Figure 101-2. Protocol for low–tidal volume mechanical ventilation of patients with acute lung injury or acute respiratory distress syndrome (ARDS) in use at the University of California, San Francisco (UCSF). The protocol is based on that used in the ARDSnet trial. *A/C*, Assist/control; *BP*, blood pressure; *CPAP*, continuous positive airway pressure; *FiO_2*, fraction of inspired oxygen concentration; *ICU*, intensive care unit; *I:E*, inspiratory-to-expiratory ratio; *NHLBI*, National Heart, Lung, and Blood Institute; *NIH*, National Institutes of Health; *PaO_2*, partial alveolar pressure of oxygen; *PEEP*, positive end-expiratory pressure; *Pplat*, plateau pressure; *PS*, pressure support; *RR*, respiratory rate; *SpO_2*, saturation of peripheral oxygen; *TV*, tidal volume; *V_E*, minute ventilation.

position would change these relationships and improve gas exchange. Prone positioning is fraught with difficulty and can result in accidental extubation, dislodgement of the line or chest tube, and patient injury, but it can lead to higher functional residual capacity, better drainage of secretions, and improved oxygenation. Gattinoni and colleagues performed a multicenter, prospective randomized trial, enrolling 304 patients with ARDS to compare supine positioning with prone positioning for 6 or more hours per day for 10 days.[88] Oxygenation was improved in the prone group, but mortality did not differ between the two groups. Most recently, Guerin and colleagues studied patients with severe ARDS (PaO_2/FiO_2 ratio < 150 mm Hg).[89] All the participating medical centers had more than 5 years' experience with prone positioning. Patients were placed in the prone position early in the disease process (within 1 hour of randomization) for more than 16 consecutive hours per day, as well as sedated and paralyzed with neuromuscular blockers. Twenty-eight day mortality decreased from 32.8% in the control group to 16.0% in the prone group ($p < 0.001$), and the incidence of complications was not significantly increased in the intervention group. Although specific patients may benefit from this technique, the data do not

C. Unassisted breathing trial
1. Place on a T-piece, trach collar, or CPAP < 5 cm H_2O.
2. Assess for tolerance as below for 2 hours.
3. If tolerated, consider extubation.
4. If not tolerated, resume PS 5 cm H_2O.

Definition of Unassisted Breathing Tolerance:
1. RR ≤ 35 and
2. SpO_2 ≥ 90% and/or PaO_2 ≥ 60 mm Hg and
3. Spontaneous TV ≥ 4 mL/kg IBW and
4. Respiratory distress is absent (<2 of the following):
   pulse > 120% of usual rate for > 5 minutes, marked use of accessory muscles;
   abdominal paradox, diaphoresis, marked complaints of dyspnea.

OXYGENATION GOAL:
PaO_2 55 to 80 mm Hg or SpO_2 88% to 95%
Use incremental FiO_2/PEEP combinations below to achieve goal:

FiO_2	0.3	0.4	0.4	0.5	0.5	0.6	0.7	0.7
PEEP	5	5	8	8	10	10	10	12
FiO_2	0.7	0.8	0.9	0.9	0.9	1.0	1.0	1.0
PEEP	14	14	14	16	18	20	22	24

PLATEAU PRESSURE GOAL: ≤ 30 cm H_2O
Check Pplat (0.5 sec insp. Pause), SpO_2, total RR, TV and pH at least q4h and after each change in PEEP or TV

If Pplat > 30 cm H_2O: decrease TV by 1 mL/kg steps (min = 4 mL/kg)
If Pplat < 25 cm H_2O: increase TV by 1 mL/kg until Pplat > 25 cm H_2O or TV > 25 cm H_2O or TV = 6 mL/kg

pH GOAL: 7.25 to 7.45
Acidosis Management:
pH < 7.25 but ≥ 7.20
1. Notify ICU resident of pH < 7.25.
2. Increase RR until pH > 7.25 or $Paco_2$ < 25.
3. If RR = 35 and/or $Paco_2$ < 25, MAY give $NaHCO_3$ or choose to leave as is until pH < 7.20.

pH < 7.20
1. Increase RR to 35 (if not already 35).
2. If pH remains < 7.20 and $NaHCO_3$ considered or infused, TV may be increased in 1 mL/kg steps until pH > 7.20. (Pplat target may be exceeded.)

Alkalosis Management (pH > 7.45)
1. Decrease ventilator rate if possible.

I:E RATIO GOAL: 1:1 to 1:3. Adjust flow rate to achieve goal.
If FiO_2 = 1.0 and PEEP = 24 cm H_2O, may adjust I:E to 1:1.

Figure 101-2, cont'd.

currently support the routine use of prone positioning at all hospitals. The use of specialized beds that can provide significant side-to-side rotation may be an alternative to prone positioning, but these beds have not been tested in prospective trials.

Inhaled Nitric Oxide. Numerous cells synthesize endogenous nitric oxide (NO) in the human body, including macrophages, mast cells, and smooth muscle cells. NO modulates vascular tone and neurotransmission, inhibits platelet aggregation and cell cytotoxicity, and interacts with free radicals.[90,91] NO binds to hemoglobin and is then metabolized by conversion to nitrites and nitrates, which are excreted in urine.[92] This process is extremely rapid and results in a half-life on the order of seconds, so the effect of NO is limited to the immediate area in which it is released. Selective delivery of NO by inhalation (iNO) to well-ventilated areas of the lung improves $\dot{V}/\dot{Q}$ mismatching and improves oxygenation by dilating the local pulmonary capillaries (Fig. 101-3). This effect is in contrast to other pulmonary vasodilators, which usually worsen gas exchange by indiscriminately dilating vessels (also see Chapter 104). In particular, hemoglobin inactivates iNO in the lung , which minimizes harmful systemic vasodilation.

Initially, iNO was used as salvage therapy to improve oxygenation in patients with severe ARDS.[93] Further studies then used iNO earlier in the course of ARDS and were able to demonstrate decreased pulmonary artery pressure, decreased venous admixture, and increased oxygenation with no change in systemic blood pressure, systemic vascular resistance, or cardiac output.[94,95] The average improvement in the PaO_2/FiO_2 ratio was 42%.[96]

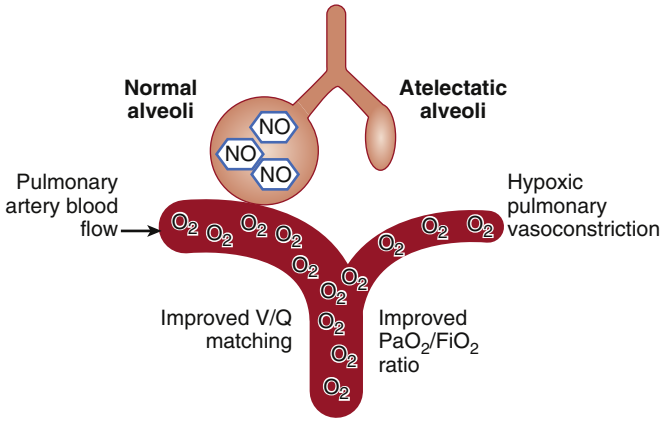

Figure 101-3. Mechanism of action of inhaled nitric oxide. *FiO_2*, Fraction of inspired oxygen concentration; *NO*, nitric oxide; *O_2*, oxygen; *PaO_2*, partial alveolar pressure of oxygen; *$\dot{V}/\dot{Q}$*, ventilation-perfusion. *(Adapted from Liu LL, Aldrich JM, Shimabukuro DW, et al: Special article: rescue therapies for acute hypoxemic respiratory failure,* Anesth Analg *111:693-702, 2010.)*

The beneficial effects appear to be sustained during long-term therapy, but a rebound phenomenon has been reported after the abrupt removal of iNO therapy.[97]

Three randomized controlled trials of iNO in patients with ARDS were published in 1998. Two of the studies were small (<40 patients), and the results were consistent with the larger multicenter placebo-controlled, double-blinded trial.[98] In the third study, patients in the iNO group had an acute improvement in oxygenation, but no differences in FiO_2 were observed between the iNO and placebo groups from days 2 through 7. Most importantly, no differences in mortality or the number of days alive and not requiring mechanical ventilation were found through day 28. In patients who were responders to iNO, defined as a 20% or greater increase in PaO_2, no differences in 30-day mortality were reported between responders given iNO and responders given conventional therapy.[96] A recent meta-analysis examining 12 trials involving 1237 patients also found an increased PaO_2/FiO_2 ratio in the iNO group and, again, no significant effect of iNO on hospital mortality, duration of ventilation, or ventilator-free days. However, an increased risk for renal dysfunction (risk ratio [RR], 1.5; 95% CI 1.1 to 2.02) was reported in the patients receiving iNO.[99]

Because of the data available, routine use of iNO in patients with ARDS cannot be recommended. However, no data are available that address the use of iNO as rescue therapy for patients with critically low oxygenation. Further randomized studies of patients with specific disease states (e.g., rapidly progressive hypoxia, severe pulmonary hypertension, right ventricular failure) may identify the subgroup that could potentially benefit from iNO.

Neuromuscular Blocking Drugs. First reported in 1977, severe muscle weakness was described in patients exposed to a combination of mechanical ventilation, high-dose corticosteroids, and neuromuscular blocking agents (NMBAs) (see also Chapter 34).[100] Since then, more than 20 studies have been published; most were observational study designs. The majority of the data from previous studies indicate only a causal relationship between NMBAs and ICU-acquired weakness (ICU-AW).[101] Kesler and colleagues, after a change in clinical practice to avoid muscle paralysis, compared the records of 74 patients with asthma admitted between 1995 and 2004. They found no difference in the incidence of ICU-AW, despite this deliberate reduction in the use of NMBAs (20% versus 14%, $P = 0.23$).[102]

More recently, Papazian and colleagues reported a study investigating the use of cisatracurium on the outcome of patients with severe acute respiratory distress syndrome (PaO_2/FiO_2 ratio <150).[103] In this study, 340 patients were randomized to receive 48 hours of cisatracurium or placebo. Although the primary outcome was 90-day survival, muscle testing was performed to look for signs of weakness. No difference was observed between groups in the incidence of ICU-AW (29% versus 32%, $P = 0.49$). In the subgroup that received corticosteroids, no difference in the frequency of ICU-AW was observed (37% versus 30%, $P = 0.32$). The hazard ratio for death at 90 days in the cisatracurium group, as compared with the placebo group, was 0.68 (95% CI 0.48 to 0.98, $P = 0.04$).

With the current understanding of NMBAs, more data are clearly needed. In patients undergoing mechanical ventilation for ARDS, short periods of NMBAs may improve oxygenation and decrease ventilator-induced lung injury, but studies that can separate neuromuscular blockade from immobilization and sedation as causative factors in the pathogenesis of ICU-AW are needed before definitive statements can be made.

Indications for Tracheotomy

Tracheotomy is a common procedure in the ICU that is performed in approximately 10% of critically ill patients who require mechanical ventilation.[104] Placement of a tracheotomy is thought to allow a more secure and manageable airway, earlier and safer enteral feeding, easier oral care, and enhanced patient comfort while reducing sedation needs and facilitating mobilization. Complications from tracheotomy include stoma infection, pneumothorax, subcutaneous emphysema, tracheomalacia, and tracheostenosis.[105] Major questions concerning tracheotomy include which patients with acute respiratory failure should have the procedure and when it should be performed.

A review published in 1998 concluded that insufficient evidence supports the view that timing of a tracheotomy can alter the duration of mechanical ventilation or prevent airway injury in critically ill patients.[106] Since then, individual studies have reported decreased days of mechanical ventilation,[107] decreased duration of ICU and hospital LOS,[108] and less damage to the upper airway[107] with early tracheotomy. A meta-analysis attempted to answer this question definitively. Unfortunately, only five trials with 406 patients were found that met the inclusion criteria.[109] They reported that the timing of tracheotomy did not alter mortality or increase the risk for hospital-acquired pneumonia. Early tracheotomy did, however, lower the duration of mechanical ventilation and the overall LOS in the ICU (Table 101-3). The results were far from conclusive. Heterogeneity was high in the meta-analysis because of variability in inclusion and exclusion criteria, definitions of early and late tracheotomy,

TABLE 101-3 **DATA COMPARING EARLY-TO-LATE TRACHEOSTOMY**

	Relative Risk	95% Confidence Interval	*P* Value
Timing of tracheotomy	0.79	0.45-1.39	0.42
Development of pneumonia	0.9	0.66-1.21	0.48
	Mean Difference	**95% Confidence Interval**	***P* Value**
Time on ventilator	–8.5 days	–15.3 to –1.7 days	0.03
Length of ICU stay	–15.3 days	–24.6 to –6.1 days	0.001

Modified from Griffiths J, Barber VS, Morgan L, et al: Systematic review and meta-analysis of studies of the timing of tracheostomy in adult patients undergoing artificial ventilation, BMJ *330: 1243, 2005.*

characteristics of enrolled patients, and diagnostic criteria for hospital-acquired pneumonia.

More recently, Blot and associates compared early tracheotomy (within 4 days of intubation) with prolonged intubation in a randomized controlled trial conducted in 25 French ICUs.[110] The trial did not demonstrate any major benefit of tracheotomy as defined as 28-day mortality, incidence of VAP, ventilator-free days, or time in the ICU. The results were confirmed by Terragni and coworkers, who studied the effectiveness of early tracheotomy (6 to 8 days after intubation), compared with late tracheotomy (13 to 15 days after intubation) in reducing VAP.[111] In this randomized controlled trial performed in 12 Italian ICUs, early tracheostomy did not result in statistically significant improvement in the incidence of VAP (14% versus 21%, $P = 0.07$).

There appears to be no effect on mortality or VAP incidence whether critically ill patients undergo early or late tracheotomy. It is possible that subgroups of patients may have mortality benefit from early tracheotomy, but the difficulty comes in identifying these patients. The need to have better predictive models to identify patients who may have a simple subsequent weaning process after failing the first attempt is significant. Tracheotomies should be performed in patients who will encounter difficult or prolonged weaning. Unfortunately, no validated specific and sensitive test or scoring system is available that can predict the need for prolonged ventilation; therefore, the selection of patients for tracheotomy remains a subjective decision.

Percutaneous versus Open Tracheotomy. Percutaneous techniques are emerging as a method of securing the airway of adults in critical care settings. Advantages include smaller skin incision, less tissue trauma, lower incidence of wound infection, reduced risk associated with the transfer of patients to the surgical department, and fewer personnel requirements. Two meta-analyses showed a trend toward fewer complications, cost-effectiveness by releasing surgical resources, and greater feasibility than the open surgical approach when performing the percutaneous procedure at the bedside.[112,113] One important caveat of these results is to remember the exclusion criteria for most of these studies (e.g., emergency tracheostomy, suspicion or evidence of a difficult airway, previous airway problems, coagulopathies, previous tracheostomies). Consequently, although the procedure appears to be safe and effective, the favorable data exist only for a particular subset of patients admitted to the ICU.

Intravenous Fluid Management and Monitoring

The use of pulmonary artery catheters (PACs) in critically ill patients has dramatically decreased. Most studies have failed to show efficacy or have demonstrated harm. The best known of these investigations is the Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatments (SUPPORT), which was a retrospective, observational study involving 5735 critically ill patients.[114] In those patients, the use of a PAC was associated with increased mortality and cost. Richard and coworkers completed a prospective, observational trial of PACs versus central venous catheters (CVCs) in patients with ARDS or shock.[115] Clinical management was left to the discretion of the treating physician. In 36 French ICUs, no difference was observed in any of the outcome variables measured in 676 patients.

The Fluids and Catheters Treatment Trial (FACTT), conducted by the National Heart, Lung, and Blood Institute (NHLBI) ARDSnet, compared hemodynamic management guided by a PAC with hemodynamic management guided by a CVC in 1000 patients with established ALI.[116] Patients were treated at select academic ICUs by clinicians who were trained in interpreting hemodynamic data and who were following a specific management protocol. Although serious catheter-related complications were rare, the PAC group had a higher incidence of arrhythmias and conduction blocks. The investigators were unable to demonstrate prevention or reversal of organ failure, reduced need for support (e.g., vasopressors, assisted ventilation, renal replacement therapy), faster discharge from the ICU, or decreased 60-day mortality in the PAC group versus the CVC group. Possibly because of this growing evidence, the use of the PAC has decreased by 65% during the last decade in the United States.[117]

The interesting result from FACTT was that a conservative fluid management plan appeared more effective in patients with established ALI.[118] Although the 60-day mortality was similar in both groups, patients in the conservative fluid management group had improved lung function; improved central nervous system function; and a decreased need for sedation, mechanical ventilation, and intensive care. In addition, the patients in the conservative fluid management group did not have an increased incidence of complications, such as nonpulmonary organ failure or shock.

For the past decade, the emphasis has been less on the measurement of pulmonary capillary wedge pressure or central venous pressure and more on the assessment of fluid responsiveness. The belief is that this dynamic measurement based on physiologic responses would be better than a static indicator.[119] The measurements can be derived from an arterial pressure waveform (systolic pressure variations [SPVs] and pulse pressure variations [PPVs]), are minimally invasive, allow beat-to-beat monitoring, and permit assessment of heart-lung interactions in patients who are mechanically ventilated (Fig. 101-4).

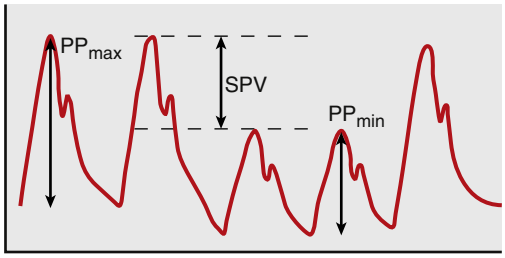

Figure 101-4. Noninvasive measurements of fluid responsiveness. PP_{max}, Maximal volume of pulse pressure; PP_{min}, minimal volume of pulse pressure: *SPV,* systolic pressure variation.

Although studies have been promising for the purpose of predicting fluid responsiveness under anesthesia,[120,121] they have been more problematic in the ICU. Patients generally have to be in sinus rhythm, have a closed chest, have normal intraabdominal pressures, and be on controlled ventilation with PEEP between 0 and 5 cm H_2O.[122]

Perhaps the most prudent approach from all these data is to base management on clinical examination findings and appropriately titrated fluid according to the patient's phase of illness. Goal-directed, liberal fluid administration during the acute phase of sepsis offers important benefits.[123] However, excess fluid is not beneficial when it is not physiologically needed during the established phase of ALI.

FLUID SELECTION: COLLOID VERSUS CRYSTALLOID

There is still no clear evidence as to what type of fluid (colloid or crystalloid) should be used for fluid administration. Finfer and associates randomized almost 7000 patients admitted to the ICU to receive either 4% albumin or normal saline.[124] Mortality from any cause during the 28-day period was similar in both groups, leading the authors to conclude that albumin and saline should be considered equivalent for intravascular volume replacement in a mixed population of ICU patients. Among colloids, evidence against the use of hydroxyethyl starch (HES), because it may increase kidney injury, seems to exist. When comparing HES versus saline, more patients in ICUs who were resuscitated with HES required renal replacement therapy (7% versus 5.8%, $P = 0.04$) and developed adverse effects (e.g., pruritus, skin rash) (5.3% versus 2.8%, $P < 0.001$).[125] In patients with severe sepsis, the use of HES compared with lactated Ringer solution led to increased 90-day mortality (RR 1.17; 95% CI 1.01 to 1.36, $P = 0.03$) and increased requirement for renal replacement therapy (RR 1.35; 95% CI 1.01 to 1.80, $P = 0.04$).[126] Presently, HES is increasingly becoming viewed as a solution that should not be administered (see Chapter 61).

