effects.

Maintenance infusions vary according to the patient's condition and surgical stimuli. Propofol (75 to 125 μg/kg/minute) and alfentanil (1.0 to 2.0 μg/kg/minute) were initially recommended. Drug infusions should be terminated 10 to 20 minutes before the end of anesthesia if N_2O is employed. Otherwise, propofol infusions should be terminated 5 to 10 minutes before anticipated patient awakening. Alfentanil infusion rates do not need to be less than 0.25 to 0.5 μg/kg/minute until the surgical procedure is terminated. A multicenter evaluation demonstrated that, in patients undergoing elective inpatient surgical procedures, intravenous administration of remifentanil (1 μg/kg followed by 1.0 μg/kg/minute), when combined with propofol (75 μg/kg/minute), effectively controlled responses to tracheal intubation.[377] Reduction of the remifentanil infusion rate to 0.25 to 0.40 μg/kg/minute after tracheal intubation was also recommended.

Midazolam-opioid combinations can also provide complete anesthesia. However, midazolam-alfentanil TIVA has not been found to compare favorably with propofol-alfentanil TIVA even with flumazenil reversal of benzodiazepine actions.[378]

TIVA techniques are especially useful when delivery of inhaled anesthetic agents is compromised. By keeping the goals of balanced anesthesia in mind, combining modern opioids and other drugs, using infusion pumps, and employing an increased understanding of pharmacokinetics, clinicians can successfully perform a variety of TIVA techniques. Approximate opioid doses and infusion rates for TIVA are listed in Table 31-7.

TABLE 31-7 APPROXIMATE OPIOID LOADING (BOLUS) DOSES, MAINTENANCE INFUSION RATES, AND ADDITIONAL MAINTENANCE DOSES FOR TOTAL INTRAVENOUS ANESTHESIA

	Loading Dose (μg/kg)	Maintenance Infusion Rate	Additional Boluses
Alfentanil	25-100	0.5-2 μg/kg/min	5-10 μg/kg
Sufentanil	0.25-2	0.5-1.5 μg/kg/hr	2.5-10 μg
Fentanyl	4-20	2-10 μg/kg/hr	25-100 μg
Remifentanil	1-2	0.1-1.0 μg/kg/min	0.1-1.0 μg/kg

OPIOID-BASED (HIGH-DOSE OPIOID) ANESTHESIA FOR CARDIAC SURGERY

Opioids can be administered as the primary or sole anesthetic in opioid-based anesthetic techniques (see also Chapter 67). High-dose opioid anesthesia was introduced as a stress-free anesthetic method for cardiac surgical procedures. High-dose opioid anesthesia was first performed with morphine; however, fentanyl and sufentanil were later recommended. Several factors have diminished the popularity of high-dose opioid anesthesia, even in cardiac anesthesia. These factors include the lack of evidence substantiating any significant outcome benefit associated with the use of large doses of opioids, the added drug costs, and the trend toward "fast track" approaches for cardiac patients that can be impeded with large doses of opioids. However, opioids, particularly when administered by continuous infusion, are still among the most effective anesthetic agents for patients undergoing cardiac or other extensive operations.

In an attempt to decrease the costs of cardiac surgery, fast-track programs have become popular. Engoren and colleagues reported that the more expensive but shorter-acting opioids, sufentanil and remifentanil, produced equally rapid extubation, similar stays, and similar costs when compared with fentanyl; these findings indicate that any of these opioids can be recommended for fast-track cardiac surgery.[379]

Fentanyl

Many different techniques have been used to achieve anesthesia with fentanyl.[380,381] Rapid or slow injections of fentanyl range from 5 to 75 μg/kg. These doses establish plasma fentanyl concentrations (10 to 30 ng/mL) that are often sufficient to provide stable hemodynamics throughout the induction and intubation sequence. Continuous infusions of fentanyl for cardiac surgery range from 0.1 to 1.0 μg/kg/minute up to or continuing through CPB. High-dose fentanyl anesthesia has also proved effective and safe for pediatric heart surgery. Investigators indicated that fentanyl (25 to 50 μg/kg) combined with isoflurane (0.2% to 0.4%) was sufficient to obtund hemodynamic and stress responses in the pre-CPB phase of open heart surgery in infants and young children[382] (Fig. 31-23). Investigators reported that 57 of 59 eligible patients were successfully extubated at 34 ± 14 minutes after termination of fentanyl administration (total dose, 127 ± 64 μg/kg) with naloxone (total bolus, 3.4 ± 2.6 μg/kg), and they recovered fully without ventilatory support under the naloxone infusion, which was terminated at 11 ± 7 hours.[383] These results suggest that naloxone infusion with individual dose titration facilitates the use of high-dose opioid anesthesia, thus maintaining the advantage of this anesthesia. Investigators also showed that high-dose fentanyl (50 μg/kg) is not associated with a difference in the incidence of postoperative cognitive dysfunction at 3 or 12 months after coronary artery bypass surgery in older adults, whereas low-dose fentanyl (10 μg/kg) leads to shorter postoperative ventilation times and may be associated with a greater incidence of postoperative cognitive dysfunction 1 week postoperatively.[384]

Alfentanil

The induction of anesthesia with large doses of alfentanil has been applied in cardiac surgery. Large doses of alfentanil (150 μg/kg) may be used with or without thiopental to induce anesthesia. However, some investigators claim that anesthesia cannot be reliably induced with alfentanil alone, at least in young and healthy adults. Continuous infusions of alfentanil (2 to 12 μg/kg/minute) have been employed to maintain moderate to very high plasma alfentanil concentrations (<3000 ng/mL) during cardiac surgical procedures. Enthusiasm for high-dose alfentanil anesthesia techniques is limited by the amount (and cost) of drug required and by suggestions that alfentanil anesthesia for cardiac surgery is inadequate and is associated with more cardiovascular adverse effects compared with

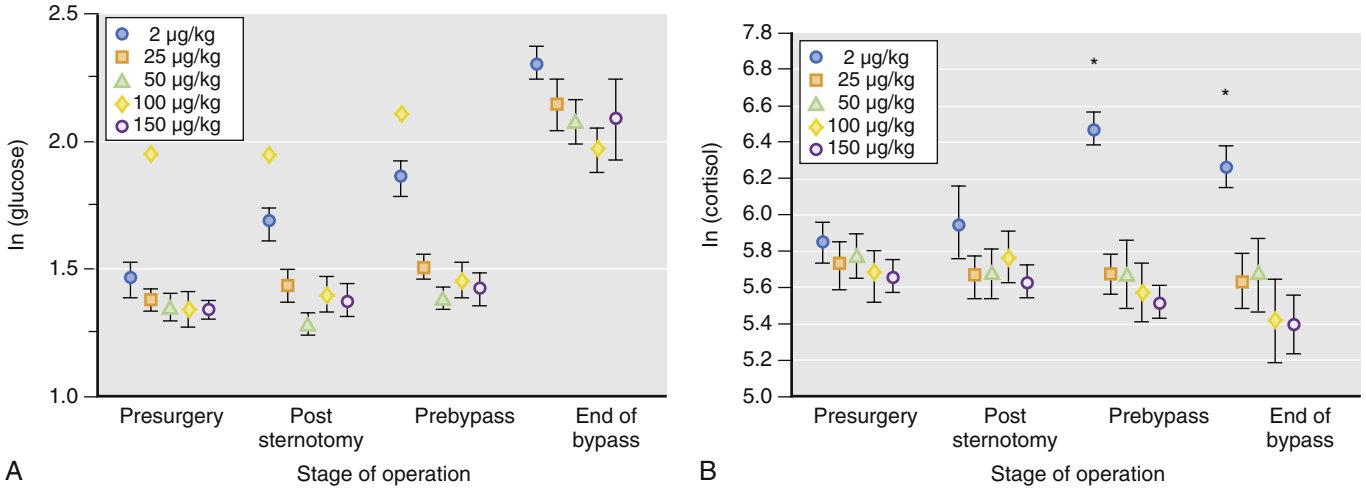

Figure 31-23. Suppression of stress responses in the prebypass phase of open heart surgery in infants and young children by fentanyl combined with a low concentration (0.2% to 0.4%) of isoflurane. Mean (± standard error) natural logarithm (ln) for glucose (**A**) or ln for cortisol (**B**) versus stage of surgery for each dose of fentanyl. The values for the 2 μg/kg group indicated by *asterisks* were significantly higher ($P < 0.01$) than in the other groups. *(From Duncan HP, Cloote A, Weir PM, et al: Reducing stress responses in the pre-bypass phase of open heart surgery in infants and young children: a comparison of different fentanyl doses,* Br J Anaesth *84:556-564, 2000.)*

fentanyl and sufentanil. More modest doses of alfentanil have been successfully administered in combination with sedative-hypnotics such as propofol for cardiac anesthesia.

Sufentanil

Advantages of high-dose sufentanil include more rapid induction, better blunting or elimination of hypertensive episodes, and greater reduction in left ventricular stroke work, with higher cardiac outputs and more stable hemodynamics intraoperatively and postoperatively. Induction doses of sufentanil range from 2 to 20 μg/kg administered as a bolus or infused over 2 to 10 minutes. Total doses of sufentanil administered in high-dose techniques usually range from 15 to 30 μg/kg. However, no additional benefit could be demonstrated in terms of hemodynamic control or EEG signs by increasing the dose of sufentanil from 3 to 15 μg/kg for the induction of anesthesia in patients premedicated with lorazepam.[385] Muscle rigidity during induction of anesthesia with high-dose opioid may cause difficult ventilation with a mask. During induction of anesthesia with sufentanil (3 μg/kg), upper airway closure occurs at the level of the glottis or above.[386]

The amount of sufentanil required can be markedly influenced by the supplements employed concomitantly. For patients undergoing coronary artery surgery, induction (0.4 ± 0.2 μg/kg) and total maintenance (2.4 ± 0.8 μg/kg) doses of sufentanil were used in combination with propofol (1.5 ± 1 mg/kg for induction and 32 ± 12 mg/kg total). Sufentanil requirements tripled when midazolam was used instead of propofol.[387] Etomidate combined with an opioid can provide excellent anesthetic conditions with few hemodynamic perturbations. Inducing anesthesia with sufentanil (0.5 to 1.0 μg/kg) and etomidate (0.1 to 0.2 mg/kg) frequently confers hemodynamic stability. Maintenance of anesthesia by using an infusion of sufentanil (1.0 to 2.0 μg/kg/hour) in a balanced anesthetic technique achieves the advantages of opioid-based anesthesia and avoids prolonged opioid action into the postoperative period.