ACUTE LIVER FAILURE

Epidemiology

Acute liver failure (ALF) is an uncommon disorder that leads to jaundice, coagulopathy, and multisystem organ failure. The development of hepatic encephalopathy within 8 weeks after the onset of jaundice in patients with no known chronic liver disease defines ALF.[127] ALF affects approximately 2000 people per year in the United States,[128] with acetaminophen overdose the cause in a majority of the cases.[129] Mortality from fulminant hepatic failure (FHF) can be high (60% to 80%) in the absence of liver transplantation, depending on the cause.[130] Causes of death are mainly multisystem organ failure, sepsis, and cerebral edema. Liver transplantation for ALF generally has a worse outcome than transplantation for chronic liver disease because of the high postoperative mortality caused by sepsis and multiorgan failure.[131]

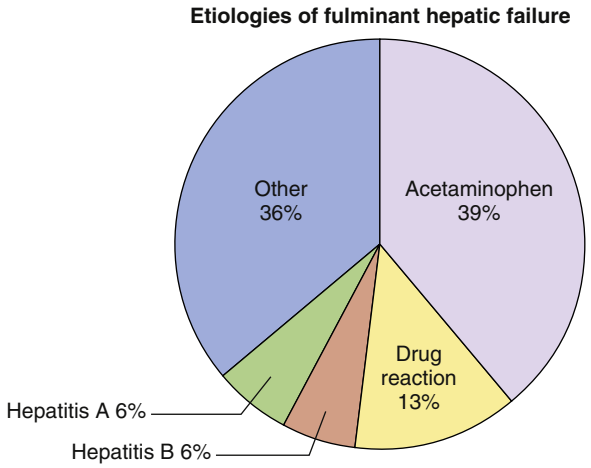

Figure 101-5. Etiologies of fulminant hepatic failure. *(Modified from Schiodt FV, Atillasoy E, Shakil AO, et al: Etiology and outcome for 295 patients with acute liver failure in the United States,* Liver Transpl Surg *5: 29-34, 1999.)*

Prognostic Factors in Acute Liver Failure

The timing of transplantation and the selection of patients are crucial because transplantation is the only therapeutic intervention proved to be beneficial.[132] Although scoring systems have been proposed, the myriad causes of ALF limit their accuracy (Fig. 101-5). Most case series are limited in number, and some span long periods during which supportive therapies may have changed. The King's College criteria have been shown to have good specificity (94.6%) for patients who will die without transplantation but lower sensitivity (58.2%), thus suggesting that a proportion of patients will die and not fulfill the criteria.[133] The criteria also have low negative predictive value, which could lead to transplantation in a patient who would have recovered without surgery. Other predictors include the Model for End-Stage Liver Disease (MELD),[134] which has been shown to be an excellent predictor of outcome in patients with ALF of various causes, excluding acetaminophen.[135] Blood lactate levels[136] and hyperphosphatemia[137] are also promising.

Management of Fulminant Liver Failure

General Supportive Measures. Patients with ALF are prone to rapid deterioration and should be closely monitored, usually in an intensive care setting. The cause of the ALF should be identified, and suitable candidates for

orthotopic liver transplantation should be moved early to a transplantation center. Early tracheal intubation may be necessary if neurologic status deteriorates and leads to airway compromise. Volume expansion with crystalloids and colloids is usually required to help maintain blood pressure. Correction of acid-base disturbances, treatment of hyperthermia, and close glucose monitoring are important to prevent cerebral edema. Renal failure from hepatorenal syndrome may develop and is reversible with the return of hepatic function. Continuous renal replacement therapy (CRRT) is often required in patients with advanced ALF to treat renal insufficiency, volume status, and cerebral edema. Early antibiotics and source control are important because the incidence of bacteremia and sepsis is higher in these patients than in the general population.[138] Although abnormalities exist in both the coagulation and fibrinolytic pathways, the defects appear to be balanced, and there is a relative preservation of hemostasis unless the platelet count is very low.[139] If a cause is identified, then initiation of antidotes is needed (e.g., *N*-acetylcysteine for acetaminophen poisoning, penicillin G for mushroom poisoning, early delivery for pregnancy-related ALF).[134]

Management of Increased Intracranial Pressure. The development of cerebral edema and intracranial hypertension is the most devastating complication associated with ALF (see also Chapter 70). Osmotically active compounds, normally cleared by the liver, accumulate in blood and diffuse into the brain parenchyma. Movement of water into neurons and glia results in swelling and can cause herniation. The exact compounds responsible for cerebral edema are unknown, but ammonia is probably a major contributor.

Diagnosis of cerebral edema can be difficult. Serial neurologic examination is essential, and frequent computed tomography of the head can identify early signs of edema. Many centers implement early invasive monitoring of intracranial pressure, although this practice has not been shown to improve outcome.[140] Monitoring can be achieved with either cranial or lumbar epidural monitors because traditional intraventricular monitors carry an unacceptable risk of bleeding.

Techniques to reduce intracranial pressure include the removal of ammonia with CRRT, hypothermia, barbiturate coma, and the administration of mannitol and hypertonic saline.[141] Although most available laboratory evidence suggests that hypothermia should be helpful in controlling the cerebral complications of ALF, randomized clinical trials in patients to demonstrate its safety or efficacy are currently lacking.[142]

Liver Support Devices

Bioartificial Livers. Bioartificial livers use hepatocytes to mimic the synthetic, detoxifying, and excretory function of the dying liver. Porcine hepatocytes are preferentially used because human hepatocytes are difficult to grow in culture.[143] The device works by passing the patient's plasma through hollow-fiber capillaries while the hepatocytes are placed in the extracapillary space. Molecules are exchanged between hepatocytes and plasma across a membrane that prevents passage of immunoglobulin, complement, and cells. A prospective, multicenter, randomized controlled trial using the HepatAssist liver support system was published in 2004.[144] The results did not show any improvement in survival in the treated group. Only during subgroup analysis were patients with fulminant or subfulminant liver failure found to have improved survival, but the results were marginal.

Artificial Extracorporeal Devices. Artificial extracorporeal devices have received renewed interest because of technology allowing the production of membranes that can increase selectivity through small pores. The system can be tailored for albumin-bound substances, which include most of the toxins that accumulate with FHF. Larger molecules such as immunoglobulins cannot cross. This system is associated with significant biochemical improvements,[145] but these studies are small and uncontrolled, and whether this will translate into improved clinical outcomes still remains a matter of debate (see also Chapter 107).

Overall, the liver support devices appear to be safe, but adverse events can include bleeding, systemic infection, disseminated intravascular coagulation, and anaphylaxis. A meta-analysis of the use of artificial and bioartificial life support systems in 8 randomized controlled trials involving only 139 patients concluded that the evaluated support systems have no significant effect on the mortality in patients with ALF.[146] Randomized clinical trials are limited, considering the patient's severity of illness. More controlled trials addressing survival are warranted before this therapy can be strongly recommended.

ACUTE RENAL FAILURE

Epidemiologic Variables

The incidence and outcomes of acute kidney injury (AKI) in the ICU are highly variable. Reported incidences can be as high as 35%.[147] Renal replacement therapy is the mainstay of support for these patients, but mortality remains high. Despite improvements in renal replacement technology over the years, mortality caused by AKI in the ICU has remained at higher than 50%.[148]

Diagnosis

The diagnosis of AKI has not been straightforward. A recent survey revealed the use of at least 35 definitions in the literature.[149] This state of confusion has given rise to the wide variation in reported incidence and clinical significance of ARF. The Acute Dialysis Quality Initiative (ADQI), which is made up of a group of experts consisting of nephrologists and intensivists, has proposed new criteria for describing renal dysfunction. They recognized the clinical importance of milder forms of renal insufficiency and that stratifying renal dysfunction (mild to severe) would better describe the disease. They proposed the RIFLE criteria (Table 101-4), which stand for risk, injury, failure, and two outcome classes (loss and end-stage kidney disease). For each increasing RIFLE class, a stepwise increase in mortality independent of comorbidity occurs.[150] These data suggest that strategies to prevent even mild AKI may improve survival, and recovery of renal function in the ICU should be a specific therapeutic target.

TABLE 101-4 **THE RIFLE CRITERIA**

	GFR Criteria	UO criteria	OR Hospital Mortality[150]
Risk	Cr increased ×1.5 or GFR decreased >25%	UO <0.5 mL/kg/hr ×6 hr	2.2 (95% CI 2.17-2.3)
Injury	Cr increased ×2 or GFR decreased >50%	UO <0.5 mL/kg/hr ×12 hr	6.1 (95% CI 5.74-6.44)
Failure	Increased Cr ×3 or GFR decrease ≥75% or Cr >4 mg/dL	UO <0.3 mL/kg/hr ×24 hr or Anuria ×12 hr	8.6 (95% CI 8.07-9.15)
Loss	Complete loss of renal function for >4 wk		
ESRD	End-stage disease

Modified from Kidney Disease: Improving Global Outcomes, Acute Kidney Injury Work Group: KDIGO clinical practice guideline for acute kidney injury, Kidney Inter Suppl *2(1):1-138, 2012.*

Management of Acute Renal Failure

General Supportive Measures. Patients with ARF should be closely monitored. The cause of the ARF should be identified by looking at prerenal, renal, and postrenal causes. Laboratory evaluations should include serum and urine electrolytes, urinalysis, and examination of urinary sediment. Careful assessment of volume status is necessary to determine hypovolemia, leading to prerenal azotemia versus hypervolemia from oliguria. Correction of acid-base disturbances may be necessary, as well as correction of electrolyte abnormalities. Continuous renal support is often required in patients with advanced renal failure to help with volume overload and electrolyte disturbances. Antibiotics and other medications should be dosed according to creatinine clearance, and serum levels, if available, should be closely monitored. Platelet dysfunction may occur as a result of uremia and require desmopressin (DDAVP) for support if bleeding is problematic.

Resuscitation fluids with high chloride concentration (0.9% saline, 4% to 5% albumin) are associated with decreased urine flow and electrolyte secretion, hyperchloremic metabolic acidosis, and renal vasoconstriction. A recent open-label, sequential study where high chloride-containing solutions were restricted in critically ill patients showed decreased progression to renal failure and a reduction in the need for renal replacement therapy.[151]

Renal Support. ARF in the ICU often requires some type of renal replacement therapy. Commonly, this is accomplished by continuous venovenous hemofiltration (CVVH), a form of CRRT. Although CRRT has several theoretic advantages over intermittent hemodialysis (IHD), such as enhanced hemodynamic stability, increased solute removal, and greater ultrafiltration capacity, individual randomized trials have not supported its superiority.[152,153] The timing and dosing of this therapy and the patients most likely to benefit from it remain unclear.

Recently, it appears that the difference in efficacy lies not in the type of dialysis (IHD versus CVVH) but in the dialysis dose. Undertreatment appears to be harmful,[154] whereas earlier application and higher filtration volumes appear to be associated with decreased mortality in patients with ARF.[155] On the other hand, intensive-dose CRRT has also not been shown to be beneficial in terms of mortality, renal function recovery, and ICU LOS.[156-158] Even with IHD, which can cause more hemodynamic lability, when studies are controlled for dialysis dose, polymer membrane, and bicarbonate-based buffer, 60-day mortality did not differ between the two groups (CRRT versus IHD).[159] Although a trend to use CRRT has developed, favorable data with IHD are intriguing because using IHD would allow more ICU resources to be allocated elsewhere.

COMPLICATIONS OF INTENSIVE CARE UNIT MANAGEMENT

Mortality in the ICU has been declining. For instance, over a 2-year period, the mortality from sepsis dropped from 37.0% to 30.8% ($P < 0.001$).[160] Although ICU care has advanced and improved, some limitations in the ability to further reduce mortality are the result of complications of the ICU care that are given. In the following sections, the prevention of ICU complications such as ICU-AW, hospital-acquired infections (HAIs), and miscommunications associated with handoffs are discussed.

INTENSIVE CARE UNIT–ACQUIRED WEAKNESS

As survival after critical illness has improved over the years, many patients now require on-going rehabilitation after discharge from the ICU. Profound neuromuscular weakness, or ICU-AW, is common and leads to severe functional impairment in many ICU survivors. Risk factors for ICU-AW are multifactorial and can include disease severity, presence of systemic inflammatory response syndrome (SIRS),[161] number of days with two or more organ dysfunctions, duration of mechanical ventilation,[162] ICU LOS, serum glucose levels,[163] and use of corticosteroids or NMBAs.[164] Controversies exist over the risks and benefits of tight glycemic control, and a causal relationship between the use of corticosteroids or NMBAs has not been clearly established. At present, few options are available to prevent or treat ICU-AW specifically.[165]

A potential therapeutic option is the avoidance of bed rest with early mobilization in the ICU. Exercise can improve strength and increase the production of

antiinflammatory cytokines, which may play an important role in muscle protection.[166] Griffiths and coworkers described the effects of continuous passive motion of one leg in patients with respiratory failure receiving NMBAs. The contralateral leg served as the control. Muscle DNA-to-protein ratio (an index of wasting) was significantly less reduced in the leg receiving passive motion.[167]

Studies are also demonstrating improved clinical outcomes with early mobility. An early mobility protocol that provided rehabilitation therapy 7 days per week via a dedicated mobility team—nurse, nurse assistant, and physical therapist—showed a trend toward decreased hospital mortality (12.1% versus 18.2%, $P = 0.125$). Early mobilization was also associated with decreased LOS in the ICU (5.5 days versus 6.9 days, $P = 0.025$) and decreased LOS in the hospital (11.2 days versus 14.5 days, $P = 0.006$) after adjusting for differences in body mass index, APACHE II score, and vasopressor use.[168]

Despite the early data showing benefits, early mobilization of critically ill patients in the ICU has unique challenges and concerns. One barrier has been the culture regarding the need for bed rest and activity restriction during critical illness because of the presence of endotracheal tubes, vascular access devices, or other medical equipment. However, studies have demonstrated that mobilization of patients who are mechanically ventilated can be safely performed. Bailey and colleagues showed that in a study of 103 patients in the ICU involving over 1400 activity events, only 14 minor events occurred in 9 patients, and no unanticipated extubations or events occurred, requiring additional cost or increased LOS in the hospital.[169] Morris and colleagues obtained similar results in their trial of early mobility on 145 patients who were intubated in the ICU. They reported no incidents of accidental removal of devices.[168]

It is becoming more apparent that early mobility is feasible in ICUs with a supportive culture, and early may be significantly sooner than what has been customary. Schweickert and colleagues studied beginning therapy an average of 1.5 days after intubation.[170] The group of patients who were mobilized early were more likely to be functionally independent when they left the hospital (59% versus 35%, $P = 0.02$), and more patients were able to go directly home (43% versus 24%, $P = 0.06$). Patients in the intervention group had shorter duration of delirium (median 2.0 days versus 4.0 days, $P = 0.02$) and more ventilator-free days (23.5 days versus 21.1 days, $P = 0.05$) during the 28-day follow-up period than did study control participants.

Early mobilization in the ICU requires a multidisciplinary team approach.[171] Targets for culture change include gaining support from institutional leaders and bedside clinicians.[172] Careful communication between physicians, nurses, and therapists is paramount. More research is necessary to identify whether specific groups of patients will benefit from early mobilization more than others, the appropriate amount of mobilization, and the absolute and relative contraindications. The potential for early mobilization to affect mortality seems promising.

HOSPITAL-ACQUIRED INFECTIONS

The most common nosocomial infections in medical ICUs are urinary tract infections (31%), followed by pneumonia (27%) and primary bloodstream infections (19%).[173] Several studies have shown that quality improvement initiatives can reduce nosocomial infections, mortality, and cost.[174,175] The Centers for Medicaid and Medicare Services, which administers federally sponsored health care, no longer reimburses hospitals for additional costs associated with common ICU complications, including urinary and CVC-associated infections. This pay-for-performance measure, in addition to the widespread adoption of public reporting of infection rates, will catalyze significant scrutiny of these infections.

Ventilator-Associated Pneumonia

VAP is defined as pneumonia developing in patients who are mechanically ventilated after more than 48 hours of intubation, with no clinical evidence suggesting the presence or probable development of pneumonia at the time of initial intubation.[176] VAP is a leading cause of morbidity and mortality in patients who are mechanically ventilated and critically ill. The incidence of VAP is estimated to be 10% to 25%,[177] and the estimated mortality rate from VAP is 5% to 27%.[178] The pathogenetic progression of VAP probably involves microaspiration of oropharyngeal or gastric secretions contaminated with bacteria. Risk factors include previous exposure to antibiotic therapy and the presence of invasive devices.[179]

The diagnosis of VAP is challenging. Frequently, a presumptive diagnosis of pneumonia is made when fever, leukocytosis, purulent secretions, and a new infiltrate on chest radiography develop and when bacteria are isolated by nonquantitative analysis of endotracheal aspirates. These nonspecific diagnostic criteria may lead to unnecessary antibiotic use, increased hospital cost, emergence of resistant microorganisms, and a potential delay in diagnosis of the true cause of the fever. These problems led several investigators to propose an invasive management strategy for the diagnosis of VAP.

Fagon and colleagues[180] used fiberoptic bronchoscopy to obtain protected specimen brush samples or bronchoalveolar lavage samples for quantitative culture. Patients were considered to have VAP if at least 10^3 colony-forming units (CFU)/mL of bacteria grew from the protected specimen brush sample or at least 10^4 CFU/mL of bacteria grew from the bronchoalveolar lavage fluid. The patients in the invasive management group had reduced mortality at day 14 (16.2% versus 25.8%, $P = .022$) and an increased number of antibiotic-free days (5.0 ± 5.1 versus 2.2 ± 3.5 days, $P < 0.001$). This study makes a compelling argument for a more definitive diagnosis of VAP before initiating antibiotic therapy. Along the same idea but with a less invasive approach, Bregeon and associates[181] showed that nonbronchoscopically guided placement of protected brush catheters is just as sensitive as directed bronchoscopy in detecting bacteria in the lungs.

Prevention of Ventilator-Associated Pneumonia

As in all nosocomial infections, prevention is the most efficacious approach. Excessive use of gastric pH–altering medications for stress ulcer prophylaxis increases gastric pH and the risk for VAP.[182] The use of sucralfate, an agent that does not increase gastric pH, may be preferable to H_2-receptor antagonists or proton pump inhibitors. Positioning of the head of the bed at 30 degrees

is the most cost-effective intervention to prevent VAP. With this intervention, Drakulovic and coworkers found a decreased rate of VAP with no adverse effects.[183] This position results in decreased gastroesophageal reflux and is easily implemented and monitored.

Pooling of secretions above the endotracheal tube cuff may increase the volume of bacteria that enter the airways. Removal of these secretions by continuous aspiration in the subglottic region requires the use of a specialized endotracheal tube with a second lumen that permits a suction catheter to exit proximal to the endotracheal tube cuff. A meta-analysis identified 13 randomized controlled trials that met the inclusion criteria. Of the 13 trials, 12 reported reduced VAP rates in the group that had subglottic secretion drainage. The overall RR for VAP was 0.55 (95% CI 0.46 to 0.66, $P < 0.00001$). The use of subglottic secretion drainage was associated with reduced ICU LOS (–1.52 days; 95% CI –2.94 to –0.11, $P = 0.03$); decreased duration of mechanical ventilation (–1.08 days; 95% CI –2.04 to –0.12, $P = 0.03$), and increased time to first episode of VAP (2.66 days; 95% CI 1.06 to 4.26, $P = 0.001$). There were no beneficial effects on adverse events or on hospital or ICU mortality.[184] In the patients anticipated to have a prolonged course of intubation with mechanical ventilation, the use of endotracheal tubes with subglottic secretion drainage appears effective for the prevention of VAP. The reduction of the number of oral microorganisms in the secretions with oral care and 2% chlorhexidine also appears to be beneficial for VAP prevention in a recent meta-analysis (RR 0.72; 95% CI 0.55 to 0.94, $P = 0.02$).[185]

CATHETER-RELATED BLOODSTREAM INFECTIONS

Central line–associated bloodstream infections are one of the leading causes of health care–associated infections. Fortunately, the rate of catheter-related bloodstream infections (CRBSI) in the United States has decreased from 43,000 in 2001 down to 18,000 in 2009.[186] This reduction represents a 58% decrease during this 9-year period. Along with a reduction in morbidity and mortality, this decrease also resulted in substantial cost savings, since each CRBSI is estimated to increase health care costs by $16,550. The recognition that many CRBSIs are preventable with the use of bundled clinical practice techniques is growing. In fact, the Centers for Medicaid and Medicare Services no longer reimburses hospitals for excess costs associated with CRBSI,[187] and many states now require public reporting of hospital-specific CRBSI rates.[188]

PREVENTION OF CENTRAL VENOUS CATHETER INFECTIONS

Many recent studies have shown that the prevention of CRBSIs is achievable through large-scale quality improvement projects that involve a bundle of evidence-based interventions.[189,190] The Health Care Infection Control Practices Advisory Committee recently released updated multidisciplinary guidelines for the prevention of intravascular catheter-related infections.[191] Recommendations include the use of ultrasound guidance for line placement,[192] skin preparation with chlorhexidine and alcohol,[193] chlorhexidine sponge for site dressing,[194] antimicrobial-impregnated CVCs,[195] and 2% chlorhexidine wash for daily skin cleansing,[196] along with maximal sterile barrier. The new guidelines also emphasize that only trained personnel should be assigned these tasks and that periodic assessment of these individuals should occur.

The need for a CVC should be reassessed daily, and unnecessary catheters should be removed because the probability of catheter-related infections increases with time. The risk of infection with catheterization stays relatively low until about the fifth to seventh days and then increases exponentially.[197] Several trials have studied scheduled replacement of catheters over a guide wire or in a new site, but none of these strategies were able to show an improved outcome.[198] Optimal catheter insertion technique and maintenance can minimize infectious risks, but the most efficacious maneuver is to remove the CVC as soon as it is no longer required. The need for central venous access should be reassessed again before discharging the patient from the ICU because the discharge procedure is often an opportune time to remove any indwelling lines, including bladder catheters.

Catheter-Associated Urinary Tract Infection

Hospital-acquired urinary tract infections (HAUTIs) make up 40% of HAIs with an estimated cost of $1200 to over $2700 per episode.[199] Approximately 80% of HAUTIs are catheter-associated urinary tract infections (CAUTIs).[200] In ICUs, where placement of Foley catheters is common, the incidence rate ranges from 3.1 to 7.4 CAUTIs per 1000 urinary catheter days.[201]

Results from a survey of 441 hospitals suggest that little attention had been focused on CAUTI prevention in ICUs in the United States.[202] To address this gap, multiple public policy incentives and private sector quality initiatives have been introduced to help reduce the rate of CAUTIs and its resultant morbidity, mortality, and cost. For instance, hospitals are held accountable by nonpayment for CAUTIs from the Centers for Medicare and Medicaid Services.[202] In 2011, The Joint Commission included the implementation of evidence-based practices to prevent CAUTIs as one of its 2012 National Patient Safety Goals.[203] This year, the Centers for Medicare and Medicaid enacted public reporting of CAUTI rates through its Hospital Inpatient Quality Reporting Program beginning in 2014.[204]

Prevention of Catheter-Associated Urinary Tract Infections

Unfortunately, no single CAUTI prevention strategy is widely used. Saint and colleagues found that only 30% of hospitals reported regularly using portable bladder ultrasound, 14% reported using condom catheters in men, and 9% reported using catheter reminders or stop orders.[205] Processes that have been introduced include a checklist of acceptable rationale for placement and a checklist to guide the orders for removal and management.[206] The elements of performance listed by the Joint Commission include the following:

1. Inserting indwelling urinary catheters according to established evidence-based guidelines that address limiting use and duration to appropriate situations and using aseptic techniques for placement

2. Managing catheters so that urine flow is unobstructed and the collection system remains sterile, and replacing the system when required
3. Measuring CAUTI prevention processes by monitoring compliance with guidelines or best practices, and evaluating the effectiveness of prevention efforts.

Further research is needed to elucidate the relationship between adherence to CAUTI prevention recommendations and CAUTI incidence rates.

HAND WASHING

Hand hygiene compliance is considered to be the single most effective factor to reduce HAIs. However, despite its importance, the rate of hand hygiene adherence among health care providers remains suboptimal.[207] Numerous hand hygiene products have been evaluated to enhance the rate of hand hygiene compliance among health care workers, including plain soap, alcohol-based antiseptics, chlorhexidine, hexachlorophene, iodine and iodophors, parachlorometaxylenol, quaternary ammonium compounds, and triclosan.[208] Although randomized controlled trial evidence is lacking, some studies suggest that the use of alcohol-based hand rub, along with a comprehensive hand hygiene campaign, can lead to reduced infection rates with methicillin-resistant *Staphylococcus aureus*.[209]

In a study examining the survey response from infection control coordinators, 86% of 95 Veterans' Administration (VA) hospitals and 85% of 416 non-VA hospitals reported the adoption of the use of an alcohol hand rub. Use of an alcohol-based hand rub was found to be more likely in hospitals where leadership support and a commitment to adopting and implementing evidence-based recommendations were present.[210] The use of alcohol-based hand rubs is easy to implement and appears to pose little risk to users. Hand hygiene compliance is an inexpensive and easy goal to achieve with a large potential of associated benefits.

COMMUNICATION AND HANDOFFS

With the limitations in resident work hours and the need for many ICUs to have physician staff available 24 hours a day and 7 days a week, *handoffs* between shifts of providers become more important for patient care. Handoffs are known to be vulnerable to communication failures, which could result in reduced patient safety and increased medical errors.[211] In 2006, The Joint Commission created a new National Patient Safety Goal on handoffs, requiring organizations to implement a standardized approach to hand off communications. The research data on this topic are relatively sparse; therefore, the Society of Hospital Medicine convened a taskforce whose goal was to develop a set of recommendations for handoffs. The taskforce reviewed the literature and identified the following recommendations: (1) have a formal recognized handoff plan; (2) dedicate time during the shift for handoffs, using a template or technology solution for recording patient information; (3) set handoff expectations among the group, giving a verbal face-to-face exchange; (4) give priority to high-acuity patients, focusing on a what-to-anticipate or a what-to-do list; and (5) highlight action items.[212] Randomized controlled trials are needed in both teaching and nonteaching settings to evaluate these recommendations further and other approaches to improving handoffs.

CONCLUSION

Critical care medicine is a growing specialty as the population ages and new procedures and technologies are brought into practice. Anesthesiologists represent a small proportion of intensivists in the United States but constitute the majority in Europe and other parts of the world. Critical care training represents a significant opportunity for anesthesia practitioners. The authors of this chapter have reviewed the management of a number of commonly encountered clinical conditions in the ICU, and the reader is referred to Section 8, Critical Care Medicine, Chapters 101 through 108 of this text for additional information related to critical care practice. The ICU is a nexus, not only for promising therapies but for complications of treatment as well. To avoid patient harm, all practitioners must be aware of best practices, from the simplest interventions such as hand hygiene to the latest technologic advances.

Chapter 102

Critical Care Protocols and Decision Support

BENJAMIN A. KOHL • C. WILLIAM HANSON

Key Points

- Protocols allow for standardization of clinical care and widespread adoption of evidence-based practices.
- Protocol implementation requires a multidisciplinary team for comprehensive planning and oversight. Frequent assessment is often necessary (particularly in the early phases) to ensure compliance and to monitor outcomes.
- Protocols should be devised with the intention of not only improving the quality of patient care but also improving patient outcome and the efficiency of care, while at the same time, decreasing practice variation and costs.
- Specific metrics should be followed after protocol implementation to measure the efficacy of the intervention and to help determine whether adjustments are necessary.
- Quality measures that were found to be valuable (based on effect, feasibility, and strength of evidence) included: (1) percentage of patients with ventilator-associated complications,[1] (2) percentage of patients with resistant infections, (3) percentage of patients with central venous catheter infections, (4) number of complications per patient, (5) average days of mechanical ventilation, (6) rate of gastrointestinal bleeding, (7) average intensive care unit length of stay, and (8) patient satisfaction.
- Computerized decision support algorithms are becoming increasingly sophisticated and more widely used. Understanding the limitations of a particular tool is essential to maintaining appropriate oversight and avoiding error.

The 2000 projection by the Committee on Manpower for Pulmonary and Critical Care Societies (COMPACCS) of an ongoing demand for critical care services in the United States appears to have been very accurate.[2,3] Because the future supply of appropriately trained physicians will unlikely match this growing demand, intensivists will face a larger, sicker population with fewer resources.[4,5] Although few would argue that an intensivist-led unit benefits from decreased morbidity and mortality, the impending staffing shortage and population growth will necessitate care paradigms that maximize efficiency, reduce practice variation, and standardize patient care.[6-9] Increasingly, intensive care units (ICUs) have adopted and implemented pathways and clinical protocols to achieve this goal. Designing such protocols, however, is not trivial. Protocols must be devised with the intention of not only improving the quality of patient care but also improving patient outcome and maximizing efficiency of care, while at the same time decreasing practice variation and costs. Lohr and colleagues defined *quality* as "the degree to which health services for individuals and populations increase the likelihood of desired health outcomes and are consistent with current professional knowledge."[10] It is essential for the well-being of our patients that health care providers use this definition as a guiding principle whether creating new or implementing known protocols. Furthermore, it is critical that clinicians not view protocol-driven care as a constraint on clinical judgment. On the contrary, protocols require greater consideration of individual subtleties among patients, and the attentive and experienced clinician understands the appropriate time and circumstance to deviate from a protocol. The goal then becomes a process: a process of learning, a process of observation, and a process of educated response. Without this goal, critical care becomes "cookbook medicine," and protocols become recipes for disaster.

In this chapter we discuss the rationale for care protocols in the context of achieving five goals: (1) enhancing quality of care, (2) improving efficiency, (3) decreasing cost, (4) decreasing errors, and (5) enabling rigorous clinical research. The focus is on more technical aspects of protocol design, including team development, evaluation of best evidence and/or consensus, preservation of

flexibility, and continuous quality improvement (CQI). Factors necessary to implement protocols are also discussed. This process begins with identifying priorities and setting goals and culminates with the ability to revise protocols continuously as new evidence builds. To illustrate these important concepts, three protocols used by many ICUs are reviewed. In the last section, the future of medicine extensively based on protocols is discussed, including the role of computer-driven decision models with closed-loop feedback and handheld computers. Additionally, areas of critical care medicine that likely will become based on protocols are described. However, protocol development and implementation, for all its intricacies and details, need the help, understanding, and sense of ownership of a large multidisciplinary team to be successful. Finally, examples of how groups have successfully integrated protocols into complex and sophisticated computerized decision support tools are described.

RATIONALE FOR PROTOCOL DEVELOPMENT

Critical care protocols or clinical practice guidelines (CPGs) evolved from the need to reduce practice variability while improving the quality of care and patient outcome by using the best available evidence. A 1994 editorial in the *British Medical Journal* predicted: "'Evidence based medicine' is a phrase that is currently familiar to only a few doctors, but all will know it by the millennium."[11] Although this forecast was accurate, the magnitude of patient care paradigm shift was not expected. Rather than treating patients based on empiric evidence or anecdote, today's intensivists must consider a plethora of objective data from which they must determine what will work best for their particular patient or population. The quality of this objective data and the robustness of statistical analysis continue to improve. Although many current protocols are based on data from multiple randomized controlled trials (RCTs), more than half of the clinical guidelines published before the year 2000 were based on no RCT evidence.[12]

Large numbers of interventions in critical care clearly improve morbidity and mortality while at the same time decreasing costs.[13-18] Despite this, a disparity continues to exist between best evidence and best practice.[19,20] As new evidence accrues, how should new data be analyzed and implemented? Using a uniform approach for each piece of evidence has advantages and disadvantages (Table 102-1).[21] Protocol or guideline development should explicitly state what, if any, objective grading system was used to categorize and classify the data.

The fundamentals of CPG development include (1) improving patient outcome, (2) establishing standards of care (either institutionally or within a specialty), and (3) changing practice patterns.[22] Although these points provide a rationale for CPGs, the primary goal of any new protocol is to enhance the quality of care. What is the definition of quality? The Institute of Medicine's definition is "the degree to which health services for individuals and populations increase the likelihood of desired health outcomes and are consistent with current professional knowledge."[10,23] The term *continuous quality improvement* (CQI) originated in the business realm and was coined by W. Edward Deming. Deming was a trained statistician but is best known for the positive impact he had on production in the United States during World War II. He taught management executives how to improve design and product quality through objective evaluation, testing, and reevaluation. CQI contrasts with the traditional, reactive, root-cause analysis, which focuses on recognizing a problem and then identifying a "seminal event" (or events) causally related to this event. In CQI, all facets of the critical care setting are evaluated and considered potential targets for improvement initiatives.[24,25] Once an initiative is identified, a system is devised to measure the efficacy or outcome of a particular intervention.[26] This change is then continuously reevaluated and modified by an internal evaluation system.[27] Depending on the goals of a particular critical care unit, interventions can be targeted appropriately.

Selecting a particular goal for quality improvement should be done very carefully. An inappropriate goal could lead to incorrect conclusions and thus unsuitable interventions. One example may be a goal of "decreasing the rate of readmission to the ICU." Although patients who are readmitted to the ICU have significantly increased mortality and length of stay, readmissions may represent a quality issue in the post-ICU setting or may represent an epiphenomenon associated with severity of illness.[24,28-31] Quality goals should extend beyond morbidity and mortality. A "change in process" goal may be equally important, such as use of aspirin or β-adrenergic blockers in patients with acute coronary syndrome. Similarly, "perceptions of care" goals (e.g., patient satisfaction, pain relief, nausea) require the same process of reevaluation as any other outcome.[32] Interventions and quality measures that, based on the literature, improved patient outcome have been defined.[14] Quality measures that are

TABLE 102-1 ADVANTAGES AND DISADVANTAGES OF USING THE SAME SYSTEM FOR GRADING EVIDENCE TO IMPLEMENT ICU PROTOCOLS

Advantages	Disadvantages
Having different systems for evaluation of various interventions may be confusing	Interventions that cannot be studied with randomized trials may not be evaluated or may lead to a false-negative conclusion
Individuals with vested interests have less chance to bias results by selecting a particular grading scheme	A single system that can adequately grade evidence across a broad range of interventions may be overly complex
Limitations of the evidence become more apparent when comparing two disparate conclusions with a similar grading scheme	
Better research can be generated as a result of identifying gaps in evidence	

Adapted from Schunemann HJ, Fretheim A, Oxman AD: Improving the use of research evidence in guideline development: 9. Grading evidence and recommendations, Health Res Policy Syst *4:21, 2006.*

valuable (based on effect, feasibility, and strength of evidence) included the following:

1. Percentage of patients with ventilator-associated complications
2. Percentage of patients with resistant infections
3. Percentage of patients with central venous catheter infections
4. Number of complications per patient
5. Average days of mechanical ventilation
6. Rate of gastrointestinal bleeding
7. Average ICU length of stay
8. Patient satisfaction

Once a protocol has met the standard of "quality," it then needs to be analyzed for efficiency and cost. *Efficiency* refers not only to the ease of implementation but also to its overall financial impact and timing of the intervention. Additionally, efficient protocols reduce management variability and, likely, errors and save lives.[6,33] Although protocol development is founded on evidence-based practice, at a local level it is a trial-and-error process. Systems theory provides us with many of the crucial aspects inherent in protocol design and necessary to maximize practicality.[34,35] Testing a new process and then evaluating the impact on the overall system were first described by Walter Shewhart, founding theorist of the field of statistical process control. Shewhart described a form of learning through action termed the Plan-Do-Study-Act (PSA) cycle.[36] One of the best examples of using the PSA cycle to implement a change in practice comes from work done by the Northern New England Cardiovascular Disease Study Group in 1996.[37] By continuously reevaluating variations in practice and morbidity and mortality from large databases, members of the group were able to develop protocols for such practices as anesthesia, hemostasis, and cardiopulmonary bypass pump management, thus achieving a 24% reduction in mortality from coronary artery bypass graft surgery within the region.

Paradoxically, protocol development and implementation negatively affect other expensive therapies, resulting in overall inefficiencies. An example is ICU protocols that were designed to optimize sedation and analgesia efficacy. Although the initial goals of anxiolysis and pain relief were attained, adverse effects include prolonged mechanical ventilation, increased risk of nosocomial pneumonia, and hemodynamic instability.[38,39] The final aspect of protocol efficiency is the timing of intervention. Ill-timed implementation of evidence-based practices is ineffective and possibly harmful. An example includes protocols designed to treat severe sepsis aggressively in the emergency department.[40] The execution of these practices late in the disease process (even by 1 day) actually increases mortality.[41] Thus, a protocol designed to treat a disease without identifying and addressing at-risk populations and diagnosis is wasteful and potentially unsafe.

Finally, protocols facilitate rigorous clinical research. Without standards, definitions, defined pathways, and explicit interventions, the interpretation of research findings, whether prospective randomized or observational, will enhance clinical equipoise. Protocols define a standard that attempts to control for confounding variables. As protocols are tested and replicated, new research is being generated. A wealth of RCTs demonstrates improved outcomes with protocol implementation.[42-46] For meaningful advances in critical care, protocols must continually embrace new findings, and intensivists must be willing to adhere to guidelines. However, the applicability of a particular guideline or protocol is based on the population studied and needs careful analysis when considered for a different population.

PROTOCOL DESIGN

Protocol design usually requires a multidisciplinary team.[46,47] However, the process mandates identification of the affected variables, grading the data, a method for continual reevaluation, and inherent flexibility (Box 102-1). Affected variables are factors that will be affected indirectly (positively or negatively) by the proposed protocol. An example is a sedation-anxiolysis protocol that does not take into account the duration of mechanical ventilation, the incidence of nosocomial pneumonia, nausea, vomiting, and other variables. Affected variables are byproducts of a purposeful change in practice. The variables can be universal, as in the previous example, or institutional. A ventilator weaning protocol may look appropriate on paper but may be unrealistic, depending on the local staffing paradigm of respiratory therapists at a particular institution. Similarly, an ICU glycemic control protocol may work at one institution but not be as effective in another or may even be deleterious.[48,49]

Evaluating and grading the literature must be based on the variables measured in a study. Moreover, "best evidence" must consider the patient population to be relevant to protocol design. Inclusion and exclusion criteria must be understood, as well as the prevalence and

BOX 102-1 *Process for Developing Guidelines*

Establishing the Process

Prioritize problems
Select a panel
Declare conflicts of interest
Agree on processes

Preparatory Steps

Perform a systematic review of the problem
Define outcomes of interest
Prepare evidence for outcomes

Grading Quality of Evidence and Strength of Recommendations

Define the quality of evidence for each outcome
Define the relative importance of outcomes
Judge the *overall* quality across all pieces of evidence
Balance benefit and harm
Balance net benefits and costs
Determine the strength of the recommendation

incidence of disease in a particular study. Only after critically analyzing studies in this fashion can practitioners begin to grade the quality of evidence. Quality of evidence traditionally refers to four components: study design, study quality, consistency, and directness.[50]

Study design refers to the basic format and aim of an investigation. Case-control studies, cohort studies, and RCTs are all examples of study designs. The aim of case-control and cohort studies is to establish an association between some potential risk factor (e.g., hyperglycemia) and morbidity (e.g., infection) or mortality. Whereas cohort studies can be either retrospective or prospective, case-control studies are, by definition, retrospective. RCTs are prospective and aim to identify causality rather than association. For various reasons, RCTs are considered the most decisive tests and are frequently deemed definitive.[51] However, RCTs are often not feasible and, particularly with regard to rare diseases or outcomes, may not be as applicable as observational studies. Many investigators have, in fact, challenged the traditional hierarchic study design paradigm that places RCTs at the top and expert opinion and anecdote at the bottom.[52,53] Regardless, study design must be evaluated and graded based on the merit it holds for a specific population and a particular outcome.

Study quality is altogether different from the "quality" referred to earlier. Study quality refers to the methodology and study implementation. Adequacy of blinding, method of randomization, selection of placebo, statistical analysis, and reduction of bias are all examples of factors to be scrutinized when evaluating study quality. The revised CONSORT statement provides a useful template with which study quality indicators can be measured (Table 102-2).[54] The ability to discern adequacy of quality is neither precise nor consistent among reviewers.[55] This fact has culminated in a collaborative effort to address

TABLE 102-2 **ITEMS TO CONSIDER IN EVALUATING STUDY QUALITY**

Section or Topic	Descriptor
Title and abstract	How participants were allocated to interventions
Introduction and background	Scientific background and explanation of rationale
Methods	
Participants	Eligibility criteria for participants and the settings and locations where the data were collected
Interventions	Precise details of the interventions intended for each group and how and when they were actually administered
Objectives	Specific objectives and hypotheses
Outcomes	Clearly defined primary and secondary outcome measures and, when applicable, any methods used to enhance the quality of measurements
Sample size	How sample size was determined and, when applicable, explanation of any interim analyses and stopping rules
Randomization	
Sequence generation	Method used to generate the random allocation sequence, including details of any restriction (e.g., blocking, stratification)
Allocation concealment	Method used to implement the random allocation sequence clarifying whether the sequence was concealed until interventions were assigned
Implementation	Who generated the allocation sequence, who enrolled participants, and who assigned participants to their groups
Blinding (masking)	Whether or not participants, those administering the interventions, and those assessing the outcomes were blinded to group assignment; if done, how the success of blinding was evaluated
Statistical methods	Statistical methods used to compare groups for primary outcome(s); methods for additional analyses, such as subgroup analyses and adjusted analyses
Results	
Participant flow	Flow of participants through each stage; specifically, for each group reporting the numbers of participants randomly assigned, receiving intended treatment, completing the study protocol, and analyzed for the primary outcome
Recruitment	Dates defining the periods of recruitment and follow-up
Baseline data	Baseline demographic and clinical characteristics of each group
Numbers analyzed	Number of participants in each group included in each analysis and whether the analysis was by "intention-to-treat"
Outcomes and estimation	For each primary and secondary outcome, a summary of results for each group and the estimated effect size and its precision (e.g., 95% confidence interval)
Ancillary analyses	Addressing of multiplicity by reporting any other analyses performed, including subgroup analyses and adjusted analyses, indicating those prespecified and those exploratory.
Adverse events	All important adverse events or side effects in each intervention group
Comment	
Interpretation	Interpretation of the results, taking into account study hypotheses, sources of potential bias or imprecision, and the dangers associated with multiplicity of analyses and outcomes
Generalizability	Generalizability (external validity) of the study findings
Overall evidence	General interpretation of the results in the context of current evidence

From Moher D, Schulz KF, Altman D: The CONSORT statement: revised recommendations for improving the quality of reports of parallel-group randomized trials, JAMA *285:1987-1991, 2001.*

these shortcomings and develop a process whereby intraobserver and interobserver variability in evaluation and grading of study quality is reduced.[56] Furthermore, study quality does not necessarily equate with superiority of study design. RCTs, for example, are not necessarily of highest quality and can have significant inherent bias.[57,58] Bias is difficult to eliminate completely, but it must be sufficiently reduced for a study to be of high quality. Jadad and colleagues defined study quality as "the likelihood of the trial design to generate unbiased results."[59] However, as Verhagen and associates indicate, although the reduction of bias enhances the internal validity of a study, study quality must take into account a study's external validity.[60] That is, consideration of the applicability and consequence of a study's result to the population as a whole must be deemed a variable when measuring quality. External validity can be ascertained by examining the consistency and directness of an investigation.