Remifentanil

Remifentanil has been used in cardiac anesthesia[341] (see also Chapter 67). Induction with remifentanil (2 μg/kg) with propofol and maintenance with remifentanil at 0.25 or 0.5 μg/kg/minute provided appropriate anesthesia for minimally invasive coronary artery bypass surgery with rapid awakening and tracheal extubation (Fig. 31-24).[388] Kazmaier and associates compared high-dose remifentanil (2.0 μg/kg/minute) and remifentanil (0.5 μg/kg/minute) combined with propofol (target-controlled infusion aiming at a plasma concentration of 2.0 μg/mL) in patients undergoing elective coronary artery bypass grafting.[389] Their results showed that a high dose of remifentanil reduced stroke volume index, heart rate, mean arterial pressure, myocardial blood flow, and myocardial O_2 uptake, and the drug's effects did not differ from those of remifentanil-propofol anesthesia. Geisler and associates examined the efficacy and safety of high-dose remifentanil anesthesia in patients undergoing coronary artery bypass graft surgery.[390] Continuous infusions of remifentanil (1.0 to 2.0 μg/kg/minute) in combination with propofol (3 mg/kg/hour) caused profound suppression of responses to surgical stimuli in most patients, but muscle rigidity occurred when remifentanil was used to induce anesthesia. These investigators concluded that starting the remifentanil infusion rate higher than 1.0 μg/kg/minute had no apparent advantage, and remifentanil is not suitable for use as a sole induction agent.

OTHER APPLICATIONS OF OPIOIDS

See also Chapter 98.

Transdermal Therapeutic System

Transdermal drug delivery generally requires high solubility in both water and oil, low molecular weight, high potency, and little or no skin irritation. Fentanyl is available in a transdermal therapeutic system (TTS). Potential advantages of delivering fentanyl transdermally include no first-pass drug metabolism by the liver, improved patient compliance, convenience and comfort, and consistent analgesia. Doses of TTS fentanyl include 20, 50, 75 and 100 μg/hour and achieve blood levels ranging from less than 1.0 to 2.0 ng/mL, although significant variability exists.

The pharmacokinetics of transdermally delivered fentanyl (50 μg/hour) was compared in 10 young adult (25 to 38 years of age) and eight older adult (64 to 82 years of age) patients.[391] Investigators shown that the mean half-time (time for plasma concentrations to double after patch application) was 4.2 hours and 11.1 hours and the mean maximum plasma concentrations were 1.9 ng/mL

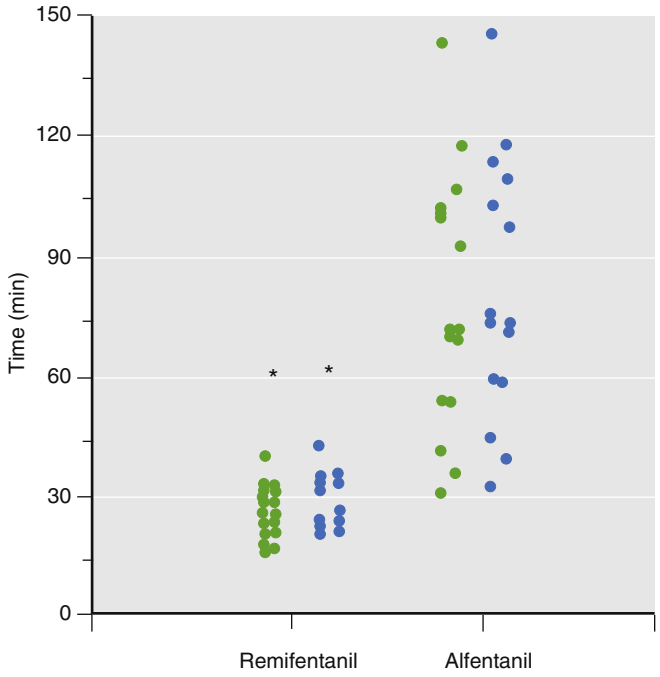

Figure 31-24. Times to awakening (*green circles*) and tracheal extubation (*blue circles*) in patients who underwent minimally invasive direct coronary artery bypass surgery after intravenous anesthesia with remifentanil and propofol or alfentanil and propofol. *(From Ahonen J, Olkkola KT, Verkkala K, et al: A comparison of remifentanil and alfentanil for use with propofol in patients undergoing minimally invasive coronary artery bypass surgery,* Anesth Analg *90:1269-1274, 2000.)*

and 1.5 ng/mL, in the younger and older groups, respectively. No differences were noted in the time at which maximum plasma concentrations occurred and the elimination $t_{½}$ after patch removal. Elevated body temperature accelerates either the release of fentanyl from the patch or the distribution from the subcutaneous fat depot. Portenoy and colleagues demonstrated that steady-state serum concentration was obtained by repeated application of TTS fentanyl, and the apparent $t_{½}$ following system removal after repeated application was relatively long, presumably because of ongoing absorption from a subcutaneous depot.[392]

Results of clinical trials using TTS fentanyl for postoperative analgesia demonstrated a high incidence of significant respiratory depression, and this application is not recommended.[393] In cancer pain, TTS fentanyl offers an interesting alternative to oral morphine, and its effectiveness and tolerability in this indication were demonstrated by several trials.[394] In general, TTS fentanyl has the same adverse effects as other opioids, mainly sedation, nausea, vomiting, and constipation. In comparison with oral morphine, TTS fentanyl causes fewer gastrointestinal adverse events. The risk of hypoventilation is comparatively low in patients with cancer. Sufentanil and buprenorphine may also be suitable for transdermal delivery, but clinical results are not yet available. Transdermal morphine is useful only if it is applied to de-epithelialized skin.

Iontophoresis

Iontophoresis is a technique by which drug passage through the skin is augmented by an external electric current. Clinically significant doses of morphine and fentanyl can be delivered iontophoretically. The fentanyl HCl iontophoretic transdermal system (fentanyl ITS) is a novel PCA system that has been approved in the United States and Europe for the management of acute moderate to severe postoperative pain.[395] This system allows patients to self-administer preprogramed doses of fentanyl noninvasively through the use of iontophoretic technology. To assess the efficacy and safety of patient-controlled ITS using fentanyl hydrochloride (40-μg infusion over 10 minutes) compared with standard intravenous morphine PCA (1-mg bolus every 5 minutes; maximum of 10 mg/hour), a prospective randomized controlled parallel-group trial was performed.[396] The results indicated that the fentanyl ITS can provide pain control equivalent to that observed with standard morphine PCA, with a similar incidence of opioid-related adverse events. The fentanyl ITS may offer certain clinical advantages over existing PCA modalities.[395] Its method of drug delivery avoids the risk of complications of needle-related injuries and infection, and its preprogramed electronics eliminate the potential for manual programing errors and excessive dosing. In addition, the compact size of the system enables more patient mobility postoperatively. The patient-controlled ITS with fentanyl has the potential to become a valuable option in the management of acute postoperative pain. Panchal and colleagues reported that fentanyl ITS was associated with a significantly lower incidence of analgesic gaps, which are defined as periods during which the patient does not access analgesia, thus contributing to ineffective postoperative pain management relative to morphine intravenous PCA.[397]

Transmucosal Drug Delivery

Similar to transdermal drug delivery, transmucosal delivery through the oropharynx and nasopharynx eliminates hepatic first-pass metabolism (drugs are absorbed directly into the systemic circulation) and improves patient comfort, convenience, and compliance.

Buprenorphine, a potent, synthetic morphine analogue with mixed opioid agonist-antagonist properties and a long half-time, is readily absorbed from sublingual mucosal tissues. The portion of the drug that is swallowed is almost completely metabolized by the liver, and only a small fraction can reach the systemic circulation when swallowed. Systemic bioavailability after sublingual buprenorphine is approximately 50% of that following intravenous administration. In several studies, sublingual buprenorphine (0.4 mg) was compared with conventional intramuscular morphine or meperidine and found to provide comparable and satisfactory analgesia.

Oral transmucosal fentanyl citrate (OTFC) is a solid dosage form of fentanyl that consists of fentanyl incorporated into a sweetened lozenge on a stick. A portion of fentanyl is absorbed through the oral mucosa, and the rest is swallowed and absorbed through the gastrointestinal tract. The recommended doses range from 5 to 20 μg/kg.[398] OTFC should be administered approximately 30 minutes before the surgical procedure (or painful procedure) to obtain peak effect. Plasma concentrations after OTFC administration peak at 2.0 ± 0.5 ng/mL, 15 to 30 minutes after OTFC administration, and then decline to less than 1 ng/mL an hour later.[399] Unlike transdermal fentanyl, OTFC leaves no significant depot in the mucosal tissues after it is removed. The systemic bioavailability of OTFC is 50% and reflects both buccal and gastrointestinal absorption. OTFC bioavailability is similar to that of buprenorphine (55%), but it is much greater than that of buccal morphine and other opioids with low lipid solubility. Egan and associates demonstrated that the pharmacokinetics of OTFC did not change with repeated dosing, and the decline of plasma concentration was as rapid as when the drug was administered by intravenous infusion[400] (Fig. 31-25). Furthermore, Kharasch and colleagues reported that the pharmacokinetics of OTFC was not altered in older volunteers (67 ± 6 years of age), and no change in OTFC dosing in older adults would appear necessary.[401] Peak fentanyl concentration and clinical effects after OTFC were minimally affected by hepatic or intestinal CYP3A induction by rifampicin and intestinal CYP3A inhibition by grapefruit juice, findings suggesting that first-pass metabolism minimally influences OTFC bioavailability.[402] Perioperative OTFC was reported to be effective for postoperative analgesia in pediatric patients undergoing tonsillectomy.[403] However, OTFC can induce perioperative emesis and respiratory depression. It is also being evaluated for the treatment of breakthrough cancer pain.[404] OTFC may be ideally suited to treat breakthrough cancer pain because fentanyl is rapidly absorbed from OTFC, and patients can easily self-administer OTFC.