Consistency refers to the reproducibility of results among different investigators. Consistency in the magnitude of effect, the direction of effect, and the statistical and clinical significance of a particular effect must be considered. Major inconsistencies among similar populations decrease the quality of evidence and generalizability for a particular outcome and should be considered when grading evidence for protocol implementation. *Heterogeneity* is a statistical term used to measure consistency among studies and is frequently used in meta-analyses. Traditionally, *Cochran's Q* statistic has been calculated by summing the squared deviations of each study's estimate from the overall meta-analytic estimate.[61] However, because this test is poor at detecting significant heterogeneity when the number of studies is small, Higgins and colleagues devised a more widely applicable test statistic, I^2, that describes the *percentage* of total variation across studies that is the result of heterogeneity rather than chance alone.[62,63] Values of I^2 range from 0% (no observed heterogeneity) to 100%. Consideration of this value must be taken into account when designing evidence-based protocols (see also Chapter 111).

Finally, the *directness* of a study more specifically addresses the generalizability and applicability aspect of external validity. Does the reduction of mortality seen in a single-center translate into reduced mortality for all surgical ICU patients, or do the results merely represent the consequences of improved patient care at a single institution? The same can be said of high-volume hemofiltration studies and the incidence of sepsis. It has been said that, "most patients to whom we would like to generalize the results of randomized trials would, for one reason or another, not have been enrolled in the most relevant study."[64] Despite this sentiment, *the data are what the data are*, and it is imperative that methods be used such as evaluation of directness to make decisions.[65] Evaluation of patient population, diagnostic criteria, and surrogate outcomes all must be scrutinized before application of principles or implementation of protocols based on such evidence.[66]

Protocol design must, in some fashion, address each of the foregoing areas and rank them based on importance of outcome, severity of illness, risks and benefits of implementation, and cost. Although difficult, the literature must be graded. A review of more than 100 of these systems found no single best scheme; rather, application of the *process* of evidence assessment was what was most important.[67]

PROTOCOL IMPLEMENTATION

Designing a critical care protocol and *implementing* a change in practice are very different. Design is based on data review, judgment of applicability, and ranking the strength of evidence, as reviewed previously. Implementation, however, necessitates communication and collaboration among various members of the ICU team. Some of the more important concepts to be addressed before implementing a new protocol include education, definition of targets and goals, data collection, analysis of variance, and measurement of impact.

Thoughtful selection of a multidisciplinary task force to evaluate strategies for critical care protocol development and implementation is very important. Most often, such groups include both physician and nursing leadership, as well as selected ancillary professionals (depending on the protocol), such as respiratory therapists, nutritionists, pharmacists, or physical therapists. Particular to the surgical ICU, physician leadership should involve members from both the critical care and primary surgical team.

Passive educational approaches such as didactics and dissemination of protocols have generally been ineffective implementation strategies.[68-70] Changes in physicians' behavior require outreach, dialogue, and discussion. Protocols that are integrated within a computerized algorithm, such that warnings, reminders, and suggestions are generated when appropriate, have been shown to be useful.[69] Education must address key points such as the evidence supporting a change in practice, the advantage of a new practice paradigm, and the compatibility of a novel protocol to the existing practice.

Targets and goals are usually related, although they are defined differently. *Targets* are frequently measured as continuous data points and often set a limit, outside which patients are not considered to be "within protocol." *Goals* define a realistic outcome presumably obtainable if targets are met. Examples of *targets* are maintaining glucose levels at 150 mg/dL or lower, elevating the head of the bed 30 degrees or more, administering antibiotics within 3 hours of presentation, and maintaining inspiratory plateau pressures at less than 30 cm H_2O for mechanically ventilated patients (see also Chapter 103). Examples of *goals* are decreasing the sternal wound infection rate, decreasing ventilator-associated pneumonia, decreasing progression of sepsis to septic shock, and decreasing ventilator-associated lung injury. Targets and goals must be defined at the outset so that analysis of protocol compliance and effect can be objectively measured.

INTENSIVE CARE UNIT PROTOCOLS

The focus of this section is on three protocols currently used in critical care units. The purpose is not to define a

particular care algorithm but rather to illustrate the process that various groups have gone through to devise best care practices. Each topic presented demonstrates a different facet of protocol development and implementation.

GLYCEMIC CONTROL

Since the publication of the landmark "Leuven" study, literally hundreds of protocols implementing tight glycemic control (TGC) have been published (see Chapter 39).[15] Furthermore, this single study changed the standard of care in surgical ICUs, and TGC was quickly adopted by various professional societies.[71,72] How best to achieve euglycemia has been the real debate, and groups must identify, within their own infrastructure, a protocol that will work for them. An illustrative example of rational protocol design can be seen with the Stamford Hospital experience (Fig. 102-1).[73] Although the actual protocol devised by this group may be different from others, the process of design and the steps taken should serve as a model for those wishing to do similar work. The problem (i.e., "hyperglycemia is associated

ICU Protocol for Glycemic Management

Approved by the ICU Committee 2/01/03
Last modified by the ICU Multidisciplinary Committee 9/26/03

Rationale

Hyperglycemia is strongly associated with increased hospital mortality as well as organ system dysfunction among critically ill patients.

Goal

The goal of this protocol is to maintain serum glucose <140 mg/dL

Monitoring

Glucose levels will be evaluated *by blood testing or fingerstick testing,* using the following schedules.

Diet	Frequency of monitoring
NPO	Q8 hours: 6AM, noon, 6PM, midnight
PO diet	1 hour AC and QHS
Tube feedings, TPN	Q6 hours: 6AM, noon, 6PM, midnight

For most patients, the 6AM glucose evaluation will be obtained from the morning BMP. If glucose <140 for two consecutive days without treatment, glucose levels can be checked Q12 hours (6AM, 8PM).

Treatment of Hyperglycemia

Glucose value	Action (subcutaneous insulin dose)
<140	No treatment
140–169	3 units Regular insulin, Recheck glucose value in 3 hours
170–199	4 units Regular insulin, Recheck glucose value in 3 hours
200–249	6 units Regular insulin, Recheck glucose value in 3 hours
250–299	8 units Regular insulin, Recheck glucose value in 3 hours
300+	10 units Regular insulin, Recheck glucose value in 3 hours

*If glucose value exceeds 200 on two successive measurements, a continuous insulin infusion will be initiated. Hourly FSG or blood glucose measurements will be obtained in all patients receiving insulin infusions. The sliding scale noted above is a guideline: it can be modified if the patient requires more or less intensive therapy.

Management of Insulin Infusion

1. Initial infusion rate

Glucose value	Insulin dose
200–249	4 units/hour
250–299	6 units/hour
300–399	8 units/hour
400+	10 units/hour

Important points

*All patients receiving continuous insulin must receive a continuous source of glucose either via IV (D5W or TPN), or enteral feeds.

*The insulin infusion is discontinued if the patient has to leave the ICU for a diagnostic test as well as upon discharge from the ICU.

2. Subsequent management, based on hourly glucose checks

Glucose value	Insulin dose
<140	Stop infusion or continue low dose to avoid "rebound"
140–169	2 units/hour
170–199	3 units/hour
200–249	6 units/hour
350–399	8 units/hour
400+	10 units/hour

If this treatment plan does not lead to a decrease in the patient's glucose values, contact the house officer.

Figure 102-1. Example of rational protocol design. *AC,* Before meals; *BMP,* basic metabolic panel; *D5W,* dextrose 5% in water; *FSG,* fasting serum glucose; *ICU,* intensive care unit; *NPO,* nothing by mouth; *PO,* oral; *qhs,* at bedtime; *TPN,* total parenteral nutrition. *(From Krinsley JS: Effect of an intensive glucose management protocol on the mortality of critically ill adult patients,* Mayo Clin Proc *79:992-1000, 2004.)*

with increased hospital mortality") was stated at the outset. A review of the pertinent literature was undertaken, and the problem was confirmed. A system was put in place to accurately quantify the problem at their institution, measure pertinent variables, and evaluate outcome. A multidisciplinary team undertook the task of devising a protocol to rectify the problem. Finally, successful implementation of the protocol was established, and statistical analysis was performed to validate the impact of the protocol.

TRANSFUSION

As many as one third of patients admitted to an ICU in the United States will receive a blood transfusion (see also Chapter 61).[74,75] Although the etiology of anemia in critical care patients is certainly multifactorial and not always obvious, the implications of treatment are becoming evident.[76-78] The risk of transfusion-related infections has markedly decreased but remains. Unfortunately, many noninfectious complications are associated with allogeneic transfusions, including acute lung injury and immunomodulation.[79-81] So what should the transfusion trigger be?

The best evidence regarding the efficacy of red blood cell transfusion in critically ill patients comes from the Canadian Critical Care Trials Group.[42] Patients who were managed with a restrictive transfusion strategy (maintenance of hemoglobin at 7.0 to 9.0 g/dL, with a transfusion trigger of 7.0 g/dL) had equivalent outcomes (with a trend toward improved outcome) compared with patients managed with a liberal transfusion strategy (maintenance of hemoglobin at 10 to 12 g/dL, with a transfusion trigger of 10 g/dL). Since that time, two large, multicenter studies have evaluated the practice of transfusion. The ABC (Anemia and Blood transfusion in Critically ill patients) trial explored the risks and benefits of transfusions in a large European population.[82] The authors were able to show a positive correlation between receipt of any blood transfusion and 28-day mortality (22.7% versus 17.1%, $P = 0.02$). Furthermore, the mortality risk increased in a dose-related fashion with increased transfusions. A second study, the CRIT trial, performed a similar analysis in the United States.[75] Again, transfusion was independently associated with mortality, and increased blood cell transfusion was associated with increased mortality.

Implementation of a transfusion protocol, however, requires an understanding of the literature. As reviewed earlier, implementation necessitates an understanding of infrastructure, organization of a multidisciplinary team, a systematic grading of the literature, and a means to measure effect and variability in practice. A comprehensive blood conservation strategy needs to be understood and developed. The net effect of protocol implementation may be inconsequential if confounding variables are not addressed. Such variables affecting the risk of transfusion include, but are not limited to, the following: contribution of phlebotomy,[77,83] inadequate salvage techniques,[84,85] and inattentiveness to proper pharmacologic hemostatic agents[86] (see also Chapters 61 to 63). One of the most cohesive and logical plans to address this topic has been published and should be used as a model for proper protocol implementation.[87]

VENTILATOR WEANING

Few process-based interventions in the ICU have been more rigorously studied than weaning from mechanical ventilation (see Chapters 101 and 103). Indeed, protocols in this area have been tested and validated, culminating in evidence-based guidelines.[88-93] Given the plethora of data, including three large RCTs that have demonstrated reduction in duration of mechanical ventilation, intensivists should have a protocol in place to address this issue.[45,94,95] The reason ventilator weaning protocols are highlighted here, however, is that they illustrate a critical point to understand when designing protocols: regardless of the design and the involvement of personnel, an ICU protocol will ultimately fail if confounding factors are not addressed and included within the protocol. With regard to mechanical ventilation in the ICU, two confounding factors are sedation and analgesia. Without some interface between the timing of ventilator weaning and the interruption of sedation, the compliance and success of the protocol are in jeopardy.[44,96]

THE FUTURE OF MEDICINE BASED ON PROTOCOLS

A frequent barrier to implementation of established protocols is practitioner compliance. Anecdotal experience is often the enemy of evidence-based practice. The decision-making process is increasingly relegated to appropriately designed computers and handheld devices.[91,97-100] More important, however, will be physicians' understanding of current technology and of recent literature, an appreciation of the limitations of these resources, and the ability to review these elements and outcomes cohesively and continuously in a pragmatic manner aimed at developing best practice guidelines.[101] Several groups have already initiated such reviews in areas such as traumatic brain injury,[102] nutritional support,[103] glycemic control,[104] and sedation and analgesia.[105] Has intensive care medicine become too complex to rely on a physician's ability to sort through and interpret the thousands of pieces of information that must be addressed each day?

Although protocols inevitably decrease the variability in practice, they do not address the multifaceted approach to ICU care. Some investigators have advocated systematic development of checklists to remind team members of the multitude of goals for every patient, rather than increased protocol generation. An example is the FAST HUG mnemonic developed by Vincent[106]:

F: Feeding
A: Analgesia
S: Sedation
T: Thromboprophylaxis
H: Head of bed elevation
U: Ulcer prophylaxis
G: Glycemic control

Each component of the mnemonic should be addressed with each patient, every day. Whereas protocols may

pertain and be applicable to any of the systems, the checklist helps prevent intensivists from oversight.

COMPUTERIZED CLINICAL DECISION SUPPORT

Although the concept of clinical decision support (CDS) has been around for decades, practical application of such algorithms using established protocols have only more recently been implemented.[107,108] Any robust system for clinical support must rely on frequent data input from multiple sources. When processed appropriately, these data can be used to assess previous responses to therapy or intervention and adjust the care being delivered. This ability to detect, respond, detect a change, and respond proportionally is the key to a successful closed-loop system.[109-111] Thus, computerized protocols must be adaptive and be able to integrate new data while the system (patient) is changing. With proper oversight, such algorithms have the potential to be more efficacious than a protocol-driven clinician.[112] Further research is needed to better assess the breadth of applicability for such applied science, but advances in technology are certain to make this a tool that will be used more frequently.

CONCLUSION

Protocol development and implementation comprise a complex and labor-intensive process. A multidisciplinary team is required and a specific educational plan is necessary to implement all facets of a protocol properly. Although evidence-based medicine is at the heart of the process and a detailed analysis of the literature is required, clinical acumen and anecdotes need not be ignored. Protocols are designed for the masses, and they require a thoughtful and educated intensivist to identify those patients for whom particular protocols may not be applicable. Protocols also allow for standardization of research protocols and minimization of confounding variables. The ability to measure the effect of a particular protocol and adapt appropriately is the key to successful protocol application. The future of critical care will certainly see an increase in the number of protocols based on quality evidence. These protocols will likely interface with various computers and handheld devices to help ensure compliance and more easily interpret the flood of information obtained on a daily basis. Intensivists will need to learn which patients are appropriate for such interventions and, with the help of checklists, ensure comprehensive patient care.

Chapter 103

Respiratory Care

SALVATORE GRASSO • LUCIANA MASCIA • V. MARCO RANIERI

Key Points

- Intermittent positive-pressure mechanical ventilation is the gold standard for assisting patients with acute respiratory failure. Positive end-expiratory pressure (PEEP) is the positive pressure applied at the end of expiration during positive-pressure mechanical ventilation. A constant level of positive pressure applied to a spontaneous breathing cycle is termed continuous positive airway pressure (CPAP).
- Modes of mechanical ventilation can be classified as totally or partially ventilator controlled.
- Although positive-pressure mechanical ventilation is usually applied through an endotracheal tube or a tracheotomy, it also may be delivered noninvasively to the patient's mouth, nose, or through helmets.
- External gas exchangers to totally or partially bypass the lung (extracorporeal support) can be used for the most severe forms of respiratory failure that are refractory to conventional mechanical ventilation).
- Acute respiratory distress syndrome (ARDS) is an inflammatory response of the lung with acute onset and presence of bilateral infiltrates on chest radiography. ARDS is characterized by a reduction in functional residual capacity and static compliance. The correct setting of mechanical ventilation in ARDS is of paramount importance to minimize ventilator-induced lung injury.

The target of ventilation is to generate flow and volume to provide adequate alveolar ventilation with the minimal work of breathing (WOB). Contraction of the respiratory muscles provides the "power" required for ventilation. The phrenic nerve regulates the timing and intensity of this power, integrating inputs from chemoreceptors, pulmonary stretching receptors, and variations in metabolic demands. During spontaneous breathing the respiratory muscles generate a pressure (3) that produces flow against the resistive and volume against the elastic properties of the respiratory system. Under these circumstances, at any instant, the act of spontaneous breathing can be described as follows:

$$\text{Pmus} = \text{Pres} + \text{Pel} \quad (1)$$

where *Pres* represents the resistive pressure and is a function of flow and respiratory system resistances (Pres = flow × resistance) and *Pel* represents the elastic recoil pressure and is a function of volume and elastance of respiratory system (Pel = volume × elastance). Assuming that resistance and elastance are linear, Equation 1 becomes:

$$\text{Pmus} = (\text{flow} \times \text{resistance}) + (\text{volume} \times \text{elastance}) \quad (2)$$

Acute respiratory failure requiring ventilatory support occurs if a pathologic process or a pharmacologic intervention (1) impairs the capacity of the respiratory muscles to generate sufficient Pmus, (2) increases the ventilatory requirements above the muscle capacity, or (3) increases the workload associated with the act of breathing. Application of positive pressure (i.e., a pressure higher than the atmospheric pressure) to a patient's airway opening during the inspiratory phase is currently the main method to administer assisted breathing and restore adequate ventilation. The resulting pressure gradient between a patient's airway opening and alveoli generates a positive flow (i.e., directed from the ventilator to the patient). The expiratory phase, which is passive, depends on the end-inspiratory pressure gradient between alveolar pressure (which is positive because of the elastic recoil pressure stored during the inspiratory phase into the respiratory system) and airway opening pressure. Under these circumstances, the pressure applied at the airway opening of the patient (Pao) includes the pressure generated by the ventilator (Pappl) plus the pressure generated by the contraction of the respiratory muscles according to the following equation:

$$\text{Pmus} + \text{Pappl} = (\text{flow} \times \text{resistance}) + (\text{volume} \times \text{elastance}) \quad (3)$$

The capability of restoring gas exchange, unloading respiratory muscles, and relieving dyspnea depend on the

match between the ventilatory setting and the ventilatory demand—that is, on the patient-ventilator interactions.[1] Depending on the relative amount of Pmus and Pappl, modes of mechanical ventilation can be classified as totally or partially ventilator controlled.

- *Total ventilator-controlled ventilatory support:* A patient's own breathing pattern is totally replaced by the ventilator, and Pmus is abolished by sedation (and eventual paralysis of the respiratory muscles) or by a pathologic process; the ventilator is responsible for generating flow, volume, and pressure, or all of these.
- *Assisted-controlled ventilatory support:* The ventilator provides a fixed amount of support, in terms of assistance and inspiratory time, in response to a patient's inspiratory effort; the patient is allowed to trigger the ventilator (assist-control mode).
- *Assisted ventilatory support:* The patient controls respiratory rate and receives positive pressure assistance to spontaneous breathing effort. Ideally the patient should maintain full control of the inspiratory time and expiratory time. The amount of Pappl assisting the spontaneous breathing effort may be fixed or proportional to the spontaneous inspiratory effort (i.e., to Pmus).

SETTINGS OF MECHANICAL VENTILATION

Positive-pressure breaths from the ventilator can be categorized by three variables: (1) the trigger variable (what initiates the breath), (2) the limit variable (the algorithm that governs positive pressure delivery), and (3) the cycle variable (what terminates the inspiratory phase). These variables can be set on the ventilator and serve as its interface with the three main physiologic variables of the breathing pattern: (1) the ventilatory drive (when inspiration begins; (2) the ventilatory requirements (how much flow and volume are necessary to satisfy the metabolic demands), and (3) the duration and ratio of inspiratory time to total breath cycle duration.[2] The variables that regulate the triggering of ventilation are time (during controlled mechanical ventilation) or flow and pressure, with the ventilator sensing the patient's inspiratory effort (trigger function, during assisted mechanical ventilation modes). Ventilator gas delivery can be regulated to deliver a fixed (during controlled modes) or variable (during assisted modes) amount of flow, volume, or pressure. The ventilator can cycle from inspiration to expiration based on a preset time, on flow or pressure, or on electrical diaphragmatic activity threshold level.

TOTAL VENTILATOR-CONTROLLED VENTILATORY SUPPORT (CONTROLLED MECHANICAL VENTILATION)

The main characteristic of controlled mechanical ventilation is that the variable used by the ventilator (and set by the health care provider) to trigger and to cycle off the breath is time. The limit variable that governs gas delivery may be flow (flow-limited controlled mechanical ventilation [CMV]) or pressure (pressure-limited controlled ventilation [PCV]) (Fig. 103-1). With the former, the ventilator applies either a constant (square) or nonconstant (in the majority of cases decelerating) flow to deliver a preset tidal volume (V_T). Flow is the independent variable (i.e., the ventilator maintains the predetermined flow pattern regardless of patient impedance) and the airway opening pressure (Pao) profile during inflation depends on the mechanical characteristics of the patient's respiratory system. With the latter, the ventilator applies a preset positive-pressure level (commonly, square) to the patient's airway opening. Pao is therefore the independent variable that is held constant by the ventilator by instantaneously replacing the volume delivered to the patient. V_T depends on the inspiratory time and on the mechanical characteristics of the respiratory system. The inspiratory flow starts with a peak followed by the exponential flow decay and becomes nil as soon as applied pressure equals alveolar pressure.

The choice between volume-cycled and pressure-cycled modes is not supported by definitive evidence. Volume-cycled modes are preferred when it is crucial to maintain minute ventilation. This is because V_T during PCV is a dependent variable affected by the interplay between the level of applied pressure, the inspiratory time, and the respiratory system impedance (mainly inspiratory system elastance and resistance). On the other hand, physiologic considerations support the use of pressure-limited modes to realize a more homogeneous distribution of V_T within lung parenchyma.[3] Pathologic conditions often increase lung parenchyma inhomogeneity so that lung regions with different elastance and resistance (i.e., with different time constants: τ = elastance × resistance) may coexist. From a

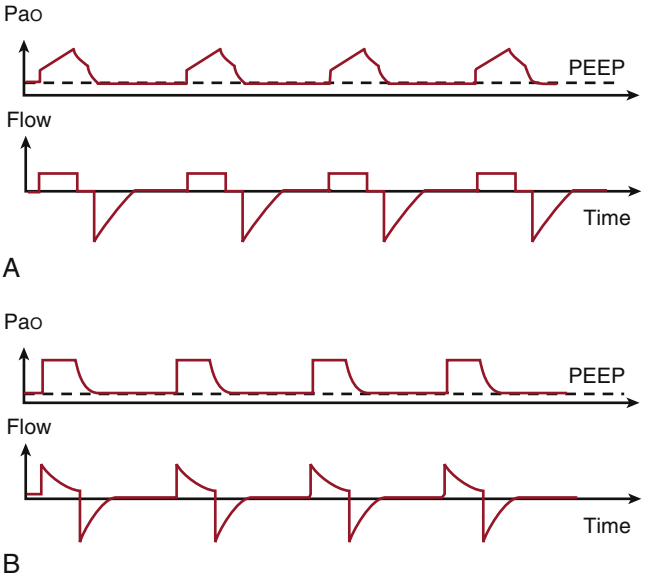

Figure 103-1. Tracings of flow and airway opening pressure (*Pao*) during the two basic controlled intermittent positive pressure ventilation modes. **A,** Volume-cycled. **B,** Pressure-cycled. *PEEP,* Positive end-expiratory pressure.

theoretical point of view, the flow-limited controlled mode could induce hyperinflation of regions with lower elastance resistance and, at the same time, underinflation of regions with higher elastance and/or resistance. Based on these theoretical assumptions, the pressure-limited mode should be the preferred ventilator mode in patients with inhomogeneous lungs, because this mode allows a more homogeneous V_T distribution between regions with different elastance resistance.

A controlled mode able to share the theoretical advantages of constant pressure with the guarantee of delivering a preset V_T has been recently introduced in clinical practice (pressure-regulated volume control, volume plus). It consists of a closed-loop algorithm that, based on the automatic measurement of static compliance of the respiratory system, continuously adapts the level of applied pressure on a breath-by-breath basis to match a target V_T.

ASSISTED MECHANICAL VENTILATION

Assisted ventilatory techniques are intended to unload the respiratory muscles and relieve dyspnea in patients with impaired neuroventilatory coupling. The degree of freedom gained by the patient depends on the regulating algorithm and includes respiratory rate, breathing pattern (inspiratory time, expiratory time, duration, and ratio of inspiratory time to total breath cycle duration), and level of assistance. The capability of restoring gas exchange, unloading respiratory muscles, and relieving dyspnea with these modes of partial ventilatory support critically depends on the matching between the ventilator settings and the patient's ventilatory demands.[1,2,4]

The rationale for preserving diaphragmatic activity in critically ill patients is to reduce sedation and paralysis, minimize cardiovascular side effects of mechanical ventilation,[5] and, most importantly, decrease the disuse diaphragm atrophy that arises very quickly with controlled modes. Indeed, Levine and associates[6] showed that inactivity associated with controlled mechanical ventilation results in marked atrophy of diaphragm myofibers within 18 to 69 hours, likely as a result of inactivity-induced diaphragmatic proteolysis. Furthermore, compared with controlled modes, partial ventilatory support modes have the potential to improve ventilation-perfusion mismatch by reaerating dependent lung areas, as a result of aeration of dependent lung regions that occurs with contraction of the diaphragm.

A potentially severe problem with assisted modes is patient-ventilatory asynchrony, mainly documented by ineffectual inspiration, double triggering, and a discrepancy between neural and mechanical inspiratory time. The Brochard group developed an asynchrony score to evaluate assisted mechanical ventilation modes and showed that higher scores were associated with weaning delays and higher tracheostomy rates in critically ill patients.[7]

Assist/Control Mechanical Ventilation

The patient is allowed to set the respiratory rate by activating the inspiratory trigger function (as a safety measure, if no spontaneous effort occurs, the ventilator will deliver controlled breaths at a preselected backup rate). The variable used by the ventilator to cycle off the breath is time. The limit variable that governs gas delivery is flow and volume (assisted/controlled mechanical ventilation [A/CMV]) or pressure (assisted pressure-controlled ventilation [A/PCV]).

To activate a pressure trigger, the patient decreases pressure in the respiratory circuit at a preset threshold level, in contrast to the flow-trigger system, in which the patient generates a preset amount of inspiratory flow. Patient-ventilator synchrony during A/CMV depends on the quality of the trigger mechanism (pressure versus flow triggers) and on the kind of controlled breath delivered (volume-cycled versus pressure-cycled); combining flow trigger and A/PCV improves patient-ventilator interactions because of the higher inspiratory peak flow compared with the volume-cycled mode.[8]

Can A/CMV meet patient inspiratory demand? Marini and co-workers[9] demonstrated that during patient-triggered breaths, effort does not cease with the onset of gas delivery and that total inspiratory workload may even exceed the work performed during spontaneous breathing, particularly in the assist/controlled constant-flow mode.[9] Indeed, once the patient triggers the ventilator, a rapid increase in inspiratory flow occurs similar to that during spontaneous breathing. The patient then struggles with the constant flow applied by the ventilator. In contrast, with the pressure-limited algorithm, the ventilator increases volume delivery in response to the patient effort and therefore the patient obtains a peak inspiratory flow nearer to his or her physiologic needs.[10]

In conclusion, with assist/control (A/C) the neuroventilatory coupling is not restored. The amount of work performed by the ventilator actually decreases at expense of patient effort. In contrast, to restore normal neuroventilatory coupling, higher inspiratory efforts should ideally be supported by a higher assistance level and vice versa.[11] This ventilatory mode is in general poorly tolerated in awake patients. In patients with dynamic hyperinflation (see later discussion) and increased respiratory drive (resulting from fever, hypermetabolic states, and sepsis), ongoing air trapping and respiratory alkalosis during A/CMV may occur.

Synchronized Intermittent Mandatory Ventilation

Synchronized intermittent mandatory ventilation (SIMV) allows the patient to breathe spontaneously between intermittent mandatory controlled breaths. Controlled breaths are delivered in a synchronous manner, in the sense that based on the set mandatory respiratory rate the ventilator software establishes a time window in which each mandatory breath can be triggered by the patient's spontaneous effort. If the patient does not exert effort in this time window, the ventilator independently delivers the mandatory breath. Depending on the SIMV modality, controlled breaths may be volume-cycled or pressure-cycled. Spontaneous breathing is usually supported by a variable degree of pressure support (see later discussion). Varying the rate of mandatory breaths allows near total ventilatory support or

fully spontaneous breathing. Regarding patient-ventilator interactions during mandatory breaths, SIMV shares the same limitations as A/CMV.

Pressure Support Ventilation

Pressure-support ventilation (PSV) is the most popular partial ventilatory-assist mode for weaning patients from controlled ventilatory modes and to provide ventilation in patients with acute respiratory failure, provided their respiratory drive is preserved.[12] During PSV, the patient's spontaneous effort triggers the ventilator and is subsequently assisted by a constant positive pressure (Pappl, see Equation 3) applied at the airway opening, either invasively or noninvasively. V_T depends on the interplay between Pmus, Pappl, and respiratory system impedance (mainly, elastance and resistance) (see Equations 2 and 3). PSV is intended to unload the respiratory muscles and improve the relation between the patient's effort and V_T. For a given inspiratory effort, the patient generates a larger volume than during spontaneous breathing. PSV relieves dyspnea in several clinical conditions. However, with PSV the assistance delivered by the ventilator is not related to the patient's inspiratory effort and consequently neuroventilatory coupling is only partially restored.[11]

Cycling from the inspiratory to the expiratory phase in PSV occurs when inspiratory flow rate decreases to a preset level. The decay of inspiratory flow is clearly a surrogate signal to infer a patient's neural inspiratory time—as soon as the spontaneous inspiratory effort ceases, the flow rate will decay to less than the expiratory trigger threshold.[13] Depending on the ventilator software, the "expiratory trigger" sensitivity may be at a fixed minimal flow rate or at a fixed percentage of peak inspiratory flow. In several intensive care unit (ICU) ventilators, the percentage of the peak inspiratory flow that triggers expiration (expiratory trigger sensitivity) can be adjusted from 5% to 90%. Unfortunately, a delay between the end of neural inspiratory effort and the end of ventilator assistance usually exists and may cause a severe disturbance of patient-ventilator interactions resulting in patient-ventilator asynchronies.[7] This is particularly true if the patient has weak inspiratory effort, the applied pressure is relatively high in contrast to the patient's effort, or both; under these circumstances, the ventilator will prolong its assistance well beyond the duration of spontaneous inspiration, generating a severe discrepancy between neural and mechanical inspiratory time.[14] One intervention is matching neural and mechanical inspiratory time to minimize asynchronies and trying to adjust the expiratory trigger sensitivity. In addition, several ventilators allow adjusting the time for pressure increase at the beginning of inflation (inspiratory pressure slope), thus affecting the peak inspiratory flow value.[15] Unfortunately, a quantitative estimation of the inspiratory effort is not available in the PSV mode. Adjustment of expiratory trigger sensitivity is largely empirical in clinical practice. Studies show that when a patient's inspiratory effort is nil the respiratory rate is slower than 20 breaths/minute and V_T is greater than 8 mL/kg.[16] A common clinical approach is to regulate ventilatory support to maintain the respiratory rate between 20 and 35 breaths/minute and V_T between 5 and 8 mL/kg[17]; then inspiratory pressure slope and expiratory trigger sensitivity can be adjusted to minimize patient-ventilator asynchronies.[7]

Proportional Assisted Ventilation

During proportional assisted ventilation (PAV), the ventilator amplifies patient effort in generating pressure in proportion to the patient's generated flow and volume. What is preset is not a target pressure but rather the proportion between the patient's inspiratory muscle effort and the ventilator-applied pressure.[11,18]

To realize proportional assistance, the ventilator measures spontaneous patient instantaneous flow and volume by its internal sensors and the clinician measures and then sets the values for elastance and resistance. Knowing all these variables, the ventilator processor then estimates instantaneous Pmus (see Equation 2) and assists patient effort in a proportional fashion (according to a factor of proportionality set by the operator).

In this PAV version, a reliable estimation of elastance and resistance (see Equation 2) is needed. If the estimate is correct, the pressure generated by the ventilator will be lower than the pressure required to offset the passive properties of the respiratory system. Both underestimation and overestimation of elastance and resistance could critically impair patient-ventilator interactions. If elastance and resistance are underestimated, the level of assistance provided by PAV will be insufficient to relieve patient dyspnea. In contrast, if elastance and resistance are overestimated, a positive feedback develops and the ventilator continues to deliver flow and volume while the patient stops inspiratory effort (the "run-away" phenomenon).

To overcome the clinical problem of estimating respiratory system elastance and resistance in a spontaneously breathing patient, the recently proposed PAV plus (PAV+) algorithm allows an automatic and noninvasive measure of elastance and resistance through the ventilator's internal sensors to continuously adapt the proportional assistance accordingly. The noninvasive assessment of respiratory system mechanics is based on the application of brief (100 to 300 msec) occlusions on airway opening at end inspiration during PAV.[19,20]

The most evident difference between PAV and PSV is a more variable V_T over time.[21] A sudden hypercapnic stimulus during PAV triggers a compensatory increase in minute ventilation mostly obtained by an increase in V_T, with no change in respiratory rate. On the contrary, patients ventilated with PSV react by increasing respiratory rate but are unable to significantly increase V_T. In contrast to PSV, PAV better mimics the physiologic response to hypercapnia.[8] PAV significantly unloads the inspiratory muscles and improves the breathing pattern in patients with chronic obstructive pulmonary disease (COPD).[22]

Neurally Adjusted Ventilatory Assist

The neutrally adjusted ventilatory assist (NAVA) algorithm is based on the measurement of electrical diaphragm activity by means of an electrode array inserted

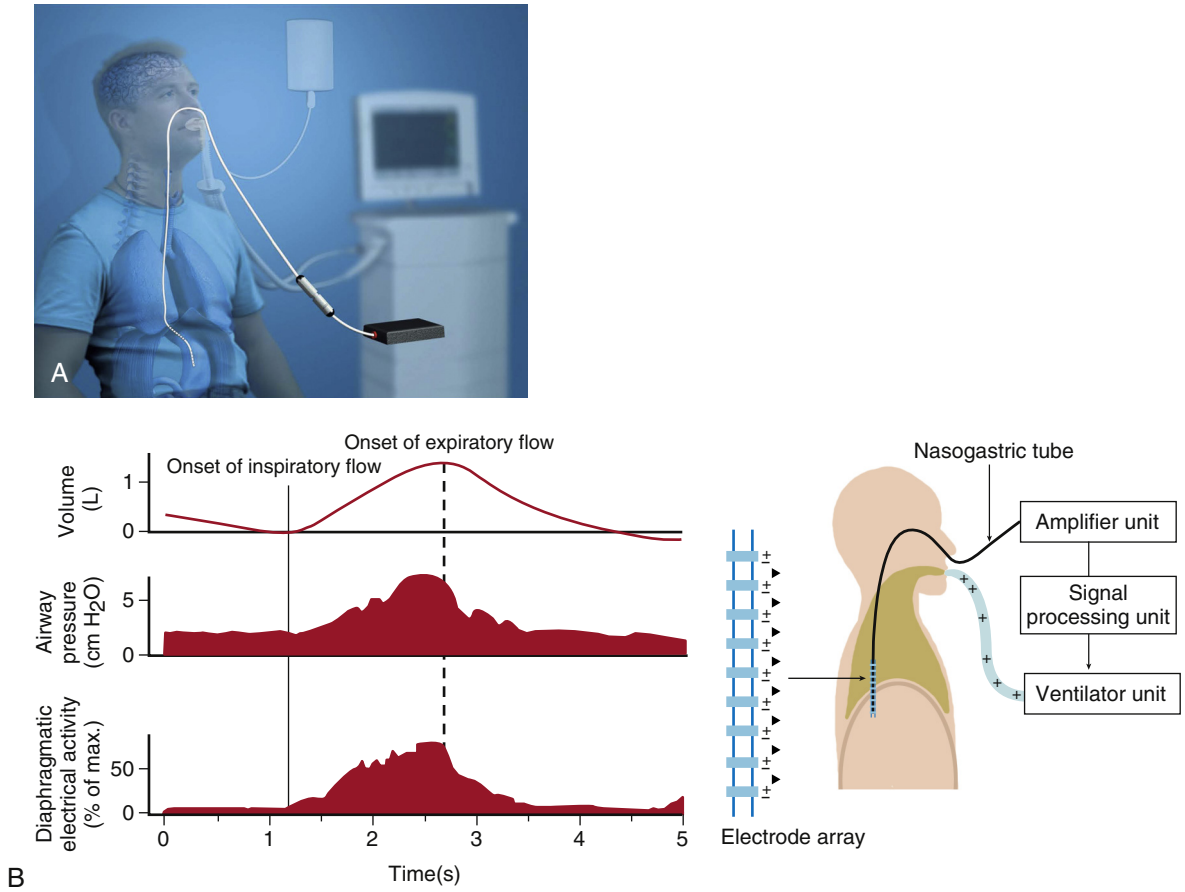

Figure 103-2. Neurally adjusted ventilatory assist (NAVA) concept. An electrode array, inserted into a nasogastric tube and placed in the lower esophagus, is able to sense the diaphragmatic activity. This signal is used to trigger the ventilator (neural trigger function) and assist the patient's inspiratory effort in proportion to the diaphragmatic electrical activity.

into a nasogastric tube and placed in the lower esophagus. This signal is used both to trigger the ventilator (neural trigger) and to deliver assistance in proportion to the instantaneous diaphragmatic electrical activity. With NAVA, the respiratory drive controls the assisted positive breaths in all phases of the ventilation cycle from triggering to cycling between the inspiratory and the expiratory phase (Fig. 103-2) and any change in ventilatory output is matched on a breath-by-breath basis. The potential physiologic advantages of NAVA to correctly restore the neuroventilatory coupling are well established.[23,24] Nevertheless, similar to PAV, adequately designed clinical trials showing a significant impact on meaningful clinical outcomes (faster weaning, tracheostomy rate, patient ICU survival) are not yet available.

During NAVA, the electrical signal of diaphragmatic activity drives the ventilator. How should the amount of pressure be set to be delivered for each microvolt (μV) of diaphragmatic activity? Several methods have been proposed: (1) recording the diaphragmatic activity during PSV and setting NAVA on a virtual basis to obtain the same peak pressure read during ongoing PSV (NAVA preview system), (2) progressively increasing NAVA assistance to identify a plateau in peak pressure and V_T,[25] (3) setting the NAVA level to maintain a respiratory rate between 20 and 35 breaths/minute and V_T between 5 and 8 mL/kg (clinical method, in analogy with PSV). More clinical studies to clarify this crucial issue are required.

Recording the diaphragm electrical activity signal offers the unique opportunity of studying patient-ventilator interactions in the different ventilatory modes. Diaphragm neuroventilatory efficiency (NVE) can be clinically measured as the ratio between spontaneously generated V_T and peak diaphragm electrical activity level, whereas diaphragm neuromuscular efficiency (NME) can be measured by the ratio between the negative Pao deflections during a brief airway opening occlusion period (10 to 20 seconds) and the corresponding peak diaphragm electrical activity level. The NVE and NME measured just before an attempt to wean correlates with the chance for successful weaning.[26]

POSITIVE END-EXPIRATORY PRESSURE AND CONTINUOUS POSITIVE AIRWAY PRESSURE

Positive end-expiratory pressure (PEEP) is the positive pressure applied at the end of expiration during mechanical ventilation. A constant level of positive pressure applied to a spontaneous breathing cycle is termed continuous positive airway pressure (CPAP). Physiologic consequences of PEEP and CPAP depend on its effects on gas exchange, pulmonary compliance, and systemic hemodynamics.

Effects on Gas Exchange

PEEP/CPAP may improve arterial oxygenation by reexpanding functionally collapsed alveoli, redistributing lung water, and reducing ventilation-perfusion mismatch ($\dot{V}/\dot{Q}$), if the lung is recruitable and normal regions of the lung exist.