Delivery of opioids through the nasal mucosa has also been investigated. No difference was noted in the efficacy of intranasal fentanyl (2 μg/kg), intramuscular morphine (0.1 mg/kg), and intravenous morphine

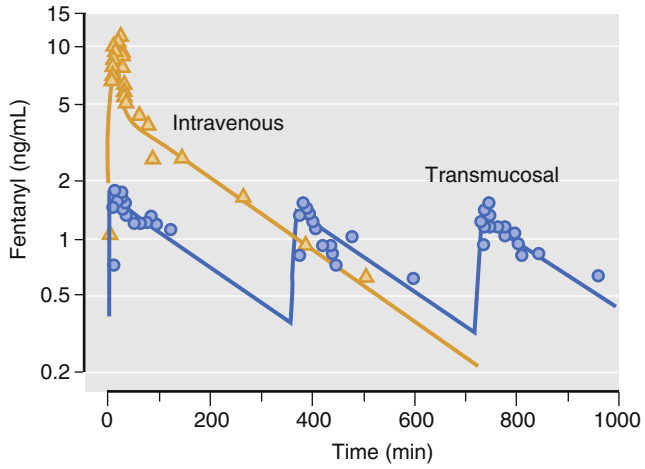

Figure 31-25. A typical result of time-dependent change in plasma concentration of fentanyl after oral transmucosal fentanyl citrate (OTFC) application and intravenous administration. Three 800-μg doses of OTFC were administered with 6-hour intervals between doses, and fentanyl was infused at a constant rate of 50 μg/minute to a total of 15 μg/kg. *(From Egan TD, Sharma A, Ashburn MA, et al: Multiple dose pharmacokinetics of oral transmucosal fentanyl citrate in healthy volunteers,* Anesthesiology *92:665-673, 2000.)*

(0.1 mg/kg) in controlling postoperative pain and emergence delirium in children undergoing bilateral myringotomy and placement of ventilating tubes.[405] A novel transnasal morphine formulation composed of morphine monohydrate and chitosan, a nontoxic, naturally occurring mucoadherent derived from shellfish, was shown to offer a noninvasive alternative to intravenous morphine for postoperative analgesia in patients after third molar extraction.[406] Intranasal administration of remifentanil (4 μg/kg) produces good intubating conditions in 2 to 3 minutes after induction of anesthesia with sevoflurane in children.[407]

Fentanyl (300 μg) inhalation produces low plasma drug level (0.1 ng/mL) after 15 minutes and analgesia that may be disproportionately greater than expected.[408] Inhaled liposome-encapsulated fentanyl was also demonstrated to provide a noninvasive route of administration with a rapid increase and prolonged maintenance of plasma fentanyl concentration.[409] In patients terminally ill with cancer, inhalation of nebulized fentanyl citrate significantly improved patients' perception of breathing, respiratory rate, and O_2 saturation.[410] This inexpensive and readily available treatment may offer substantial relief of end-of-life dyspnea. The advent of specialized and efficient pulmonary drug delivery systems has facilitated the evaluation of inhaled opioids, such as morphine and fentanyl, for management of severe pain associated with surgery or malignant disease.[411]

The rectal mucosa is another site for transmucosal drug delivery. The bioavailability of 30 mg morphine sulfate controlled-release suppository formulation was significantly greater than that of 30 mg oral controlled-release morphine sulfate tablets; this increase may be the result of partial avoidance of hepatic biotransformation with rectal administration.[412] The hydrogel formulation of rectal morphine may also be useful for premedication and analgesia in pediatric patients.[413]

Oral Controlled-Release Medications

Despite the high first-pass metabolism of opioid analgesics, morphine has been formulated into an oral, sustained-release tablet (MST) and has been evaluated for premedication, for postoperative analgesia, and as an analgesic for chronic cancer pain. MST provides unreliable preoperative anxiolysis and postoperative pain relief, possibly because of delayed time to onset of peak effects (3 to 5 hours), which can be increased by impaired gastric emptying and absorption from the small intestine. As an analgesic for chronic cancer pain, MST was shown to be an excellent formula.[414]

The relative analgesic potency of single doses of oral controlled-release oxycodone (20 or 40 mg) and oral controlled-release morphine (45 or 90 mg) was compared in a randomized double-blind trial in women with moderate to severe pain following abdominal hysterectomy.[415] Controlled-release oxycodone at doses of 20 mg or 40 mg was comparable with controlled-release morphine at doses of 45 mg or 90 mg, respectively, for total and peak analgesic effects, thus indicating that oral controlled-release oxycodone was twice as potent as oral controlled-release morphine. A randomized double-blind crossover trial indicated that controlled-release oxycodone is as safe and effective as controlled-release morphine in the treatment of cancer pain.[416]

Extended-Release Epidural Morphine (DepoDur)

DepoDur is a novel drug that delivers morphine by using DepoFoam technology, a drug-delivery system composed of multivesicular lipid particles containing nonconcentric aqueous chambers that encapsulate the active drug. When the plasma morphine concentration after epidural administration of 5 mg of standard morphine was compared with that of 5 mg of DepoDur, the terminal $t_{½}$ was comparable, but the peak concentration was significantly smaller, and peak systemic absorption occurred later with DepoDur. Randomized controlled studies demonstrated that 5 to 15 mg of DepoDur can be a potentially beneficial analgesic after elective cesarean delivery with no significant increases in adverse events for the period from 24 to 48 hours postoperatively.[417,418] A large dose of epidural lidocaine before DepoDur administration alters the pharmacokinetics and drug effects of DepoDur.[419]

OTHER OPIOID AGONISTS

CODEINE

Codeine (methylmorphine) is one half as potent as morphine, has a high oral-parenteral potency ratio (2:3), and has a plasma $t_{½}$ of 2 to 3 hours. Codeine has mild to moderate analgesic but strong cough-suppressant properties after oral administration. Cytochrome P450 2D6 (CYP2D6) is the enzyme responsible for *O*-demethylation of codeine to morphine.[420] Intravenous codeine produces profound hypotension and is neither approved nor recommended.

OXYCODONE

Oxycodone is extensively metabolized in humans mainly by hepatic cytochrome P450, and only 10%

of oxycodone is excreted in unchanged form in urine. Rifampin, a strong inducer of several drug-metabolizing enzymes, induces cytochrome P450, reduces the plasma concentration of intravenous and oral oxycodone, and modestly attenuates the pharmacologic effects of oxycodone.[421] The role of several metabolites in oxycodone's analgesic activity is still not fully understood.[422] Oxycodone is a potent analgesic after systemic administration, but its analgesic potency is poor after intrathecal administration.[423] Investigators showed that oxycodone is more potent than morphine for visceral pain relief in intravenous PCA after laparoscopic hysterectomy.[424] With respect to pharmacologic effects other than analgesic effects, investigators reported that the extent and speed of onset of oxycodone-induced respiratory depression were dose dependent and greater than those of an equivalent dose of morphine.[425]

MEPERIDINE (PETHIDINE)

Meperidine is predominantly a μ-opioid receptor agonist that produces pharmacologic effects similar but not identical to those of morphine. Meperidine sometimes causes excitation of the CNS that is characterized by tremors, muscle twitches, and seizures largely caused by accumulation of a metabolite, normeperidine. Meperidine has well-known local anesthetic properties.

Unlike morphine, after intravenous injection, first-pass uptake of meperidine by the lungs is approximately 65%. Meperidine is more highly bound to plasma proteins than is morphine, principally (70%) to α_1-acid glycoprotein. As with morphine, a relatively high hepatic extraction ratio results in biotransformation that depends on hepatic blood flow. The major metabolite normeperidine has analgesic activity and is roughly twice as potent as meperidine in producing seizures in animals. The elimination $t_{½}$ of normeperidine is considerably greater than that of meperidine, and thus repeated doses can easily produce accumulation of this toxic metabolite in patients with renal disease, with the potential for inducing seizures.

Meperidine is frequently used for postoperative pain management. A comparative study demonstrated that morphine, meperidine, and tramadol resulted in equivalent pain scores in intravenous PCA after abdominal hysterectomy.[426] Meperidine (12.5 to 35 mg) is also effective for prevention and treatment of postoperative shivering.[427,428]

HYDROMORPHONE

Hydromorphone is structurally related to morphine but is approximately 5 to 10 times as potent. Hydromorphone may be better tolerated than morphine in patients with renal failure; because of the keto-group in position 6 of the benzol ring, an active 6-glucuronate metabolite is not formed as in morphine.[429] A bolus dose of hydromorphone reaches its peak effect in approximately 20 minutes, whereas an equivalent morphine bolus requires 94 minutes to reach peak. Analgesia after hydromorphone lasts 4 to 5 hours. Hydromorphone has been used for both acute and chronic pain conditions in adults and children.[430] Hydromorphone PCA provides adequate postoperative analgesia in patients who have undergone gynecologic surgical procedures, and no systematic difference is noted between morphine and hydromorphone in opioid-related side effects.[431]

LEVORPHANOL

Levorphanol is the only available semisynthetic opioid agonist of the morphinan series with a long (12 to 19 hours) $t_{½}$. It is five times as potent as morphine, with an intramuscular-to-oral potency ratio of 1:2. Levorphanol may have particular utility in patients with chronic pain who demonstrate morphine tolerance, perhaps because of differences in opioid receptor activity. Analgesia produced by levorphanol is mediated by its interactions with μ-, δ-, and κ-opioid receptors. Levorphanol is also an NMDA receptor antagonist. The long $t_{½}$ of the drug increases the potential for drug accumulation.[432]

METHADONE

Methadone has an equivalent potency but longer duration of action than morphine. The plasma $t_{½}$ of methadone is very long and variable (13 to 100 hours). Despite this property, many patients require doses every 4 to 8 hours to maintain analgesic effects. The major clinical applications of methadone are in the prevention of opioid withdrawal symptoms and in the treatment of chronic pain. Investigators showed that the same dose of intravenous methadone (20 mg) that is effective for postoperative pain is also suitable for the induction of anesthesia in combination with etomidate, and that methadone may have the potential for producing histamine release.[433]

OXYMORPHONE

Oxymorphone is a semisynthetic opioid agonist that is specific for the μ-opioid receptor and is approved to treat both acute and chronic pain. Because of its extensive liver metabolism, oral oxymorphone is contraindicated in patients with moderate to severe hepatic impairment.[434] Oxymorphone is structurally related to morphine and is almost 10 times as potent, but with a similar duration of action. In patients with acute moderate to severe postsurgical pain, oral immediate-release oxymorphone (10, 20, or 30 mg) provided significant dose-related pain relief compared with placebo, and this relief was maintained over several days, with a safety profile comparable to that of immediate-release oxycodone.[435]

PIRITRAMIDE

Piritramide, a synthetic opioid structurally related to meperidine, is devoid of emetic activity and is used for postoperative analgesia in several European countries.[436] Pharmacokinetic analysis showed that piritramide is distributed extensively and is eliminated slowly and recommended intermittent bolus administration.[437] A randomized controlled trial showed that intravenous PCA with piritramide can produce pain management as satisfactory as that observed with oral oxycodone after cesarean section.[438]

TRAMADOL

Tramadol is a synthetic 4-phenyl-piperidine analogue of codeine with a dual mechanism of action. Tramadol stimulates the μ receptor and, to a lesser extent, the δ- and κ-opioid receptors. Like tricyclic antidepressants, tramadol also activates spinal inhibition of pain by decreasing the reuptake of norepinephrine and serotonin.[439] Investigators suggested that tramadol may have direct serotonin-releasing action.[440] Tramadol is one fifth to one tenth as potent as morphine. In rats, tramadol reduced the MAC of isoflurane in a naloxone-sensitive manner.[441] Intravenous tramadol was effective for postthoracotomy pain relief.[442] Analgesic doses of tramadol may produce less respiratory depression, in part because of its nonopioid receptor–mediated actions, and may have minimal effects on gastrointestinal motor function.[443] Seizures have been reported in patients taking the drug. Caution should be exercised when combining tramadol with MAOIs, neuroleptic agents, and other drugs that lower the seizure threshold. Investigators suggested that tramadol has local anesthetic properties on peripheral nerves when it is used alone.[444]