Alveolar recruitment, defined as the amount of noninflated tissue that is reexpanded by a given level of PEEP/CPAP, results in a more homogeneous distribution of the V_T and an increase in the functional residual capacity. Moreover, application of PEEP/CPAP leads to the redistribution of lung water from the alveolar space to the perivascular interstitial space and improves $\dot{V}/\dot{Q}$ by diverting blood flow from shunt regions to normal regions.

These effects strongly depend on whether PEEP/CPAP recruits previously collapsed alveoli.[27,28] If the applied PEEP/CPAP induces alveolar recruitment, a reduction in shunt with improvement in oxygenation and reduction in dead space is expected. However, if hyperinflation of normal alveoli is the predominant effect, an increase in $Paco_2$ resulting from an increase in dead space is expected, whereas the PaO_2 will change slightly, depending on whether the applied PEEP/CPAP induced variations in cardiac output, because varying cardiac output has per se an impact on intrapulmonary shunt.

Effects on Respiratory Mechanics

Compliance of the respiratory system (i.e., $V_T \div$ Plateau pressure – PEEP) represents a good estimate of the elastic properties of the respiratory system. Application of PEEP/CPAP may lead to the following effects on lung compliance:

- Increase in compliance, suggesting alveolar recruitment
- No change in compliance, indicating that ventilation is occurring on the linear portion of the volume-pressure relationship of the respiratory system
- Decrease in compliance, indicating lung overdistention

Effects on Hemodynamics

The application of PEEP/CPAP may affect hemodynamics through several mechanisms: decreased venous return to the right heart, increased right ventricular afterload, decreased ventricular compliance, and decreased ventricular contractility.[29-31] Overall, the hemodynamic consequences of PEEP/CPAP depend on the prior ventricular loading conditions, ventricular function, and the effect of PEEP/CPAP on lung mechanics.

In patients with normal cardiac function, the main consequence of increased intrathoracic pressure is the reduction of venous return and consequently of cardiac output. Because the right ventricular preload decreases, an adequate circulating blood volume is required before application of PEEP/CPAP to prevent depression of right ventricular output. In patients with poor left ventricular function or congestive heart failure, the increase in intrathoracic pressure reduces the left ventricular transmural pressure, leading to a reduction in left ventricular afterload and an improvement in left ventricular function. In these patients, cardiac output is relatively insensitive to reduction in venous return because diastolic volume is increased.[32]

NONINVASIVE VENTILATION

Mechanical ventilation is usually applied by an endotracheal tube or a tracheotomy. The efficacy of mechanical ventilation noninvasively applied to patient's mouth, nose, or both to restore respiratory function is well established. The side effects of invasive ventilation are then minimized. Noninvasive ventilation is delivered almost exclusively through partial ventilatory support techniques. Potential advantages of avoiding endotracheal intubation include less patient discomfort, reduced need for sedation, and a less frequent incidence of ventilator-associated pneumonia and sepsis[33] (see also Chapter 101). These advantages result in significant improvement in outcome variables.[34] However, the success of noninvasive ventilation critically depends on correct patient selection and expertise of the clinical team. If a trial of noninvasive ventilation is not successful, patients who then undergo endotracheal intubation will experience longer duration of invasive mechanical ventilation and longer ICU stay.[35]

Established indications for noninvasive ventilation are acute COPD exacerbation, acute cardiogenic pulmonary edema, postoperative respiratory failure, and respiratory failure in immunocompromised patients (solid organ transplant recipients and bone marrow transplanted) (see later discussion).[35]

In some clinical situations, noninvasive ventilation should be applied with caution. A less frequent endotracheal intubation rate and hospital length of stay occurred in patients with community-acquired pneumonia treated with noninvasive ventilation.[36] In experienced centers the application of noninvasive ventilation to patients with acute respiratory distress syndrome (ARDS) as a first-line intervention avoided endotracheal intubation in approximately 54% of cases,[37] whereas CPAP was not associated with better survival and length of hospital stay.[38] The use of noninvasive ventilation as a means to accelerate weaning from invasive ventilation has been the object of extensive, but not conclusive, clinical investigations. The use of noninvasive ventilation as a weaning technique in patients with COPD who are difficult to wean when the standard criteria for spontaneous breathing are not met may lengthen the duration of mechanical ventilation and increase mortality.[39,40] Noninvasive ventilation did not prevent reintubation of the trachea in patients developing acute respiratory failure after extubation.[41] Whether noninvasive ventilation should be used in patients with acute asthma, upper airway obstruction, and trauma is not clear (see also Chapters 38 and 81). Other possible fields of application are during fiberoptic bronchoscopy in hypoxemic or hypercapnic patients[42] and as a palliative therapy in patients who are not candidates for invasive ventilation.[43]

Two recent publications evaluated the efficacy on noninvasive ventilation in two large and distinguished hospitals (Massachusetts General Hospital, Boston, Mass., and Molinette Hospital, Turin, Italy).[44,45] Both studies indicated that noninvasive ventilation as part of routine standard medical care has limitations. A similar percentage of patients with respiratory failure resulting from

cardiogenic pulmonary edema and COPD exacerbation needed subsequent endotracheal intubation. Failure of noninvasive ventilation was associated with frequent hospital mortality for patients with hypoxemic respiratory failure.[44,45]

Predictors of success for noninvasive ventilation include younger age, lower acuity of illness (as quantified by the Acute Physiology and Chronic Health Evaluation II [APACHE II] or Simplified Acute Physiology Score II [SAPS II]), ability of the patient to cooperate, intact dentition, technical ability to minimize air leaks, moderate hypercapnia (i.e., between 45 and 90 mm Hg), and moderate (i.e., instead of severe) acidosis (i.e., between 7.35 and 7.10).[46] A successful trial of noninvasive ventilation should induce a trend toward increase, reduction in respiratory rate, and decrease in Pa_{CO_2} within 30 to 60 minutes.

The ideal interface for noninvasive ventilation should provide optimal patient comfort and minimal air leaks. Both masks (oronasal or nasal) and helmets are currently available. The oronasal mask induces air leaks in 80% to 100% of patients, facial skin reddening in 20% to 34%, mask intolerance in 8% to 32%, nasal and mouth dryness and nasal congestion in 10% to 20%, nasal bridge ulceration in 2% to 31%, eye irritation in 16%, gastric distention in 8%, and aspiration in 6%. These side effects may be minimized by using the helmet, but this interface may induce delay in ventilatory assistance with PSV and significant acoustic noise.[47]

Monitoring patients during noninvasive ventilation includes frequent checking of the interface to evaluate carbon dioxide rebreathing, accidental disconnection from the ventilator, air leaks, skin necrosis, and the ability of the patient to clear secretions. Monitoring of physiologic parameters (pulse oximetry, analysis of arterial blood gases, exhaled V_T, respiratory rate, use of accessory respiratory muscles, paradoxical abdominal motion, gastric distention, heart rate, arterial blood pressure) and of subjective variables (mental alertness, comfort, dyspnea) is of paramount importance for patient safety. Respiratory therapists spent more time with patients treated with noninvasive ventilation than with patients with endotracheal intubation in the first 8 hours, but this trend is reverted in the subsequent 8 hours.[48]

NONCONVENTIONAL VENTILATORY SUPPORT

Modalities of ventilatory support described earlier are defined as conventional; they are based on two principles: a V_T larger than the dead space volume and application of positive pressure at the airway opening. The following section describes modalities of ventilatory support that are defined as nonconventional because they are based on the application of a V_T lower than that of the dead space volume (high-frequency ventilatory oscillation [HFVO]).

High-Frequency Oscillatory Ventilation

The goal of conventional ventilation with PEEP is to keep the lung recruited while the cyclical increase in P_{AO} deliver V_T. At variance, the HFOV ventilator resembles a CPAP device in the sense that it basically applies a continuous mean airway pressure ($P_{AO,MEAN}$). Fresh gas (40 to 60 L/minute) continuously flows into the respiratory circuit, and the expiratory valve allows maintaining the preset $P_{AO,MEAN}$ level. The substantial difference with CPAP is that oscillatory pressure stroke at a very high frequency (i.e., between 180 and 900 beats/minute—i.e., from 5 to 15 Hz) are superimposed on the $P_{AO,MEAN}$. Technically, the high-frequency oscillating ventilators are based on an oscillating piston pump that generates pulse pressure "strokes" in the CPAP circuit (see Fig. 103-2, *A*). Each oscillation produces a sinusoidal cycle of pressure with increases and decreases more and less than $P_{AO,MEAN}$ (increase as the piston pump goes toward the patient, immediately followed by decrease as the piston pump draws away from the patient). An important issue is that HFOV provides both active inspiration (the positive stroke waves) and expiration (the negative stroke waves). The operator determines the overall oscillation amplitude—that is, the pressure amplitude (ΔP) that can be regulated up to 70 to 90 cm H_2O. Of note, the ΔP is read immediately near the piston, whereas the pressure transmission to the airway opening (because of the high oscillation rate and the very limited piston movement) is greatly attenuated and the ΔP in the endotracheal tube and alveoli is greatly attenuated (commonly 2 to 4 cm H_2O); accordingly, the resulting V_T is approximately 1 to 2 mL/kg—that is, lower than anatomic dead space. The observation that delivering pressure stroke waves at very high rates is a means of scavenging CO_2 from inside the lungs to the airway opening in intubated patients derived from a serendipitous observation—very fast oscillation applied at the airway opening to measure lung mechanics was able to scavenge CO_2. CO_2 removal, during HFOV is obtained through mechanisms including (1) direct ventilation of the alveoli located more proximally, (2) air movements occurring between nearby lung units with different time constants, (3) streaming of inspiratory and expiratory flow in diverging alveolar ducts, and (4) axial convection and lateral mixing.[49] Once scavenged from the lungs, CO_2 diffuses in the respiratory circuit and is eliminated by the bulk of fresh gas continuously flowing into the circuit. The main determinants of oxygenation during HFOV are $P_{AO,MEAN}$ and FiO_2. The main determinants of CO_2 elimination are the pressure amplitude (ΔP), the frequency of pressure oscillations, and (to a limited amount) the bias flow; CO_2 elimination can be enhanced by increasing ΔP or by decreasing oscillation frequency. Briefly, the higher the Δ pressure, the higher is the V_T; the higher the CO_2 clearance and the slower the oscillation rate, the higher are the V_T and higher CO_2 clearance.

In summary, HFVO offers the unique option of ventilating with very low V_T at relatively high mean airway pressure while maintaining acceptable CO_2 clearance. This constitutes an "extreme" lung protective approach because V_T is minimized and the lung can be kept recruited by adequately high distending pressures without the risk for hyperinflation that would ensue with conventional V_T delivery. Traditionally, HFVO

has been viewed as a rescue strategy to support patients with ARDS requiring very high positive pressure levels to maintain alveolar recruitment.[50] Thus, it has been applied in very sick patients in small studies with relatively increased mortality rates according to the studied population. Two recent multicenter randomized large clinical studies, the OlmeSartan and Calcium Antagonists Randomized (OSCAR)[51] and the Oscillation for Respiratory Distress Syndrome Treated Early (OSCILLATE)[52] trials, the first including 398 patients and the second 548 patients, tested the hypothesis that HFVO could reduce ARDS mortality when applied early in the course of ARDS as a lung-protective ventilatory strategy. Unfortunately, these trials did not document superiority of HFVO over the traditional approach to lung-protective strategy in ARDS (see later discussion). Based on these findings, at present HFVO cannot be recommended on a routine basis to treat patients with ARDS.

MONITORING CONTROLLED MECHANICAL VENTILATION

The analysis of the airway opening–time (Paot) signal obtained when applying volume-cycled constant-flow ventilation with a brief end-inspiratory pause, allows monitoring of the mechanical properties of the respiratory system. The Paot during constant flow includes the following information (Fig. 103-3):

- *Resistive pressure increase* (see *A-B segment* in Fig. 103-3) represents the step increase in Pao that occurs at the beginning of inspiratory flow delivery. It is not perfectly perpendicular to the time axis but shows a discrete slope because of the inability of the ventilator to generate a sudden increase in flow and to the inhomogeneities of different lung regions.
- *Elastic pressure increase* (see *B-C segment* in Fig. 103-3) represents the increase in Pao generated by the progressive

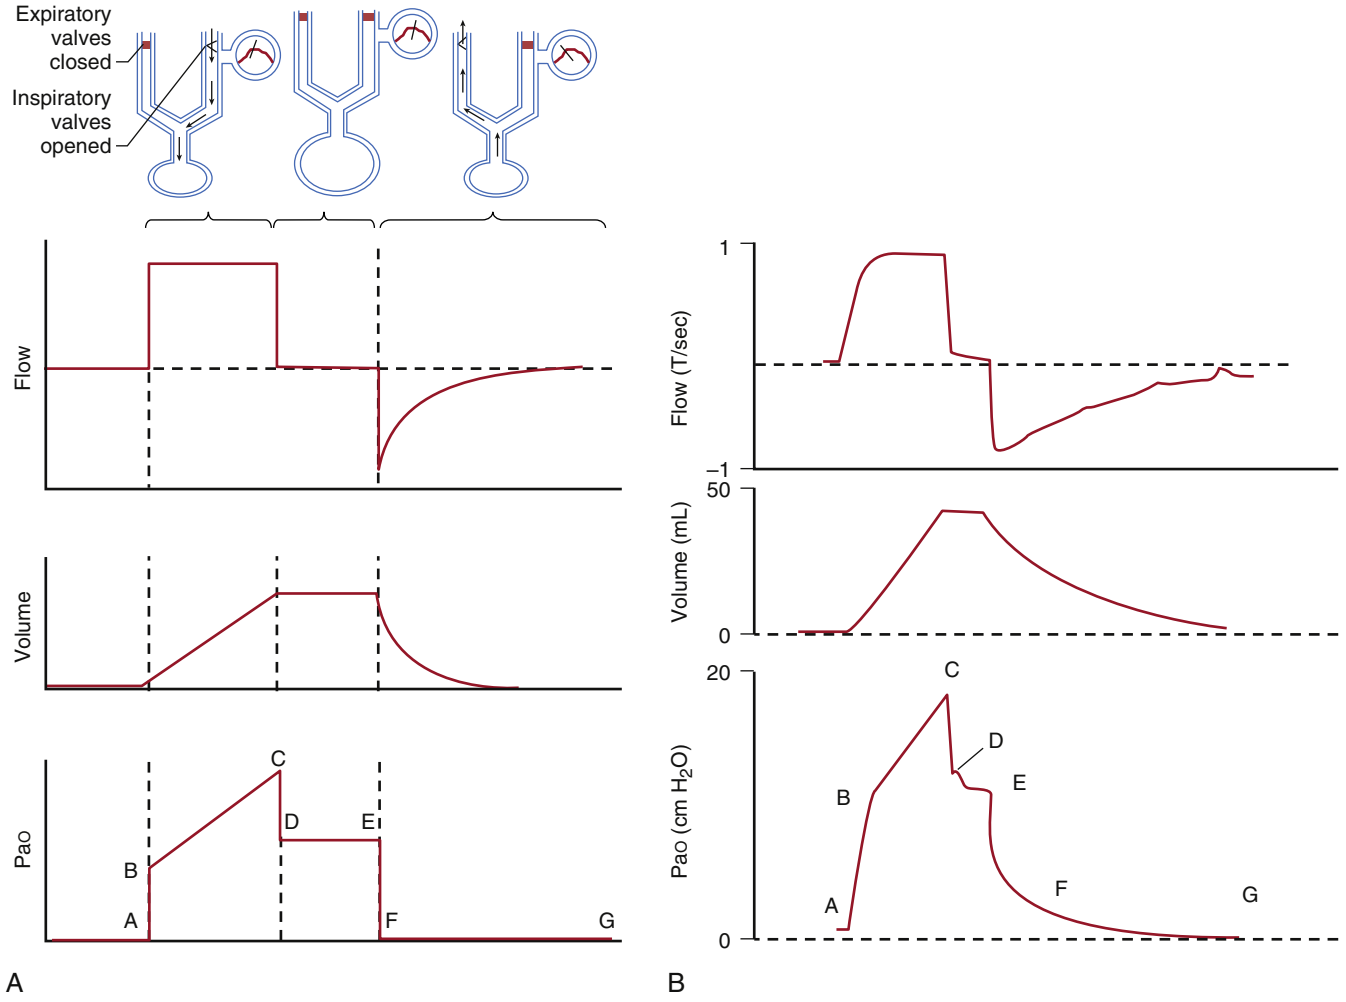

Figure 103-3. Flow, volume, and airway opening pressure (Pao) tracings recorded during controlled constant-flow mechanical ventilation. **A,** Theoretical traces related to the different phases of the ventilator duty cycle in a monocompartmental lung model. The model does not take into account the respiratory system viscoelastic and inertial properties and the inhomogeneity among different lung regions. **B,** Real traces. *A-B segment* (resistive pressure increase), *B-C* elastic pressure increase after the *C* point (Pao_{peak}), the Paot profile from Pao_{peak} to Pao_{plat} (*E*) can be divided into two regions: (1) an immediate pressure drop from Pao_{peak} to $Pao_{occlusion}$ (*D*) and, (2) a slower decay from $Pao_{occlusion}$ to Pao_{plat}, that take place in 2 to 5 seconds. The latter is principally due to alveolar gas redistribution between areas with different elastic and resistive characteristics (whose pressures at end-inspiration are not in equilibrium). Hence, the $Pao_{occlusion} - Pao_{plat}$ difference is proportional to the inhomogeneity between different lung regions.

inflation of the respiratory system, whose slope depends on the elastic properties of the respiratory system. It is not always linear, because its profile may be curvilinear when respiratory system compliance varies with lung inflation (see later discussion).

- Pao_{peak} (see *point C* in Fig. 103-3) is the peak in Pao reached at end inspiration. For a given flow rate and inspiratory time, Pao_{peak} expresses both the resistive and elastic pressure increase. After Pao_{peak}, the Paot profile during the end-inspiratory pause (when both the inspiratory and the expiratory valves are closed) can be divided into two regions: (1) an immediate decrease in pressure from Pao_{peak} to $Pao_{occlusion}$ (see *point D* in Fig. 103-3) as a result of the interruption of flow that makes the resistive pressure nil and (2) a slower decay from $Pao_{occlusion}$ to the end-inspiratory pressure (Pao_{plat}) (see *point E* in Fig. 103-3) that depends on a gas redistribution process between areas with different elastic and resistive characteristics and by the inertial properties of lung tissue. For a given V_T, Pao_{plat} expresses the elastic properties of the respiratory system. After the end-inspiratory pause, the expiratory valve is open while the inspiratory valve is closed and the respiratory system is allowed to passively exhale to the elastic equilibrium point of the respiratory system (see *E-F segment* in Fig. 103-3). If an end-expiratory valve is added to the expiratory limb of the ventilatory circuit, the *F-G segment* is equal to the value of the applied PEEP.

The rate of change of the airway pressure–time curve during constant flow inflation corresponds to the rate of change of respiratory system compliance during tidal inflation—a progressive increase in slope of the curve indicates that compliance is progressively increasing, whereas a progressive decrease in slope of the curve indicates that compliance is decreasing with tidal inflation; a linear increase of pressure indicates that compliance is constant throughout inflation.[53,54] Progressive increase and decrease in compliance during inflation are associated with tidal alveolar opening and collapse and tidal alveolar hyperinflation, respectively[55]—that is, with the main mechanisms responsible for mechanical ventilation–induced lung mechanical stress.[56] Hence, by analyzing the Paot profile during the period of constant-flow inflation (see *segment B-C* in Fig. 103-3) the occurrence of tidal alveolar recruitment and derecruitment and/or overinflation may be detected noninvasively (the stress index concept [Fig. 103-4]). Titrating the PEEP level according to the stress index analysis allows ventilator-induced lung mechanical stress in patients with ARDS to be minimized. Continuous monitoring of the stress index may be useful in establishing lung-protective ventilatory strategies.[57]

Respiratory resistance is the opposition to gas flow through the respiratory system and is quantified as the amount of pressure required to cause a unit rate of gas flow, according to the Ohm law:

$$\text{Resistance} = \text{driving pressure}/\text{flow rate}$$

where driving pressure is the resistive pressure applied to generate a given constant laminar flow in the airways. The total resistance of the respiratory system is the sum of pulmonary resistance (airway resistance plus lung tissue resistance) and chest wall resistance (essentially tissue resistances) and is expressed in centimeters of H_2O per

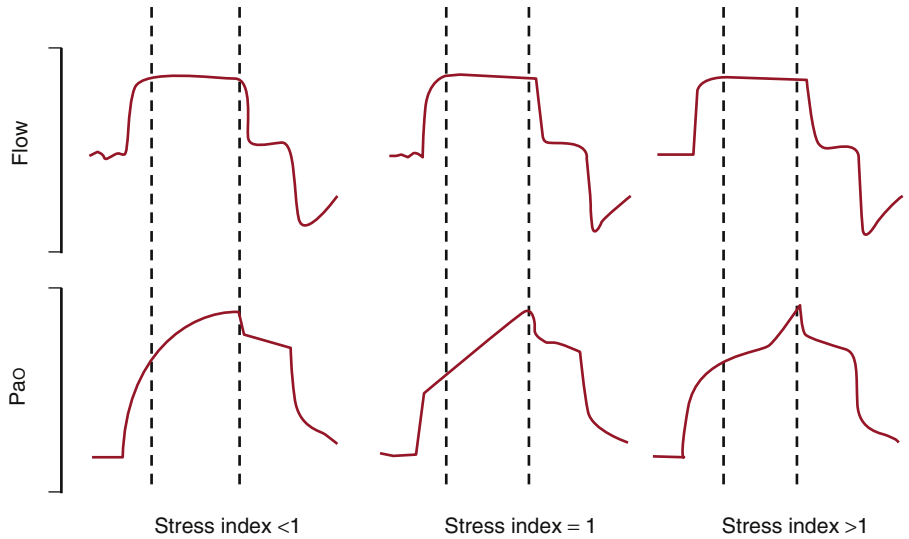

Figure 103-4. The stress index concept. Tidal alveolar recruitment, derecruitment, and overinflation may be detected through the analysis of the Paot profile during the period of constant flow inflation. A downward Paot concavity indicates progressive increase in compliance during tidal inflation, resulting from ongoing alveolar recruitment with inflation, whereas an upward Paot concavity indicates progressive decreases in compliance during tidal inflation as a result of ongoing alveolar overinflation with inflation. To measure the stress index, a power equation ($Pao = a \times t^b + c$) is fitted on the Paot profile. Here, the coefficients *a* and *c* are constants and the coefficient *b* is a dimensionless number that describes the shape of the Paot profile (stress index). For a coefficient $b < 1$ the Paot profile has a downward concavity (compliance increases with inflation), whereas for a coefficient $b > 1$ the Paot profile has an upward concavity (compliances decreases with inflation). Finally, when *b* is equal to 1, the Paot profile is straight and compliance remains constant during inflation.

liter per seconds. The total resistance of the respiratory system (Rmax,rs) is therefore proportional to the Ppeak minus Pplat pressure decay when the constant flow is suddenly interrupted, according to the equation:

$$\text{Rmax,rs} = (\text{Ppeak} - \text{Pplat})/\text{Flow}$$

Rmax,rs may be further partitioned into the airway resistance (Rmin) and additional resistances (ΔR). The immediate drop of pressure from P_{peak} to $Pao_{occlusion}$ is proportional to the airway resistances:

$$\text{Rmin} = (\text{Ppeak} - PaO_{occlusion})/\text{Flow}$$

while the slower decay from $PaO_{occlusion}$ to P_{plat} is proportional to the additional resistances:

$$\Delta R = \text{Rmax,rs} - \text{Rmin}$$

In normal patients during general anaesthesia, for a flow of 0.4 L/second and in the normal V_T range, Rmax,rs is 5 to 6 cm H_2O/L/second and Rmin is 2 to 3 cm H_2O/L/second.

Rmin,rs is increased in pathologic conditions characterized by increased airway resistance, such as asthma, acute cardiogenic pulmonary edema, ARDS, and COPD. However, because Rmin,rs is the sum of airway resistances and includes the resistance in the ventilatory circuit and the endotracheal tube, a differential diagnosis of an increase in airway resistance should include endotracheal tube obstruction. Both lung and chest wall inertial properties and lung inhomogeneities (expressed by ΔR) may be increased in some pathologic conditions; this is seen in patients with severe COPD and in morbidly obese patients.

Measuring intrinsic PEEP (PEEPi) in passive patients during controlled mechanical ventilation (static intrinsic PEEP [PEEPi,st]) is easily accomplished through a 5- to 10-second end-expiratory hold maneuver—that is, during the closure of both inspiratory and expiratory valves at end-expiration, which allows the ventilator's pressure transducer to read the end-expiratory alveolar pressure (Fig. 103-5). This is the total respiratory system positive end-expiratory pressure (PEEPtot). In patients with dynamic hyperinflation, the value of PEEPtot is higher than the value of the applied PEEP (PEEPext) and PEEPi,st is the difference between PEEPtot and PEEPext.

When using partial ventilatory support techniques, PEEPi needs to be measured in a dynamic fashion (PEEPi,dyn). The gold standard method is based on continuous recording of flow, Pao, esophageal pressure (Pes), and eventually gastric pressure (Fig. 103-6).

Static respiratory system compliance (C,st,rs) is defined as the change in respiratory system volume per unit change in applied pressure (expressed in milliliters per centimeters of H_2O):

$$\text{C,st,rs} = V_T/(PaO_{plat} - \text{PEEPtot})$$

where Pao_{plat} is measured at the end of a 2- to 5-second end-inspiratory pause (see *point E* in Fig. 103-3). Elastance, the mathematical inverse of compliance, is expressed in centimeters of water per milliliter as:

$$\text{Est,rs} = (Pao_{plat} - \text{PEEPtot})/V_T$$

For a correct calculation of C,st,rs, PEEPtot must be used instead of PEEPext to discriminate between an increase in Pao_{plat} as a result of dynamic hyperinflation (where PEEPtot is higher than PEEPext and Cst,rs is not affected) and an increase in Pao_{plat} resulting from reduction of Cst,rs (where PEEPtot is equal to PEEPext).

Role of Chest Wall Mechanics

Lung and the chest wall are "in series": hence, Cst,rs is the sum of lung and chest wall compliances (respectively, Cst,L and Cst,cw) and, Est,rs is the elastance of respiratory system, lung, and chest wall (respectively, Est,L and Est,cw):

$$1/\text{Cst,rs} = 1/\text{Cst,L} + 1/\text{Cst,cw}$$

and hence

$$\text{Est,rs} = \text{Est,L} + \text{Est,cw}$$

Cst,cw and Est,cw are calculated as:

$$\text{Cst,cw} = V_T/(\text{Pes, end inspiratory} - \text{Pes, end expiratory}$$

and

$$\text{Est,cw} = (\text{Pes, end inspiratory} - \text{Pes, end expiratory})/V_T$$

From a theoretical point of view, pleural pressure variations should be used instead of esophageal pressure to measure the pressure surrounding the lungs. However, pleural pressure measurements are virtually impossible in clinical practice, whereas the esophageal pressure recording is commonly used as a substitute.

Pes is recorded with the patient in semirecumbent position through a balloon-equipped catheter inserted in the lower third of the esophagus and connected to a pressure transducer. Partitioning between lung and chest wall elastic properties may be useful in the differential diagnosis of the decrease in respiratory compliance. Because the chest wall and abdomen are coupled through the diaphragm, an increase in abdominal pressure is one of the most important factors leading to chest wall stiffness. However, patients without abdominal hypertension may have chest wall mechanical impairment related to chest wall deformities, fluid overload, or pleural effusions.

Role of Transpulmonary Pressure

Conventional ventilatory treatment is titrated on P_{AO} based on the assumption that P_{AO} closely approaches transpulmonary pressure (P_L)—that is, the difference between airway opening pressure (P_{AO}) and pleural pressure (P_{PL}). Although this assumption is reasonable for patients with normal chest wall elastance (E_{CW}), in the presence of a substantial increase of the E_{CW} a relevant portion of P_{AO} is dissipated in distending the chest wall, leading to a lower than expected P_L. This is relevant in patients with ARDS because E_{CW} can be increased as a result of intraabdominal hypertension, pleural effusions, fluid overload, and body wall edema.[58] In these patients, targeting ventilation to P_L rather than P_{AO} would be important.[59-61] According to the elastance-derived method originally proposed by Gattinoni and co-workers,[62] any positive pressure applied at the airway opening (P_{AO}) acts on two elastic structures posed in series (the lung and the chest wall) and results in an increase in static pleural and transpulmonary pressure that can be inferred from the ratio between chest wall and lung

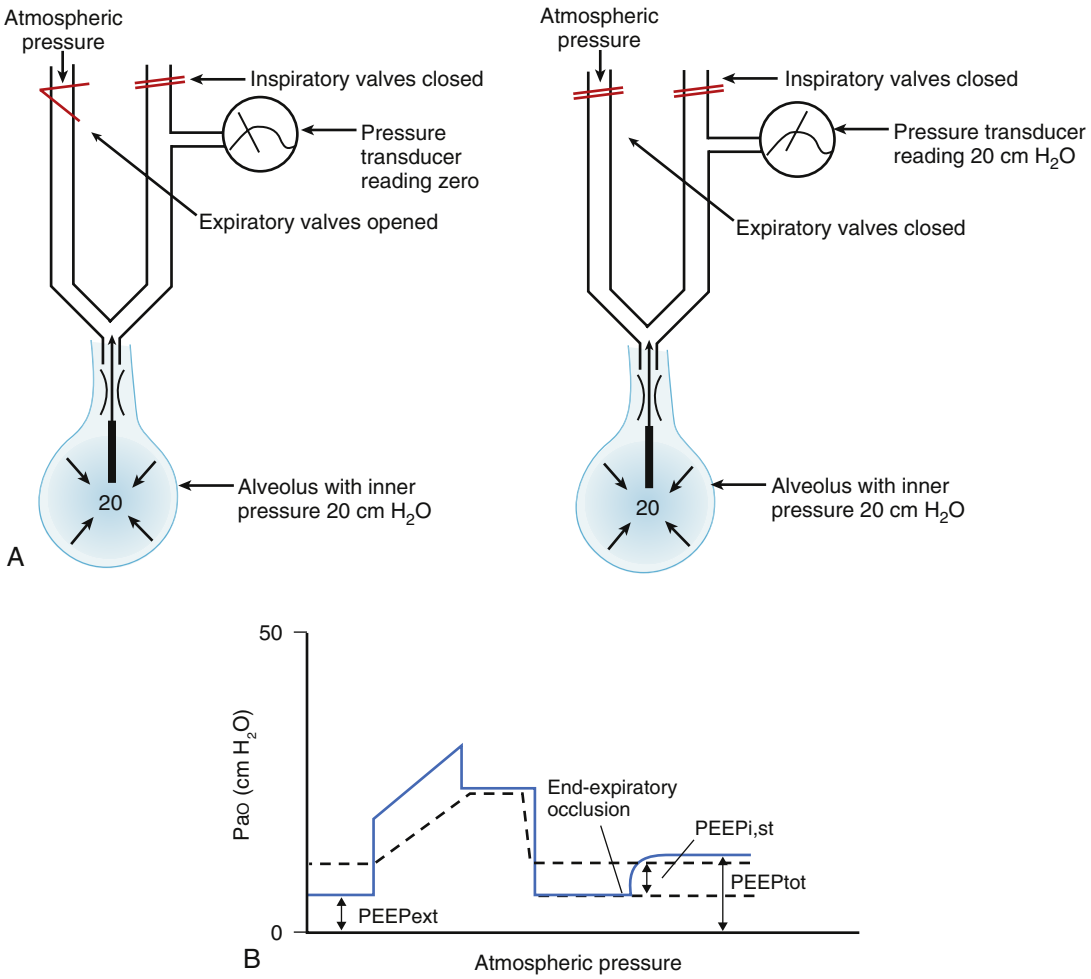

Figure 103-5. Static intrinsic PEEP (*PEEPi,st*) measurement. Schematic representation of the end-expiratory hold maneuver. **A,** Schematic representation of the respiratory system and of a ventilatory circuit. During the expiratory phase the ventilator opens the expiratory valve while the inspiratory valve is closed. Consequently the pressure transducer reads atmospheric pressure. When the end-expiratory hold maneuver is performed, both inspiratory and expiratory valves are closed at end-expiration. As a consequence, the pressure transducer reads the end-expiratory alveolar pressure. **B,** Recording of the Pao tracing obtained during a cycle of constant-flow mechanical ventilation, followed by an end-expiratory hold maneuver. At the end of the maneuver, the *PEEPtot* value is obtained. The *dotted line* refers to the theoretical value of alveolar pressure. *PEEP,* Positive end-expiratory pressure; *PEEPext,* applied PEEP; *PEEPi,st,* static intrinsic PEEP; *PEEPtot,* total respiratory system positive end-expiratory pressure.

elastance. Accordingly, $P_{PL} = P_{AO} \times (E_{CW}/E_{RS})$ and $P_L = P_{AO} \times (E_L/E_{RS})$. Hence, *elastance-derived* P_L is the Δ lung distending pressure applied during positive-pressure controlled mechanical ventilation, neglecting the absolute P_{PL} and P_{PL} value at functional residual capacity (FRC).[61,63] For mathematical reasons, the elastance-derived P_{PL} (and hence P_L) must be zero when P_{AO} is zero, but this does not mean that absolute P_{PL} and P_L are equal to zero in the same circumstances. For these reasons, *elastance-derived* P_{PL} and P_L must be clearly distinguished from *measured* or *absolute* P_{PL} (and P_L). Chiumello and colleagues[63] found that in patients with ARDS the contribution of chest wall elastance to the whole respiratory system elastance was 7% to 67%.

At variance with the elastance-derived method, the protocol proposed by Talmor and associates[64] optimizes the absolute PL at end-expiration independently from the presence of impairment of E_{CW}. They showed in a randomized clinical trial that this approach improves oxygenation and lung mechanics in patients with ARDS. In the Talmor study, PEEP was titrated to counterbalance the abdominal extra weight compressing dependent lung regions at end-expiration and esophageal manometry was used to quantify the extra weight after subtracting 5 cm H_2O for the weight of the mediastinal organs. The physiologic background is that in some patients with ARDS, oxygenation is impaired by the compression exerted by the abdominal organs. The pressure recorded inside an esophageal balloon positioned in the lower third of the esophagus is significantly affected by the extra weight exerted by the abdominal contents.[65] However, defining a single "real" absolute P_{PL} value is virtually impossible, and, as a matter of fact, chest wall elastance may be normal despite a high absolute P_{PL} measured in the lower third of the esophagus and vice versa.[66] Furthermore, counterbalancing with PEEP (a globally applied pressure) the "local" absolute P_{PL} acting on the dependent lung surface could induce overdistention in nondependent lung areas.

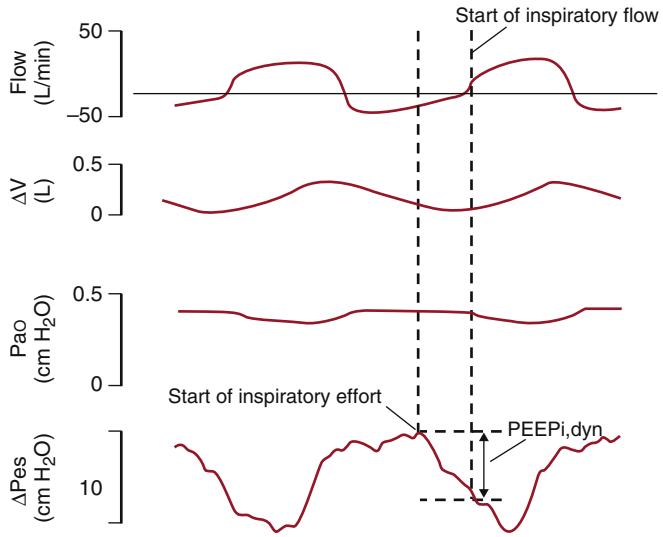

Figure 103-6. Flow, volume, Pao, and Pes tracings recorded in a spontaneously breathing patient receiving positive continuous airway pressure. PEEPi,dyn is the value of Pes deflection of from the beginning of the inspiratory effort to the point in which a positive inspiratory flow begins. *Pes,* Esophageal pressure; *PEEP,* positive end-expiratory pressure; *PEEPi,dyn,* dynamic intrinsic PEEP.

Substituting the $P_{AO,plat}$ target with an elastance-derived $P_{L,plat}$ target improved lung aeration both in a pig model[68] and in a cohort of patients with severe influenza A H1N1–induced ARDS.[69]

The straightforward physiologic concept that P_L is the real lung distending pressure must be taken in account when ventilating patients with ARDS and compromised chest wall mechanics.

MONITORING-ASSISTED MECHANICAL VENTILATION

The main parameters to be clinically observed during assisted mechanical ventilation include evaluation of patient-ventilator interactions and the occurrence of asynchrony between the patient and ventilator.

Inspiratory Trigger Asynchrony

A phase lag between the commencing of inspiratory muscle activity and the beginning of mechanical inflation is virtually always present, although the amount is minimized with the neural trigger of NAVA.[70] The presence of PEEPi may complicate patient-ventilator interactions during the triggering phase.[71] Ineffective triggering is due to the inability of the ventilator to detect patient initiation of an assisted breath despite the patient producing a substantial inspiratory effort. This phenomenon usually occurs in the presence of high levels of ventilator assistance and short expiratory times. Mechanical characteristics that are associated with ineffective triggering include low elastance, high resistance, and PEEPi.[7]

Ventilatory Requirement–Gas Delivery Asynchrony. Asynchrony between ventilatory requirement and gas delivery occurs when the ventilator-delivered flow, volume, and pressure are insufficient to meet patient ventilatory requirements. Pressure-targeted breaths may better satisfy patient ventilatory requirements because the rapid pressurization of the airways is coupled with high inspiratory flow rates just at the beginning of inspiration, thus reproducing the physiologic flow profile.

Inspiratory Time and Time Total Cycling Asynchrony. Inspiratory time (Ti) and time total (Ttot) cycling asynchrony occurs when the patient is trying to exhale, but the ventilator is still continuing to deliver gas. Parthasarathy and co-workers[72] demonstrated that prolonging the mechanical inflation during the neural expiration reduces the time available for unopposed exhalation.[72] When PSV is delivered noninvasively, air leaks may cause an abnormal prolongation of the inspiratory time preventing cycling off in inspiration and expiration. In this condition, the patient performs several efforts to exhale against the machine or inhale without receiving any ventilatory support (inspiratory hang-up).[73]

Work of Breathing. Estimating patient WOB during partial ventilatory support modes would allow setting the optimal level of support, which is the one able to normalize inspiratory muscle workload, avoiding excessive muscle unloading (overassistance). Unfortunately it requires a complex apparatus, continuous measurement of esophageal and gastric pressures, and physiologic expertise. As discussed later, the PAV+ algorithm allows continuous estimation of WOB and the NAVA technology allows continuous detection of diaphragmatic electrical activity. Although WOB may be referred to a single breath, from a clinical point of view it is useful to measure WOB per minute and WOB per liter of minute ventilation (WOB/L = WOB per minute/minute ventilation). In a normal patient, WOB per liter at rest is between 0.3 and 0.6 J/L, whereas during any invasive available partial ventilatory support technique the patient is submitted to additional iatrogenic work, wasted to overcome the endotracheal tube and ventilatory circuit resistance and to trigger the ventilator.[74]

PRINCIPLES OF RESPIRATORY PHYSIOLOGY APPLICABLE TO THE CLINICAL SCENARIO

ELASTIC PROPERTIES OF NONHOMOGENEOUS LUNG AND VENTILATOR-INDUCED LUNG INJURY

Mechanical ventilation is almost invariably used in patients with ARDS. In the majority of those patients, once mechanical ventilation is applied, the gas exchange parameters improve together with the overall clinical condition. Unfortunately, since the mid-1980s, a large number of studies have shown that mechanical ventilation can worsen preexisting lung injury (ventilator-induced lung injury [VILI]).[56,75] The main feature of ARDS predisposing to VILI is the heterogeneous

distribution of lung lesions. Pivotal computed tomography (CT) scan studies have clearly documented that in the ARDS lung normally aerated areas coexist with poorly aerated, consolidated, and hyperinflated areas[76] (Fig. 103-7). A systematic review of the pattern of distribution of these areas allowed classification of the distribution pattern of atelectasis into focal (≈36% of patients, in whom consolidated dependent areas coexisted with normally aerated nondependent areas), diffuse (≈23%, with a generalized opacification of the lung), and patchy (≈41%, in whom consolidated areas were unevenly distributed in the whole lungs).[76-78] This heterogeneity affects the mechanical characteristics of the respiratory system, as documented by the shape of the static or quasi-static inspiratory volume–pressure curve of the respiratory system.[79] When inflating the respiratory system in discrete volume steps or in a very slow fashion, the increase in airway opening pressure will reflect the variations in elastic properties of the respiratory system. A progressive increase in compliance at the beginning of lung inflation (lower inflection point [LIP]) suggests that alveoli collapsed at end-expiration are being progressively reopened during inflation (alveolar recruitment), whereas a progressive decrease of compliance toward the end of inflation (upper inflection point [UIP]) suggests that some alveoli are progressively stretched (hyperinflated) toward the end of inflation. In normal patients, LIP occurs below the elastic equilibrium point of the respiratory system and the UIP occurs at a volume close to total lung capacity. In patients with ARDS, LIP and UIP occur within tidal ventilation and indicate the pressure at which recruitment of collapsed alveoli and alveolar hyperinflation, respectively, start to occur (Fig. 103-8). The classic view remains valid, particularly in patients with early ARDS and very recruitable lungs. However, in the majority of the cases, lung recruitment occurs along the entire incremental limb of the inspiratory volume–pressure curve and is a rather progressive phenomenon. Furthermore, a significant hysteresis between the inspiratory and the expiratory volume–pressure curve has been observed by constructing the decremental (i.e., the expiratory) limb of the volume–pressure curve, meaning that (1) lung recruitment is a pan-inspiratory phenomenon, and complete lung recruitment may require very high opening pressures; and (2) that once recruited, atelectatic lung areas tend to collapse at lower pressure than those necessary to open them during inspiration.[80,81]