Tramadol used as a sole drug cannot be considered the drug of choice after moderately painful surgical procedures. The doses needed to relieve pain in 80% of patients are much larger than the usual dose of 100 mg.[445] Tramadol added to lidocaine for intravenous regional anesthesia provided a shorter onset time of sensory block.[446] Tramadol added to 1.5% mepivacaine for brachial plexus block enhances the duration of analgesia in a dose-dependent manner with acceptable side effects.[447] Intraarticular tramadol was also used for management and prevention of pain after arthroscopic knee surgery. The intraarticular admixture of tramadol 100 mg with 0.25% bupivacaine provides pronounced prolongation of analgesia than with either drug alone in patients undergoing arthroscopic knee surgery.[448] Clinical studies to determine the analgesic efficacy of neuraxial tramadol added to epidural anesthesia in adults have yielded contradictory results.[449,450]

Tramadol has dose- and time-dependent bactericidal activity against *Escherichia coli* and *Staphylococcus epidermidis*, as well as antibacterial activity against *Staphylococcus aureus* and *Pseudomonas aeruginosa*. The antibacterial properties of tramadol may be useful for reduction of bacterial infection after regional anesthesia.[451]

MORPHINE-6-GLUCURONIDE

M6G is a potent metabolite of morphine. In contrast to morphine, M6G is not metabolized but is excreted by the kidneys and exhibits enterohepatic cycling because it is a substrate for multidrug resistant transporter proteins in the liver and intestines.[452] M6G exhibits a delay in its analgesic effect (blood–effect-site equilibration $t_{½}$ 4 to 8 hours), which is partly related to slow passage through the blood-brain barrier and distribution within the brain compartment. In humans, M6G's potency is just half that of morphine. Trials to use M6G as an analgesic have been reported. Osborne and co-workers reported that 0.5 to 4 mg of intravenous M6G was effective for treatment of cancer pain for 2 to 24 hours without causing nausea and vomiting.[453] M6G (100 mg given intrathecally) provided excellent analgesia after total hip replacement, as did intrathecal morphine sulfate (500 mg).[454] In a randomized double-blind study, M6G had an analgesic effect similar to that of morphine over the first 24 hours postoperatively. However, the initial onset of M6G effect may be slower than that of morphine.[455] M6G can paradoxically increase pain sensitivity in mice and humans. The pronociceptive effect of M6G can be shown in knockout mice lacking μ-, κ- and δ-opioid receptors, and it may result from activation of the NMDA receptors.[456]

AGONIST-ANTAGONIST OPIOID COMPOUNDS

Nalorphine, the first agonist-antagonist opioid, was successfully synthesized by Weijland and Erickson in 1942 and was found to be strongly antagonistic to almost all the properties of morphine. Although nalorphine was found to possess strong analgesic actions, it was unsuitable for clinical use because of its psychotomimetic effects. Nalorphine was used in lower doses as an opioid antagonist.

Agonist-antagonist opioids are usually produced by alkylation of the piperidine nitrogen and the addition of a three-carbon side chain such as a propyl, allyl, or methyl allyl to morphine. Buprenorphine is a partial agonist at the μ receptor. The other compounds are μ-receptor antagonists and full or partial agonists at the κ receptors. Agonist-antagonist opioids are less prone (but not immune) to abuse because they cause less euphoria and are associated with less drug-seeking behavior and physical dependence.

Dosing data of these compounds are shown in Table 31-8. The agonist-antagonist compounds depress respiration in a manner similar to that of morphine, but ceiling effects exist (Table 31-9). Effects on the cardiovascular system differ among these compounds (Table 31-10).

PENTAZOCINE

Analgesia produced by pentazocine is primarily related to κ-receptor stimulation. Pentazocine is one half to one fourth as potent as morphine. Ceilings to both analgesia and respiratory depression occur after administration of 30 to 70 mg of pentazocine. Although the potential for abuse is less than with morphine, prolonged use of

TABLE 31-8 DOSING DATA FOR AGONIST-ANTAGONIST OPIOIDS AND MORPHINE

	Equianalgesic IM Dose (mg)	Duration of Analgesia (hr)	Oral-IM Efficacy Ratio
Morphine	10	4-5	1:6

pentazocine can lead to physical dependence. Nalorphine-like dysphoric side effects are common, especially after high doses (>60 mg) of pentazocine in older patients. The dysphoric effects of pentazocine can be reversed with naloxone. Pentazocine depresses myocardial contractility and increases arterial blood pressure, heart rate, systemic vascular resistance, pulmonary artery pressure, and left ventricular work index. Pentazocine also increases blood catecholamine levels. Pentazocine inhibits gastric emptying and gastrointestinal transit in rats, whereas U50488H, a pure κ-agonist, did not significantly inhibit either.[457] Therefore, one may speculate that pentazocine affects gastrointestinal function through a mechanism other than the opioid receptors.

Pentazocine has limited application because it is associated with a high incidence of postoperative nausea and vomiting, it provides limited analgesia, it partially antagonizes other opioids, and it can produce undesirable cardiovascular and psychotomimetic effects.

BUTORPHANOL

Butorphanol is an agonist at κ receptors. Its activity at μ receptors is either antagonistic or partially agonistic. It is five to eight times as potent as morphine and is available only in parenteral form. After intramuscular injection, the onset of effect is rapid, and peak analgesia occurs within 1 hour. Whereas the duration of action of butorphanol is similar to that of morphine, its plasma $t_{1/2}$ is only 2 to 3 hours. Although butorphanol (10 mg IM) causes as much respiratory depression as the same dose of morphine, higher doses reach a ceiling. Side effects after butorphanol include drowsiness, sweating, nausea, and CNS stimulation. In healthy volunteers, butorphanol (0.03 or 0.06 mg/kg IV) produces no or minimal cardiovascular changes. However, in patients with cardiac disease, butorphanol causes significant increases in cardiac index, left ventricular end-diastolic pressure, and pulmonary artery pressure.

Because butorphanol decreases the MAC for enflurane by only a small fraction, it cannot serve like the fentanyl congeners as an anesthetic. Butorphanol is subject to less abuse and has less addictive potential than does morphine or fentanyl. Acute biliary spasm can occur after butorphanol administration, but increases in biliary pressure are lower than after equipotent doses of fentanyl or morphine.

Transnasal butorphanol is effective in relieving migraine and postoperative pain.[458]

BUPRENORPHINE

Buprenorphine is a thebaine derivative, μ-receptor partial agonist, and it is similar in structure to morphine but approximately 33 times more potent. Whereas fentanyl dissociates rapidly from μ receptors ($t_{1/2}$ of 6.8 minutes), buprenorphine has a higher affinity and takes much longer ($t_{1/2}$ of 166 minutes). The onset of action of buprenorphine is slow, its peak effect may not occur until 3 hours, and the duration of effect is prolonged (<10 hours). The volume of distribution of buprenorphine is 2.8 L/kg, and its clearance is 20 mL/kg/minute. Plasma concentrations of the metabolites of buprenorphine (norbuprenorphine, buprenorphine-3-glucuronide, and norbuprenorphine-3-glucuronide) may approximate or exceed those of the parent drug. Glucuronide metabolites are biologically active and may contribute to the overall pharmacology of buprenorphine.[459]

Subjective effects (e.g., euphoria) of buprenorphine are similar to those of morphine. Buprenorphine produces depression of minute ventilation that levels off at doses higher than 3.0 μg/kg to approximately 50% of baseline, in contrast to the case of fentanyl, in which dose-dependent respiratory depression results in apnea at doses higher than 2.9 μg/kg[460] (Fig. 31-26). Buprenorphine has been successfully used for premedication (0.3 mg IM), as the analgesic component in balanced anesthesia (4.5 to 12 μg/kg), and for postoperative pain control (0.3 mg IM). Buprenorphine, like the other agonist-antagonist compounds, is not acceptable as a sole anesthetic, and its receptor kinetic profile restricts its usefulness if other μ-agonists are used. Opioid withdrawal symptoms develop slowly (5 to 10 days) after buprenorphine is discontinued following long-term use.

NALBUPHINE

Nalbuphine is an agonist-antagonist opioid that is structurally related to oxymorphone and naloxone. It binds to μ receptors as well as to κ and δ receptors. Nalbuphine acts as an antagonist at the μ receptor and an agonist at the κ receptor. Activation of supraspinal and

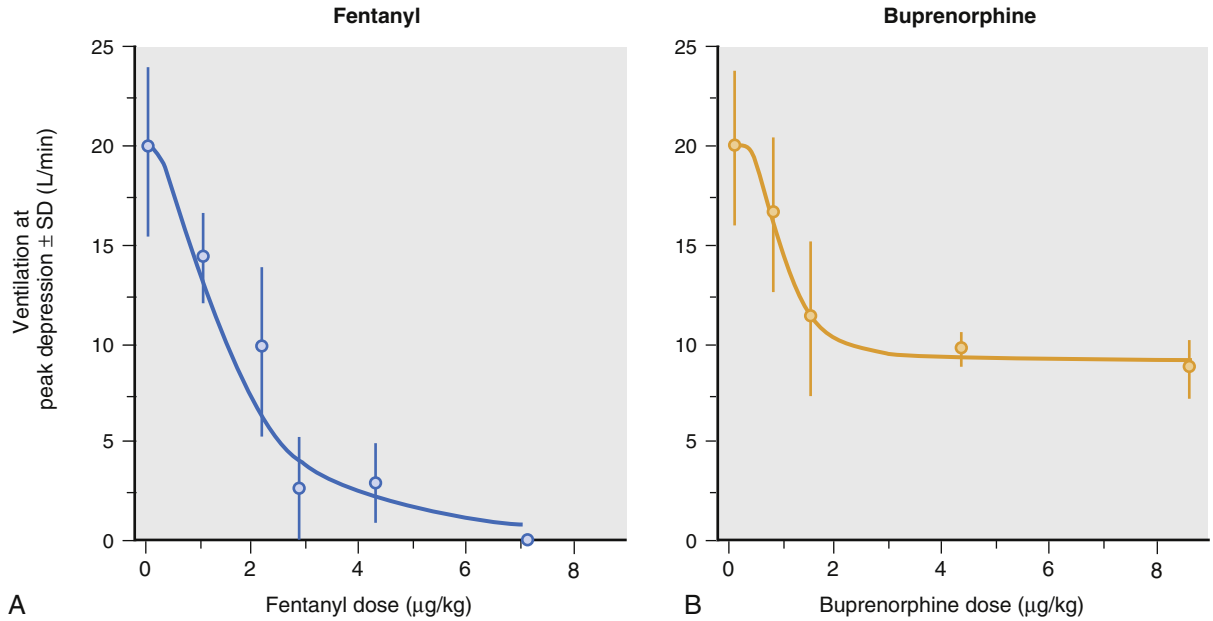

Figure 31-26. Dose-response relationships for reduction of minute ventilation induced by fentanyl (**A**) and buprenorphine (**B**). The response is the peak ventilatory depression at each dose. The *line through the data* is the fit to the Hill equation. Placebo is 0 μg/kg. Data are mean ± standard deviation. *(From Dahan A, Yassen A, Bijl H, et al: Comparison of the respiratory effects of intravenous buprenorphine and fentanyl in humans and rats,* Br J Anaesth *94:825-834, 2005.)*

spinal κ receptors results in limited analgesia, respiratory depression, and sedation. Nalbuphine, like other agonist-antagonist compounds, interferes with the analgesia produced by pure μ-agonists. In rats, coadministration of nalbuphine with morphine dose dependently blocked the development of morphine tolerance and dependence, without attenuation of the antinociceptive effect of morphine.[461] Nalbuphine is available only for parenteral use. The onset of effect is rapid (5 to 10 minutes), and its duration is long (3 to 6 hours) because of a long plasma elimination $t_{½}$ (5 hours).

Nalbuphine has been administered as an analgesic supplement for conscious sedation or balanced anesthesia and as an analgesic for postoperative and chronic pain problems. In patients undergoing myocardial revascularization, continuous infusion of nalbuphine (0.05 to 0.1 mg/kg/minute) and that of fentanyl (0.15 to 0.3 μg/kg/minute) were compared.[462] Nalbuphine lacked the ability to attenuate cardiovascular and hormonal responses to tracheal intubation and surgical procedures. The investigators concluded that continuous infusion of nalbuphine cannot be recommended for anesthesia in patients undergoing myocardial revascularization. For postoperative epidural PCA, the combination of hydromorphone (0.075 mg/mL) and nalbuphine (0.04 mg/mL) resulted in a lower incidence of nausea and a decreased need for bladder catheterization compared with hydromorphone alone.[463] A randomized double-blind controlled study in patients undergoing gynecologic surgical procedures demonstrated that the interaction between morphine and nalbuphine in an intravenous PCA admixture is additive, and the combination of the two drugs can decrease the incidence of pruritus.[464]

A prospective randomized double-blind study demonstrated that nalbuphine (4 mg IV) was as effective as ondansetron (4 to 8 mg IV) for prevention of intrathecal morphine-induced pruritus after cesarean delivery.[465] Whereas one study reported that nalbuphine provides a rapid and potent antishivering effect similar to that of meperidine,[466] a quantitative systematic review of randomized controlled trials did not support this conclusion.

DEZOCINE

Dezocine is slightly more potent and acts faster than morphine, with a similar duration, and it is a partial agonist of the μ receptors. Side effects are similar to those of morphine. Although dezocine was shown to be an effective alternative to fentanyl when administered during outpatient laparoscopy with propofol and N_2O, dezocine was associated with a high incidence of postoperative nausea and a delayed discharge time.[467] In adult patients who underwent arthroscopic surgical procedures performed using general anesthesia, dezocine (5 mg IV) and morphine (5 mg IV) were similarly effective for postoperative analgesia and caused similar side effects.[468] One report showed that intravenous dezocine (0.1 mg/kg) can effectively suppress cough induced by 5 μg/kg fentanyl.[469]

MEPTAZINOL

Meptazinol has been reported to cause minimal respiratory depression because of its selectivity for $μ_1$ receptors. In patients receiving meptazinol (2.5 mg/kg) with a barbiturate, no cardiovascular changes were observed during tracheal intubation, whereas blood pressure and heart rate were significantly increased in patients receiving fentanyl (5 μg/kg).[470] Side effects (nausea and vomiting) limit its use to the relief of severe pain.

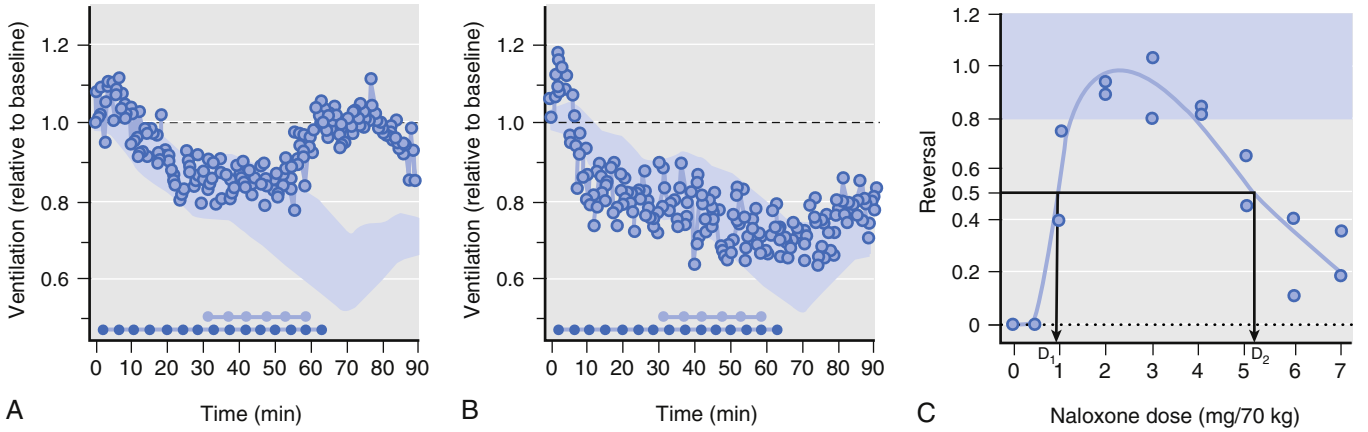

Figure 31-27. Reversal of buprenorphine-induced respiratory depression with naloxone depends on the correct naloxone dose window. Respiratory depression induced by 0.2 mg buprenorphine was reversed by naloxone 2 mg (**A**) and 6 mg (**B**) given over 30 minutes in one subject. The *blue field in the background* is the result of the placebo group in which saline was infused instead of naloxone. *Light blue dots* and *dark blue dots* represent buprenorphine and naloxone infusion, respectively. **C,** Influence of 0 (placebo) and 0.5 to 7 mg naloxone on 0.2 mg intravenous buprenorphine-induced respiratory depression. Reversal was calculated from the naloxone-induced change in ventilation, and it ranges from 0 (effect not different from placebo) to 1 (reversal to predrug baseline level). *(From van Dorp E, Yassen A, Sarton E, et al: Naloxone reversal of buprenorphine-induced respiratory depression,* Anesthesiology *105:51-57, 2006.)*

OPIOID ANTAGONISTS

NALOXONE

Clinically, opioid antagonists are used to restore spontaneous ventilation in patients who breathe inadequately after opioid overdoses or opioid anesthesia. In addition, opioid antagonists can reduce or reverse opioid-induced nausea and vomiting, pruritus, urinary retention, rigidity, and biliary spasm associated with numerous therapies employing opioids, such as neuraxial analgesic techniques. The reported potency ratio of naloxone to nalbuphine for antagonism of pruritic effects of epidural morphine was approximately 40:1.[471]

In one report, morphine requirements were significantly less in patients receiving naloxone, a finding suggesting that naloxone enhanced analgesia.[472] Proposed possible mechanisms for this apparent paradoxical effect of naloxone include enhanced release of endogenous opioids and opioid receptor up-regulation.

Although naloxone is generally considered a pure opioid receptor antagonist, it delays gastric emptying of saline or milk, as does morphine in the rat.[263] Furthermore, high-dose naloxone has partial agonistic activity on the μ- and κ-opioid receptors in cultured cells.[473]

Reversal of Respiratory Depression

In the early 1950s, nalorphine and levallorphan were evaluated as opioid antagonists. They were often found unacceptable because of a high incidence of side effects, as well as incomplete reversal of respiratory depression. Naloxone was introduced into clinical practice in the late 1960s. Side effects (increases in heart rate and blood pressure) and more serious complications (e.g., pulmonary edema) have been reported. The initial naloxone dose recommendations ranged from 0.4 to 0.8 mg. The onset of action of intravenous naloxone is rapid (1 to 2 minutes), and $t_{½}$ and duration of effect are short, approximately 30 to 60 minutes. If intravenous access is not available, naloxone, in doses similar to those given by the intravenous route, is effectively absorbed after intratracheal administration. Reversal with naloxone is limited by high affinity for and slow dissociation from the μ-opioid receptor of buprenorphine, and it depends on the buprenorphine dose and the correct naloxone dose window[474] (Fig. 31-27). Because respiratory depression from buprenorphine may outlast the effects of naloxone boluses or short infusions, a continuous infusion of naloxone may be required to maintain reversal of respiratory depression.[474]

Several mechanisms produce increases in arterial blood pressure, heart rate, and other significant hemodynamic alterations after naloxone reversal of opioids. These include pain, rapid awakening, and sympathetic activation not necessarily caused by pain. When patients receiving naloxone for opioid agonist reversal are hypothermic secondary to intraoperative heat loss, O_2 consumption and minute ventilation can increase two- to threefold.[475] Such metabolic demands also stress the cardiovascular system and increase cardiac output. In addition, greater degrees of hypercapnia at the time of opioid antagonism result in greater degrees of cardiovascular stimulation because of associated sympathetic stimulation. Opioid reversal may be particularly hazardous in patients with pheochromocytoma or chromaffin tissue tumors. However, investigators also reported that intravenous administration of 10 mg naloxone did not significantly change plasma catecholamine concentration and blood pressure.[476]

Recurrence of respiratory depression after naloxone results from the short $t_{½}$ of naloxone. "Renarcotization" occurs more frequently after the use of naloxone to reverse longer-acting opioids such as morphine. Although naloxone is active at μ, δ, and κ receptors, the drug has the greatest affinity for μ receptors, which mediate most potent opioid effects, including respiratory depression and analgesia. Careful titration of naloxone often can restore adequate spontaneous ventilation without reversal of adequate analgesia.

Other Applications

Naloxone may ameliorate the neurologic deficit following an ischemic or traumatic neurologic insult in animals.[477] In humans, a randomized controlled trial demonstrated that naloxone (a bolus of 5.4 mg/kg, followed by infusion at 4.0 mg/kg/hour for 23 hours) does not improve neurologic recovery after acute spinal cord injury.[478] However, the combined use of cerebrospinal fluid drainage and naloxone reduces the risk of paraplegia in thoracoabdominal aneurysm repair.[479] Naloxone may also have a therapeutic role in heat stroke disorders,[480] as well as in cholestasis-induced pruritus.[481] Although intravenous naloxone has been claimed to produce pain relief in opioid-resistant central poststroke pain, a double-blind trial concluded that intravenous naloxone was of no value in alleviating central poststroke pain.[482]

NALTREXONE

Naltrexone is a μ-, δ- and κ-opioid receptor antagonist. It is longer acting than naloxone (plasma $t_{½}$ of 8 to 12 versus 0.5 to 1.5 hours), and it is active when taken orally. A double-blind placebo-controlled study for patients undergoing cesarean section indicated that naltrexone (6 mg) was an effective oral prophylactic against the pruritus and vomiting associated with intrathecal morphine, but it was associated with a shorter duration of analgesia.[483]

NALMEFENE

Nalmefene has a greater preference for μ than δ or κ receptors. Nalmefene is equipotent to naloxone. Nalmefene is long acting after oral (0.5 to 3.0 mg/kg) and parenteral (0.2 to 2.0 mg/kg) administration. Bioavailability after oral administration is 40% to 50%, and peak plasma concentrations are reached in 1 to 2 hours. The mean terminal elimination $t_{½}$ of nalmefene is 8.5 hours, compared with 1 hour for naloxone. Prophylactic administration of nalmefene significantly decreased the need for antiemetics and antipruritic medications in patients receiving intravenous PCA with morphine.[484]

METHYLNALTREXONE

Methylnaltrexone is the first quaternary ammonium opioid receptor antagonist that does not cross the blood-brain barrier.[256] It can reverse the effects of opioid medications mediated by peripheral opioid receptors, whereas the opioid effects mediated by opioid receptors in the CNS, such as analgesia, are not affected. Delayed gastric emptying induced by 0.09 mg/kg morphine could be attenuated by 0.3 mg/kg methylnaltrexone in healthy volunteers.[262] Investigators also reported that methylnaltrexone was effective for reversal of constipation resulting from long-term methadone use.[485] Because methylnaltrexone does not cross the dura, it could have the potential to reverse peripherally mediated side effects of epidural opioids.[486] Randomized double-blind placebo-controlled studies have shown the effectiveness of methylnaltrexone and alvimopan, another peripherally acting opioid receptor antagonist, in the management of postoperative ileus.[256]

DRUG INTERACTONS WITH OPIOIDS

GENERAL PRINCIPLES

Opioids are frequently combined with other anesthetic drugs to produce optimal anesthetic conditions. In anesthesia, most drugs concomitantly administered interact. Although some of these interactions are intentionally sought, others are unwanted and adverse. The three general types of mechanisms of drug interactions are pharmaceutical, pharmacokinetic, and pharmacodynamic.[487]

Pharmaceutical interactions are chemical, as illustrated when an alkaline solution of thiopental and an acidic solution of succinylcholine precipitate when they are simultaneously administered by the intravenous route.

Pharmacokinetic interactions occur when the administration of one agent alters the pharmacokinetics or disposition of another. Hemodynamic changes induced by one agent can affect the pharmacokinetic behavior of the other agent. Sufentanil, which has a greater hepatic extraction ratio than does alfentanil, is more likely to be affected by decreases in hepatic blood flow. Cimetidine can prolong opioid effects by decreasing hepatic blood flow or by diminishing hepatic metabolism. Opioid plasma levels also increase in the presence of propofol.[488] Decreased opioid metabolism, by the CYP3A4 isoform of the cytochrome P450 enzyme responsible for the oxidative metabolism of more than 50 drugs, may also underlie pharmacokinetic interactions. A wide range of chemical compounds, including many drugs, can interact with the cytochrome P450 system and cause either increased activity (enzyme induction) or enzyme inhibition (Box 31-5).[487] Alfentanil, but not sufentanil, may have prolonged action as a result of impaired metabolism in patients receiving erythromycin.[489,490]

Pharmacodynamic interactions between opioids and inhaled anesthetic agents were assessed with classic MAC reduction evaluations in animals and humans. Although marked synergism between opioids and inhaled anesthetic agents occurs with analgesic doses of opioids, the MAC reduction by opioids has a ceiling effect. The pharmacodynamic synergism between opioids and sedative-hypnotics such as propofol is profound. Choosing an opioid with a short context-sensitive $t_{½}$ allows greater doses of that opioid to be administered, along with reduced doses of propofol, without compromising the time for recovery from anesthesia. Thus, the optimal plasma level of propofol is estimated to be approximately 30% less when it is combined with remifentanil instead of alfentanil.[488]

Drug dosing regimens and plasma concentrations of opioid and sedative-hypnotics that provide optimal hemodynamic control during a range of noxious stimuli are necessary. However, complicating our understanding of drug interactions is the observation that the same degree of interaction does not apply across different types of stimuli.

BOX 31-5 *Drugs That Inhibit or Induce Cytochrome P450 Enzymes*

INHIBITORS

Antibiotics
- Macrolides
- Troleandomycin
- Erythromycin
- Fluoroquinolones
- Isoniazid

Azole antifungal drugs
- Ketoconazole
- Itraconazole

Calcium entry blockers
- Diltiazem
- Verapamil

Omeprazole
Cimetidine
Propofol
Grapefruit juice

INDUCERS

Barbiturates
Antiepileptics
- Carbamazepine
- Phenytoin
- Primidone

Rifampicin
Dichloralphenazone
Ethanol
Tobacco smoke

SEDATIVE-HYPNOTICS

See also Chapter 30.

Benzodiazepines

Alfentanil reduces the median effective dose (ED_{50}) of midazolam for the induction of anesthesia in a dose-dependent fashion. On the contrary, with regard to the antinociceptive effect, the interaction between these two types of drugs may be less than additive.[491] Midazolam enhances opioid-induced antinociception at the spinal level but inhibits it at the supraspinal level.[492] Many studies reveal that benzodiazepine-opioid interactions for many properties other than analgesia are synergistic (supraadditive). Both the cardiovascular and respiratory actions of opioids can be significantly altered by the concomitant administration of benzodiazepines.[493] In anesthetized rabbits, fentanyl and midazolam synergistically caused depression of phrenic nerve activity.[494] Combinations of benzodiazepines and opioids, although occasionally preserving ventricular function, can cause significant and at times profound decreases in blood pressure, cardiac index, heart rate, and systemic vascular resistance. Fluid loading may attenuate circulatory depression that occurs when benzodiazepines and opioids are combined.

Barbiturates

Barbiturates can potentiate or produce hypotension if a large dose is administered with opioids. Hypotension after barbiturate-opioid combination results from venodilatation, decreased cardiac filling, myocardial depression, and decreased sympathetic nervous system activity. Reducing induction doses of barbiturates administered concomitantly with opioids is recommended.

Propofol

Administration of propofol-opioid combinations provides unconsciousness and block responses to noxious stimuli. However, when given as an intravenous bolus for induction of anesthesia, propofol can create moderate to severe preintubation hypotension. Propofol-fentanyl and propofol-sufentanil anesthesia for coronary artery bypass surgery may provide acceptable conditions, but mean arterial pressure can decrease to levels that may jeopardize coronary perfusion, especially during induction of anesthesia. In healthy volunteers, the addition of alfentanil (effect-site concentration of 50 or 100 ng/mL) did not affect the changes in the BIS induced by propofol, but it blocked the BIS increase induced by painful stimuli.[495] In patients undergoing spine fusion, infusion of fentanyl (blood levels of 1.5 to 4.5 ng/mL) reduced the infusion rate of propofol necessary to maintain mean arterial pressure but delayed spontaneous eye opening and recovery of orientation.[360] In patients undergoing ambulatory gynecologic laparoscopy, the administration of fentanyl (25 to 50 μg IV) at the time of induction of anesthesia reduced the maintenance propofol requirement but failed to provide effective postoperative analgesia and increased the need for postoperative use of antiemetics.[496] Pharmacokinetic interaction, as well as pharmacodynamic interaction, between propofol and opioids has been reported. Target-controlled infusion of alfentanil (target concentration of 80 ng/mL) was shown to increase the blood propofol concentration by 17% and decrease the elimination clearance, distribution clearance, and peripheral volume of distribution of propofol.[497]

Etomidate

Etomidate can be combined in low doses with opioids with little loss of cardiovascular stability. In patients scheduled for coronary artery bypass grafting, etomidate (0.25 mg/kg) combined with fentanyl (6 μg/kg) resulted in less hypotension after induction and intubation than did propofol (1 mg/kg) combined with fentanyl (6 μg/kg).[498]

Ketamine

A prospective randomized double-blind controlled study demonstrated that intraoperative and postoperative administration of ketamine for the first 48 hours postoperatively (2 μg/kg/minute after a 0.5 mg/kg bolus) improved postoperative analgesia with a significant decrease of morphine consumption.[499] Furthermore, investigators reported that small doses of ketamine and memantine, a long-acting oral NMDA-receptor antagonist, were effective in managing intractable pain in an opioid-tolerant patient.[500] Webb and co-workers reported that low-dose ketamine could be a useful addition to perioperative tramadol administration in patients undergoing abdominal surgical procedures.[501]

INHALED ANESTHETIC AGENTS

Volatile anesthetic agents are frequently combined with opioids to ensure amnesia and to promote immobility and hemodynamic stability (see Chapter 26). Clinical trials of opioids supplemented with volatile anesthetic agents for cardiac surgery demonstrated well-preserved cardiac output and minimal decreases in mean arterial blood pressure.[502] Myocardial ischemia may not, however, always be ameliorated by approaches that combine opioids with potent inhaled anesthetic agents in spite of apparent "good" hemodynamic control. Some of the potent inhaled anesthetic drugs can increase sympathetic nervous system activity and may increase the risk of myocardial ischemia in the patient with cardiac disease.[503] Prior administration of fentanyl, in doses as low as 1.5 μg/kg, can markedly attenuate such responses. Alfentanil (10 μg/kg) is also effective in attenuating these effects.

MUSCLE RELAXANTS

Pancuronium bromide has been frequently used for muscle relaxation during high-dose opioid anesthesia (see also Chapter 34). The vagolytic action of pancuronium can attenuate opioid-induced bradycardia and support blood pressure. In patients undergoing coronary artery bypass grafting who were administered sufentanil (3 to 8 μg/kg), pancuronium (120 μg/kg) caused significant increases in mean arterial pressure, heart rate, and cardiac output but did not induce myocardial ischemia.[504]

Combinations of vecuronium and high doses of opioids may produce negative chronotropic and inotropic effects that result in decreases in heart rate, cardiac output, and blood pressure and increases in the need for vasopressor support. In patients scheduled for coronary artery surgery who received 40 μg/kg sufentanil in combination with vecuronium (0.1 mg/kg), heart rate, mean arterial pressure, and systemic vascular resistance decreased from baseline values after tracheal intubation, with no significant change in cardiac output or evidence of new myocardial ischemia.[505]

In patients anesthetized with fentanyl (50 μg/kg) and scheduled to undergo elective coronary artery bypass grafting, rocuronium (0.6 mg/kg; approximately equivalent to 2 × ED_{95} doses) was associated with minimal changes in hemodynamic variables, including increases in stroke volume index (+15%) and cardiac index (+11%) and a decrease in pulmonary capillary wedge pressure (–25%).[506] In patients undergoing coronary artery bypass surgery performed using fentanyl anesthesia, mivacurium (0.15 or 0.2 mg/kg) produced decreases in mean arterial pressure and systemic vascular resistance index possibly mediated by histamine release, whereas atracurium (0.5 mg/kg) produced no significant hemodynamic changes.[507]

MONOAMINE OXIDASE INHIBITORS

MAOIs can underlie the most serious and potentially fatal opioid-other drug interaction. The combination of meperidine and MAOIs can induce the serotonin syndrome, which is caused by excess serotonin availability in the CNS at the serotonin type 1A (5-HT_{1A}) receptor. The serotonin syndrome is characterized by confusion, fever, shivering, diaphoresis, ataxia, hyperreflexia, myoclonus, or diarrhea. The phenylpiperidine series opioids, including meperidine, tramadol, and methadone, appear to be weak serotonin reuptake inhibitors and have all been involved in serotonin toxicity reactions with MAOIs, whereas morphine, codeine, oxycodone, and buprenorphine are known not to be serotonin reuptake inhibitors and do not precipitate serotonin toxicity with MAOIs.[508] Alfentanil can be used with MAOIs without complications.[509,510]

CALCIUM CHANNEL BLOCKERS

Because opioids can inhibit voltage-dependent Ca^{2+} channel activity through the activation of G proteins, [2]opioid action may possibly be potentiated by Ca^{2+} channel blockers. Numerous animal studies and a few clinical studies documented that opioid-induced analgesia is potentiated by L-type Ca^{2+} channel blockers. However, another report noted that L-type Ca^{2+} channel blockers do not potentiate morphine analgesia at clinically relevant doses.[511] N-type Ca^{+} channels are involved in the release of neurotransmitters from sensory neurons in the spinal cord. The intrathecal administration of a blocker of this channel, ω-conotoxin GVIA, produced antinociception and interacted synergistically with opioids at the spinal cord level.[512]

MAGNESIUM

Magnesium has antinociceptive effects, probably because of its antagonistic action on the NMDA receptor. Intravenous administration of magnesium sulfate (50 mg/kg preoperatively and 8 mg/kg/hour intraoperatively) significantly reduced intraoperative and postoperative fentanyl requirement.[513] However, passage of magnesium across the blood-brain barrier is limited. Intrathecal administration of fentanyl (25 μg) in combination with magnesium sulfate (50 mg) provided significantly prolonged analgesia compared with fentanyl alone in patients requesting analgesia for labor.[514] It is likely that magnesium can potentiate opioid analgesia by both central and peripheral mechanisms.[515] A randomized double-blind prospective study showed that a relatively high dose of remifentanil (0.2 μg/kg/minute) enhances periincisional hyperalgesia in patients undergoing thyroidectomy, and intraoperative magnesium sulfate (30 mg/kg at induction, followed by 10 mg/kg/hour) can prevent remifentanil-induced hyperalgesia.[516]

NONSTEROIDAL ANTIINFLAMMATORY DRUGS

NSAIDs, such as ibuprofen, diclofenac, or ketorolac, have been perioperatively administered to reduce opioid requirement. Perioperative administration of diclofenac (75 mg twice daily) reduced morphine consumption and the incidence of adverse effects such as sedation and nausea after total abdominal hysterectomy.[517] In a randomized double-blind trial, 0.1 mg/kg morphine was superior to 30 mg ketorolac in providing postoperative pain relief; however,

the addition of ketorolac to morphine reduced the postoperative opioid requirement and opioid-related side effects in the early postoperative period.[518] NSAIDs are thought to prevent opioid-induced hyperalgesia or acute opioid tolerance that could cause an increase in postoperative opioid requirement. A randomized double-blind placebo-controlled study showed that 8 mg of lornoxicam prevented an increase in postoperative morphine consumption induced by intraoperative fentanyl in female patients undergoing abdominal hysterectomy with spinal anesthesia.[519]

Acetaminophen has analgesic and antipyretic effects similar to those of NSAIDs, but it has a weak antiinflammatory effect. Acetaminophen has significant fentanyl-sparing effects and reduces side effects when it is combined with fentanyl in intravenous parent- or nurse-controlled analgesia for postoperative pediatric pain management.[520]

GABAPENTIN

Gabapentin, a structural analogue of γ-aminobutyric acid, binds to the $\alpha_2\delta$ subunit of the spinal voltage-gated Ca^{2+} channel and has analgesic effects in neuropathic pain. Investigators suggested that both pharmacodynamic and pharmacokinetic interactions between morphine and gabapentin lead to increased analgesic effects.[521] Furthermore, intrathecal administration of gabapentin prevents the development of opioid tolerance induced by repeated intrathecal injections of morphine.[522] Systemic and intrathecal applications of gabapentin may possibly prevent the development of opioid-induced hyperalgesia.[523]

ANTIDEPRESSANTS

Tricyclic antidepressants may cause respiratory depression in patients with chronic obstructive pulmonary diseases, and reduced CO_2 sensitivity has also been reported in patients receiving tricyclic antidepressants. An animal study demonstrated that pretreatment with amitriptyline increases morphine-induced hypercarbia through pharmacodynamic processes.[524] This finding suggests that morphine doses should be reduced with careful titration if patients are receiving concomitant treatment with tricyclic antidepressants.[524] Perioperative administration of duloxetine, a potent selective serotonin and norepinephrine reuptake inhibitor, can reduce the requirement for morphine after knee replacement surgery.[525]

DIPHENHYDRAMINE

Diphenhydramine, a histamine H_1-receptor antagonist, is used as a sedative, an antipruritic, and an antiemetic agent. When administered alone, this drug modestly stimulates ventilation by augmenting the interaction of hypoxic and hypercarbic ventilatory drives. Diphenhydramine counteracts the alfentanil-induced decrease in the slope of the ventilatory response to CO_2.[526]

LOCAL ANESTHETIC AGENTS

Systemic administration of local anesthetic agents can significantly reduce pain and allow more rapid discharge. Perioperative systemic lidocaine significantly reduced opioid requirements in the ambulatory setting.[527]

Chapter 32

Nonopioid Pain Medications

LUCY CHEN • JIANREN MAO

Key Points

- With a better understanding of pain pathways and mechanisms, it has been recognized that ion channels play an important role in the transduction, transmission, and modulation of nociceptive signals. This opens a new avenue of developing novel therapeutic agents for the treatment of chronic pain, particularly neuropathic pain.
- Although the exact mechanism of action remains unclear for many drugs listed in this chapter, they often are a component of a multidrug treatment strategy that has been increasingly used for the management of chronic pain conditions.

INTRODUCTION

Recent advances in our understanding of pain mechanisms allow treatment of chronic pain conditions by a variety of nonopioid pain medications. Besides acetaminophen and nonsteroidal antiinflammatory drugs, several new categories of nonopioid pain medications can be used for the management of chronic pain, particularly neuropathic pain. Examples of nonopioid pain medications include drugs that block voltage-sensitive sodium channels and voltage-sensitive calcium channels, facilitate opening of chloride channels, increase function of the endogenous γ-aminobutyric acid (GABA) system, and modulate the N-methyl-D-aspartate (NMDA) receptor activity. In particular, ion channel blockers possess the antihyperalgesic effect by targeting specific mechanisms of pathologic pain, although most analgesics in this category do not necessarily produce the typical analgesic effect (i.e., raising the pain threshold above the normal baseline).[1]

This chapter focuses on describing several ion channel blockers that are commonly used in the treatment of chronic pain conditions, as listed in Box 32-1. They are grouped into two categories: calcium channel blockers and sodium channel blockers.

CALCIUM CHANNEL BLOCKERS

Opening of calcium channels is an important step of synaptic transmission because it facilitates release of neurotransmitters and neuromodulators from presynaptic sites. Changes in intracellular calcium concentration also modulate cell membrane excitability and initiate a cascade of intracellular responses. Therefore, blocking calcium channels can play a significant role in modulating both nociceptive and antinociceptive processes. Drugs that reduce calcium influx into the intracellular compartment of neuronal or glial cells may be used as adjunctive or alternative medications for the treatment of various pain conditions, particularly chronic neuropathic pain conditions. Gabapentin, pregabalin, zonisamide, ziconotide, and levetiracetam are examples of drugs that block calcium channels as a part of their mechanisms of action.

GABAPETIN

Gabapentin was initially approved by the U.S. Food and Drug Administration (FDA) as an anticonvulsant and later for the treatment of neuropathic pain conditions. Although gabapentin's mechanism of action is unclear, it does block voltage-gated calcium channels by binding to the α_2-δ subunit,[2] producing a reduced calcium influx. The blocking calcium influx reduces the release of glutamate and substance P from primary nociceptive afferents, thereby modulating nociceptive transmission. Gabapentin can treat painful diabetic neuropathy, postherpetic neuralgia, trigeminal neuralgia, complex regional pain syndrome, and painful peripheral neuropathies caused by human immunodeficiency virus (HIV), cancer, multiple sclerosis, and spinal cord injury (see also Chapters 31 and 64).

Painful diabetic neuropathy is a debilitating condition commonly seen in patients with diabetes mellitus (see also Chapter 39). Up to 25% of patients with diabetes may suffer from spontaneous pain, allodynia, hyperalgesia, paresthesias, and other pain symptoms.[3] Postherpetic neuralgia is another common neuropathic pain condition (see also Chapter 64). The incidence of postherpetic neuralgia is estimated to be 9% to 34%, which increases significantly with age (see also Chapter 80). Multiple classes of drugs have been tried to treat pain associated with painful diabetic neuralgia and postherpetic neuralgia, including tricyclic antidepressants (TCAs) such as amitriptyline, nortriptyline, imipramine, and desipramine. Because of the significant

BOX 32-1 *Ion Channel Blockers as Pain Medications (Recommended Dosing)*

Calcium Channel Blockers

Gabapentin: Starting dose 100-300 mg/day; titrating up to 1800-3600 mg/day
Pregabalin: Starting dose: 75-150 mg/day; titrating up to 450-600 mg/day
Zonisamide: Starting dose: 50-100 mg/day; titrating up to 450 mg/day
Ziconotide: Starting dose: 0.1 mcg/hr; titrating up to 0.4 mcg/hr
Levetiracetam: Starting dose: 250-500 mg/day; titrating up to 2000 mg/day

Sodium Channel Blockers

Lidocaine: Used in a lidocaine test: 1 mg/kg via slow intravenous push or drip
Mexiletine: Starting dose: 150-300 mg/day; titrating up to 600 mg/day
Carbamazepine: Starting dose: 100 mg/day; titrating up to 600 mg/day
Oxcarbazepine: Starting dose: 150 mg/day; titrating up to 900 mg/day
Lamotrigine: Starting dose: 25-50 mg/day; titrating up to 250-500 mg/day
Topiramate: Starting dose: 50-100 mg/day; titrating up to 300-400 mg/day

side effects of TCAs, gabapentin has been increasingly used in these pain conditions.

Gabapentin is effective in reducing several salient symptoms of neuropathic pain such as burning and shooting pain, allodynia, and hyperalgesia.[4,5] The number needed to achieve at least 50% pain relief with antidepressants and gabapentin are 3.4 and 2.7, respectively.[6] Although both antidepressants and gabapentin may provide moderate pain relief, antidepressants have major side effects.

The recommended gabapentin dose range is 1800 to 3600 mg/day, starting at 100 to 300 mg/day and increasing 100 to 300 mg every 1 to 3 days. Adverse effects are usually mild to moderate and typically subside within 7 to 10 days after the treatment is started. In general, a slow titration process can significantly reduce some otherwise intolerable side effects, such as dizziness. In addition to its use as a monotherapy, gabapentin has been extensively used in multidrug therapy in conjunction with TCAs and other anticonvulsants.[1] Multidrug therapy provides better pain control, requiring a smaller dose range for each drug included in the regimen. Gabapentin also can treat complex regional pain syndrome, phantom pain, trigeminal neuralgia, cancer-related neuropathic pain, multiple sclerosis, spinal cord injury, HIV-associated painful sensory neuropathy, and glossopharyngeal neuralgia (see also Chapter 64). The role of gabapentin in postoperative pain management remains unclear (see also Chapter 98).

PREGABALIN

Pregabalin is an anticonvulsant that has a high affinity to the α_2-δ subunit of voltage-sensitive calcium channels. The mechanism of action of pregabalin is similar to that of gabapentin. Pregabalin decreases calcium influx, thereby reducing the release of excitatory neurotransmitters, including glutamate, substance P, and calcitonin gene-related peptide. Pregabalin has no activity on GABA or benzodiazepine receptors; therefore, it has no significant drug-drug interactions with such agents.

Pregabalin has been used to treat painful diabetic neuropathy and postherpetic neuralgia with a significant therapeutic effect.[7,8] It has a quick onset, and, in some cases, pain reduction can be expected on the first day of treatment with pregabalin (300 mg/day). Sustainable sleep improvement is also observed 1 week after the therapy is initiated. Common side effects are dizziness, somnolence, and mild to moderate peripheral edema.[9] Moreover, pregabalin (at an average dose of 450 mg/day) is effective with patients with fibromyalgia, who often have clinical presentations including diffuse musculoskeletal pain, sleep disturbance, and fatigue.

ZONISAMIDE

Zonisamide blocks both voltage-sensitive sodium channels and N-type calcium channels. Recent studies suggest that zonisamide may be used to treat mania, Parkinson disease, and central poststroke pain or to provide migraine prophylaxis.[10,11] Its possible mechanisms of action include modulation of monoamine neurotransmitter release and free radical scavenging. Zonisamide is effective for the treatment of painful diabetic neuropathy (540 mg/day). The tolerability of zonisamide is difficult to assess because it is often used in multidrug therapy. Thus, the effectiveness and side effects of zonisamide remain limited.

ZICONOTIDE

Ziconotide is a synthetic peptide analogue of omega conotoxin derived from a marine snail, *Conus magus*. Ziconotide potently and selectively blocks N-type voltage-sensitive calcium channels. This drug is approved by the FDA only for intrathecal use in patients with severe pain who are refractory to other treatment options, including intrathecal morphine. In early clinical trials, ziconotide exhibited severe central nervous system and psychiatric adverse effects with an initial intrathecal infusion rate of 0.4 mcg/hr and frequent dosing titration.[12] More recently, ziconotide has been shown to be effective for chronic pain conditions resulting from cancer, acquired immunodeficiency syndrome, and trigeminal neuralgia.[13,14] The role of ziconotide in postoperative pain management is less clear. Given ziconotide's significant side effects and restrictive delivery route, its routine use in acute postoperative pain management is not well justified (see also Chapter 98).

The initial infusion rate of ziconotide should start at 0.1 mcg/hr, with a slow titration of no more than 2 to 3 times the initial dose per week. An implanted intrathecal infusion system is required for the long-term use of this therapy if the initial ziconotide trial is effective.[15] Patients with severe psychiatric disorders may not be proper candidates for this therapy. Ziconotide may be advantageous over intrathecal morphine because patients do not develop tolerance after a prolonged use of ziconotide.

However, adverse neurologic effects associated with ziconotide therapy will require careful patient selection and monitoring. Using a smaller dose increment will help avoid systemic toxicity.

LEVETIRACETAM

Levetiracetam is an anticonvulsant that has recently received approval from the FDA for epilepsy treatment.[16] Its mechanisms of action are less clear because it may have effects on several neurotransmitter systems, including dopaminergic, glutamatergic, and GABAergic systems. But at least one of its mechanisms of action is due to inhibition of N-type voltage-sensitive calcium channels. Levetiracetam improves neoplastic plexopathies, painful peripheral neuropathy, and postherpetic neuralgia. Levetiracetam also has been used in migraine headache prophylaxis. The dose range is 500 to 2000 mg/day. At this dose range, levetiracetam is well tolerated in clinical trials. Common adverse effects are dry eyes and dizziness.[19]

SODIUM CHANNEL BLOCKERS

Sodium channels are primarily involved in nerve conduction. Sodium channels can be divided into two general categories based on their sensitivity to tetrodotoxin (TTX): TTX-sensitive (TTX-S) and TTX-resistant (TTX-R) sodium channels. TTX-S sodium channels are expressed mainly in large and medium dorsal root ganglion neurons, whereas TTX-R sodium channels are expressed mainly in small-diameter dorsal root ganglion neurons, including C-afferent neurons. Expression of both TTX-S and TTX-R sodium channels is likely to be altered when peripheral nerves are injured or severed (axotomy), producing aberrant high-frequency spontaneous ectopic discharges. Sodium channel blockers at a proper dose range are believed to suppress ectopic discharges without blocking normal nerve conduction. Several representative sodium channel blockers include lidocaine, mexiletine, carbamazepine, oxcarbazepine, lamotrigine, and topiramate.[20]

LIDOCAINE

Lidocaine is a local anesthetic and cardiac antiarrhythmic (see also Chapters 36 and 38). Since the 1980s, intravenous administration of lidocaine has been used as a diagnostic tool and, in some cases, a therapeutic tool for intractable neuropathic pain[20] (see also Chapter 64). This treatment modality has been shown to improve chronic pain conditions induced by neurologic diseases, including stroke, neurogenic facial pain, and myofascial pain.[21,22] Up to 78% of cases are associated with a positive outcome when intravenous lidocaine is used.[23] A major pitfall of intravenous lidocaine treatment is its short duration, which requires rather frequent treatment sessions.

Topical 5% lidocaine patch provides a local analgesic effect with a minimum systemic effect. Lidocaine patch has been used in patients with neuropathic pain conditions such as painful diabetic neuropathy, postherpetic neuralgia, and peripheral neuropathies. It reduces allodynia and hyperalgesia associated with such conditions.[24] Although the evidence remains weak and unclear, lidocaine patch has been used to treat chronic lower back pain. In some cases, lidocaine patch has become a part of multidrug therapy, such as a combination of topical lidocaine patch and gabapentin.[1]

MEXILETINE

Mexiletine is an oral lidocaine congener. It may be used to overcome the shortcoming of transient pain relief with intravenous lidocaine. In many cases, intravenous lidocaine is used as a test to determine whether the intended lidocaine treatment is effective. When a positive response is achieved, oral mexiletine is administered to maintain the therapeutic effect.[17,18] This treatment regimen reduces pain related to painful diabetic neuropathy refractory to other therapies.[25] Mexiletine alone has been used to treat phantom pain and pain after spinal cord injury.[25]

Fibromyalgia and myofascial pain are other clinical conditions that may be responsive to a lidocaine and mexiletine treatment regimen. In addition, anecdotal reports suggest that oral mexiletine may be used to treat primary erythromelalgia, metastasis bone pain, and headaches.

CARBAMAZEPINE

A primary mechanism of action of carbamazepine is sodium channel blockade, which is considered to decrease spontaneous firing of Aδ-fibers and C-fibers. Carbamazepine was approved by the FDA to treat trigeminal neuralgia, a neuropathic pain condition characterized by episodic lightning, lancinating, or shooting pain along the trigeminal nerve distribution.[26] Carbamazepine has been used for over 4 decades and was superior to placebo in a number of clinical trials. It was once considered a gold standard and remains a treatment of choice for trigeminal neuralgia, with a response rate of 89% within 5 to 14 days after the treatment is initiated. However, carbamazepine has significant drug-drug interactions and includes a long list of adverse effects, such as central nervous system side effects. The FDA has issued black box warnings about this drug, including aplastic anemia and agranulocytosis. Therefore, its clinical utility is rather limited considering newer anticonvulsants are available with fewer and less severe side effects.

OXCARBAZEPINE

Oxcarbazepine is an analogue of carbamazepine, which acts as a sodium channel blocker and stabilizes neuronal membrane. In contrast to carbamazepine, oxcarbazepine has fewer drug-drug interactions and side effects, particularly severe blood dyscrasias. The most common side effects of oxcarbazepine are dizziness, drowsiness, hypotension, nausea, and asymptomatic mild hyponatremia. Oxcarbazepine has been used to treat intractable trigeminal neuralgia refractory to other anticonvulsants.[27] With a median dose of 750 mg/day, this new drug appears to have the same efficacy as carbamazepine in the treatment of trigeminal neuralgia but a much lower incidence of side effects.

Oxcarbazepine also reduces pain associated with painful diabetic neuropathy and complex regional pain syndrome. For patients with postherpetic neuralgia that is unresponsive to carbamazepine and gabapentin, oxcarbazepine, starting at 150 mg/day and titrating up to a maintenance dose of 900 mg/day, may be a promising drug because it significantly reduces allodynia related to postherpetic neuralgia. Oxcarbazepine appears to be well tolerated and may serve as a reasonable alternative to other sodium channel blockers.

LAMOTRIGINE

Lamotrigine has multiple mechanisms of action although it also blocks both sodium and calcium channels.[28] Lamotrigine is effective in the treatment of trigeminal neuralgia, neuralgia after nerve section, and pain related to HIV neuropathy. With a daily dose of lamotrigine 75 to 300 mg, the intensity of burning and shooting pain is relieved by 33% to 100%, and the frequency of shooting pain attack is reduced by 80% to 100%. In patients with spinal cord injury, lamotrigine decreases overall pain sensation below the level of injury in patients with incomplete spinal cord injury but has little effect on spontaneous and evoked pain in patients with complete spinal cord injury.

A typical starting dose for lamotrigine is 25 to 50 mg/day, which can be slowly titrated up over 2 to 3 weeks to 250 to 500 mg/day in divided doses. Tolerability is usually low at high doses (>300 mg/day). Up to 10% of patients may have rashes after taking this medication, with a 3 in 1000 incidence of Stevens-Johnson syndrome. Other side effects are mild dizziness, somnolence, nausea, and constipation.

TOPIRAMATE

Topiramate is another drug that has multiple mechanisms of action. However, at least one of its actions is to block voltage-sensitive sodium channels. It also may potentiate GABA inhibitory action, block voltage-sensitive calcium channels, and inhibit subtypes of glutamate receptors (non-NMDA receptors). Topiramate can cause significant weight loss (up to 7%), a side effect that could be beneficial for certain patient populations. Topiramate, at a daily dose of 400 mg or above, attenuates neuropathic pain, improves sleep quality, and reduces body weight.[27] When used to treat chronic lumbar radicular pain, the effect of topiramate is inconclusive because of a high dropout rate and frequent side effects. However, topiramate 30 to 80 mg/day is superior to placebo for the treatment of chronic tension, migraine, and cluster headaches with a substantial tolerability.[29]