According to the concept of "baby lung," originally proposed by Gattinoni and Presenti,[82] mechanical ventilation delivering standard V_Ts (i.e., the V_Ts that normalize arterial $P_{CO}2$) will generate cyclical tidal alveolar hyperinflation in the reduced amount of normally aerated areas in patients with ARDS.[82] In addition, it may occur that some lung regions that stay collapsed at end-expiration if inadequately low levels of PEEP are applied will reopen at lung inflation, generating a cyclic tidal alveolar opening and collapse phenomenon (or tidal recruitment). Tidal alveolar recruiting and hyperinflation are the main mechanisms responsible for VILI generation. They activate proinflammatory intracellular

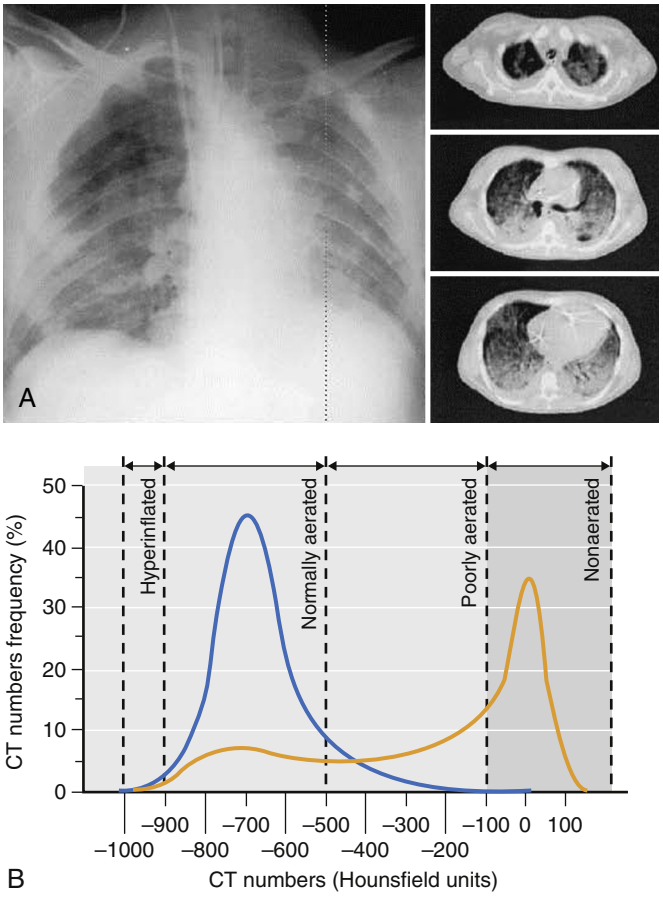

Figure 103-7. A, Anteroposterior chest radiograph and the computed tomography (CT) scans (apex, hilum, and base) in acute respiratory distress syndrome (ARDS). The radiograph shows diffuse ground glass opacification, sparing the right upper lung. The CT scans show inhomogeneous disease and both the craniocaudal and sternovertebral gradient. **B,** Lung compartments, as defined by CT numbers, in normal condition (*blue line*) and in typical acute lung injury and ARDS (*yellow line*).

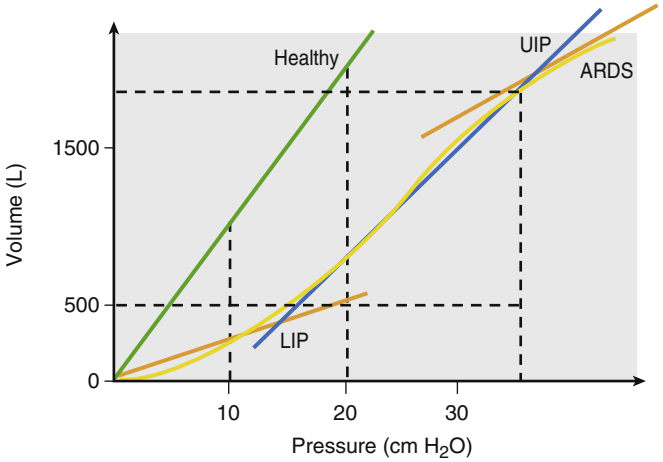

Figure 103-8. Static volume-pressure curves of the respiratory system recorded in a healthy patient and in a patient with acute respiratory distress syndrome (ARDS). LIP and UIP both occur within tidal ventilation and indicate the pressure at which recruitment of collapsed alveoli and alveolar hyperinflation start to occur, respectively. *LIP,* Lower inflection point; *UIP,* upper inflection point.

signal pathways into epithelial and endothelial cells of the alveoli and resident macrophages. As a consequence, the genes responsible for the transcription of proinflammatory and antiinflammatory mediators, respectively, are up-regulated and down-regulated, leading to alveolar inflammation.[83] This ventilator-induced biotrauma may arise after even a relatively short period of mechanical ventilation, leading to inflammation (Fig. 103-9).[75] In addition, mechanical stimuli posed on the alveolar wall are able to shed thrombomodulin (the surface molecule that proteolitically activates protein C) from the alveolar cell surface, depressing protein C activation at the alveolar level. Therefore, VILI may exacerbate the intraalveolar procoagulative and antifibrinolytic state.[84] Other expressions of biotrauma include impairment of alveolar edema clearance by inactivation of the type I and II alveolar cells NA^+/K^+-ATPase,[85] inhibition of surfactant secretion by epithelial type II cells,[86] and up-regulation of the production of matrix metalloproteinases.[87] The idea that VILI could sustain a ventilator-induced multiple organ dysfunction syndrome was originally proposed by Slutsky[75] and has been recently confirmed.[88]

Several lung-protective ventilatory strategies have been proposed to minimize VILI. Initially, the measurement of the inspiratory volume-pressure curve of the respiratory system was used. Applying a PEEP level slightly above the LIP avoids end-expiratory collapse. Also, V_T is used to obtain an end-inspiratory plateau pressure just below the UIP. Both of these moves reduced VILI-related lung and systemic inflammatory reaction[89] and VILI-related mortality.[90,91] However, selecting the PEEP level on the incremental limb of the volume-pressure curve may be misleading, because alveolar recruitment also increases above LIP.[92] Therefore, some authors suggest the "open lung approach."[81] Here PEEP is selected through a decremental trial after that maximal lung recruitment has been obtained by means of a vital capacity maneuver.

EXPIRATORY FLOW LIMITATION AND INTRINSIC POSITIVE END-EXPIRATORY PRESSURE

In normal patients at rest, the end-expiratory lung volume (EELV) closely corresponds to the elastic equilibrium point of the respiratory system (FRC). When the time available for expiration is shorter than the time required for passive exhalation to FRC, air trapping develops. Consequently, alveolar pressure will remain positive at the

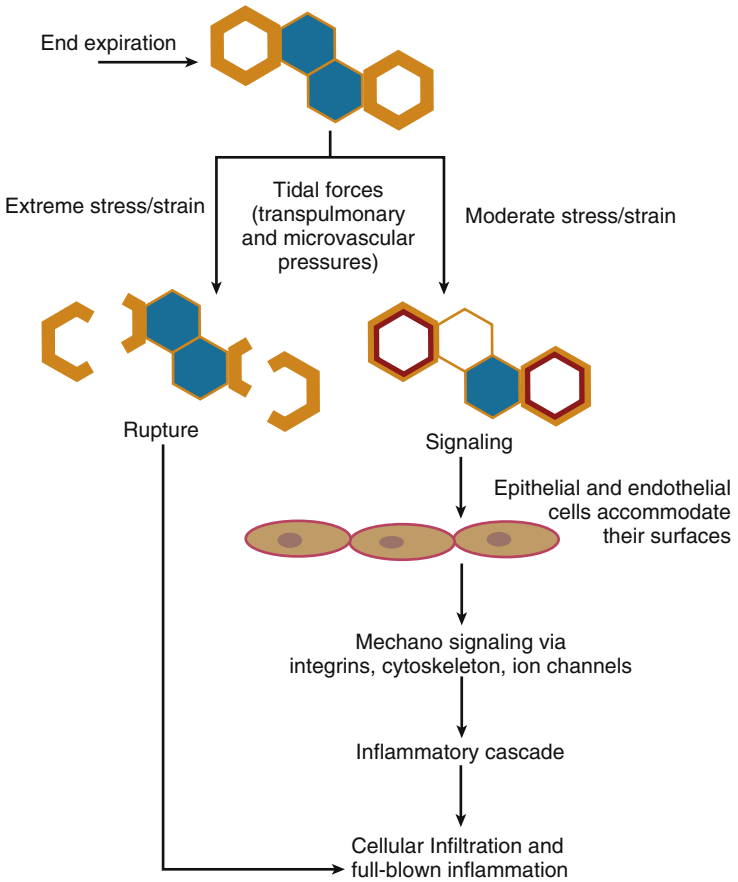

Figure 103-9. Concept of biotrauma related to ventilator-induced lung injury. The transduction of a mechanical stimulus posed on the alveolar walls (tidal alveolar opening/collapse and/or tidal alveolar stretch) leads to a biologic signaling, which translates into pulmonary inflammation. *(From Marini JJ, Gattinoni L: Ventilatory management of acute respiratory distress syndrome: a consensus of two,* Critical Care Med 33:250, 2004.)

end of expiration, generating dynamic hyperinflation—that is, a positive end-expiratory alveolar pressure, PEEPi, or auto-PEEP.[93,94] The trapped air volume may be assessed by measuring the amount of expired volume during a prolonged, passive exhalation from EELV to FRC (30 to 60 seconds) (Fig. 103-10).

Intrinsic Positive End-Expiratory Pressure Resulting From Flow Limitation

PEEPi is due to the expiratory collapse of distal airways, which severely limits expiratory flow.[95] This condition is peculiar to patients with COPD, whereas in normal patients it occurs only during forced maximal expiratory maneuvers. The pathophysiology of expiratory flow limitation was originally explained by the waterfall model (Fig. 103-11).[96] Accordingly, increasing the pressure downstream by applying an external PEEP will have no influence on either the expiratory flow or the pressure upstream of the site of critical airway closure—that is, until the value of external PEEP does not exceed the value of PEEPi.

Acting as an inspiratory threshold load, PEEPi places a burden on the inspiratory muscles, which are forced to develop sufficient force to overcome the opposite recoil pressure before inspiratory flow can begin. The WOB necessary to overcome PEEPi and initiate an inspiratory flow may be as much as 40% of total WOB in patients with COPD exacerbations,[22] and the work may be significantly reduced by applying an appropriate level of external PEEP.[97] According to the waterfall analogy, the application of an external PEEP in the range of the measured levels of PEEPi will decrease inspiratory WOB without inducing further alveolar hyperinflation.[98] However, the waterfall analogy assumes a single value of critical closing pressure for all the distal airways (Pcrit), whereas a significant heterogeneity among regional lung units has been documented.[99] Perhaps the simple waterfall analogy may not be accurate. In terms of mechanically ventilated patients with COPD, the value of external PEEP that can be safely applied without the risk for worsening dynamic hyperinflation should be somewhat less than the measured PEEPi. Applying a PEEP level equal to 75% of PEEPi is less than Pcrit in the most COPD patients.[100]

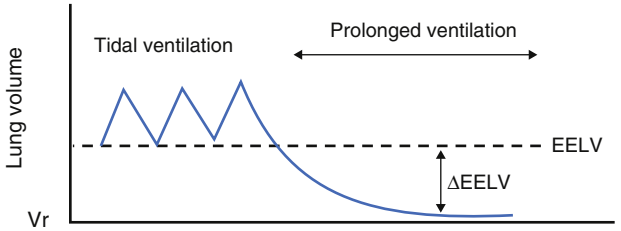

Figure 103-10. Difference (ΔEELV) between the end-expiratory lung volume (EELV) during mechanical ventilation and elastic equilibrium volume of the respiratory system (*Vr*) in a patient with dynamic hyperinflation. A complete lung emptying is obtained by disconnecting the patient from the ventilator at the end of mechanical expiratory time and allowing a prolonged (15 to 20 seconds) passive exhalation to atmospheric pressure.

Intrinsic Positive End-Expiratory Pressure Without Flow Limitation

PEEPi without flow limitation occurs when the expiratory time is shorter than the time required for passive lung emptying to FRC. The time needed to empty the lung depends on the interplay of several variables: V_T, end-inspiratory elastic recoil pressure of the respiratory system, and expiratory resistances. Moreover, in the mechanically ventilated patient, the iatrogenic resistance of endotracheal tubes, of the exhalation valve, and of the PEEP devices must be considered. Consequently, under conditions of large minute ventilation, high respiratory system compliance, and expiratory resistance, the lungs do not have time during passive deflation to reach their equilibrium point at FRC. Differently from flow limitation, applying an external PEEP in this condition will worsen dynamic hyperinflation, creating a back pressure to expiratory airflow.[101]

In the ventilated patient, dynamic hyperinflation may cause hemodynamic compromise because it critically impairs venous return and increases right ventricular afterload, leading to a low cardiac output state. This phenomenon, originally described by Pepe and Marini,[102] is more likely to occur when using controlled mechanical ventilation in patients with COPD or asthma. A rather different scenario occurs in spontaneously breathing patients with significant dynamic hyperinflation.[103] PEEPi acts as an inspiratory threshold

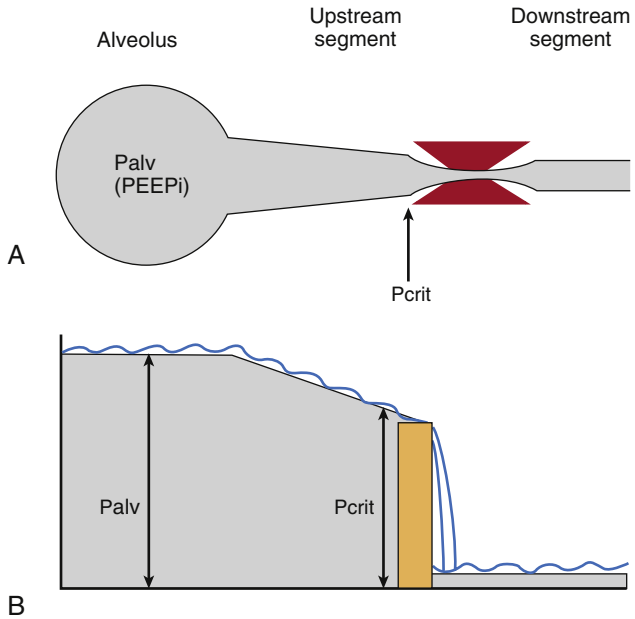

Figure 103-11. The waterfall model. As a result of the dynamic expiratory collapse of distal airways in chronic obstructive pulmonary disease, expiratory flow is severely limited; at end-expiration, alveolar pressure (*Palv*) remains positive, generating intrinsic positive end-expiratory pressure (*PEEPi*). Because of the dynamic collapse, increasing the pressure in the downstream airway segment will not have influence on the pressure upstream of the site of critical airway closure, until the applied exceeds the pressure level in the upstream airway segment (*Pcrit*).

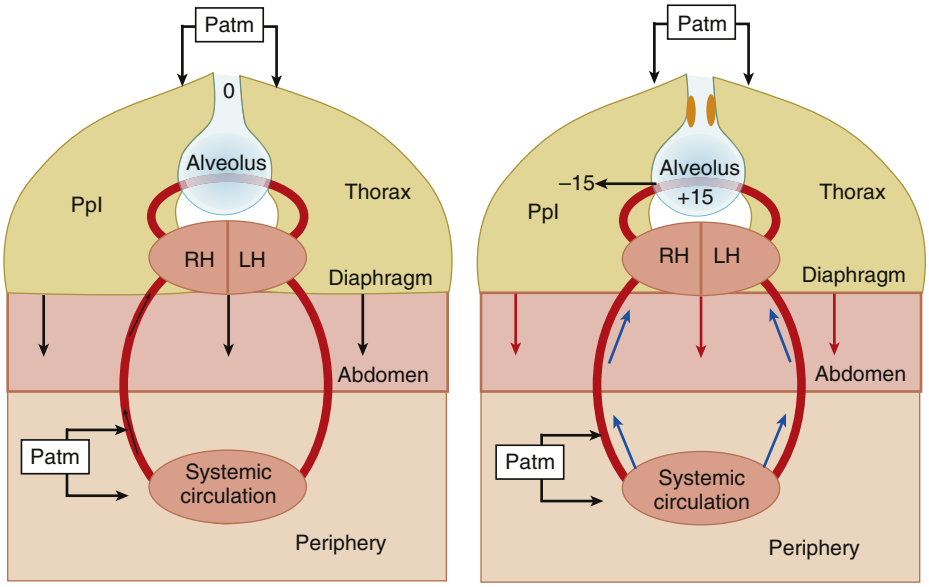

Figure 103-12. Hemodynamic consequences of dynamic hyperinflation and intrinsic positive end-expiratory pressure (PEEPi). The physiologic increase in venous return during spontaneous inspiration, as a result of the generation of a slightly negative pleural pressure (*Ppl*) in contrast to atmospheric pressure (*Patm*), is pathologically magnified in patients with dynamic hyperinflation. To initiate inspiratory flow (i.e., to generate a negative alveolar pressure) the hyperinflated patient needs to counterbalance PEEPi generating an opposite negative pleural pressure. This has a marked fostering effect on venous return. *LH,* Left heart; *RH,* right heart.

load in the sense that the patient must create an opposite negative intrathoracic pressure to generate an inspiratory flow. This decrease in pleural pressure that occurs without a change in lung volume is theoretically similar to a Müller maneuver (Fig. 103-12). The pulmonary vascular bed is relatively nonrecruitable in severe COPD; thus, pulmonary artery pressures will increase and right ventricular engorgement can ensue. Furthermore, acute right ventricular engorgement induces a leftward interventricular septum shift, leading to impairment of left ventricular diastolic relaxation and pulmonary congestion.[104-106] Besides decreasing WOB, applying a PEEP/CPAP level lower than Pcrit will limit the hemodynamic consequences of PEEPi in spontaneously breathing patients.[103]

Although PEEPi and dynamic hyperinflation are frequently thought to be synonymous, PEEPi does not necessarily imply dynamic hyperinflation or air trapping. When expiratory muscles are recruited during expiration, alveolar pressure will be positive at end-expiration without dynamic hyperinflation.[107]

MECHANICAL VENTILATION IN THE CLINICAL SCENARIO

ACUTE RESPIRATORY DISTRESS SYNDROME

ARDS is an inflammatory response of the lung to both direct and indirect insults with acute onset, presence of bilateral infiltrates on chest radiography consistent with pulmonary edema, pulmonary artery wedge pressure less than 18 mm Hg or clinical absence of left atrial hypertension, and arterial hypoxemia (see also Chapters 101 and 102). The definition of ARDS has been updated according to the recommendations of an expert task force (the Berlin definition).[108,109] The panel identified the common direct or indirect risk factors for ARDS (see later discussion) and defined ARDS as a clinical syndrome encompassing the following criteria: (1) timing, arising from a known clinical insult; (2) chest imaging (chest radiography or CT) characterized by bilateral opacities not fully explained by eventual coexisting effusions, lobar or lung collapse or nodules; (3) origin of edema not fully explained by cardiac failure or excessive intravascular fluid volume (that, of note, may coexist with ARDS); (4) oxygenation impairment—ratio of partial pressure of arterial oxygen/fraction of inspired O_2 (P/F ratio) lower than 300, evaluated at PEEP, or CPAP level of 5 cm H_2O or higher. ARDS severity is divided into three stages: mild (P/F ratio between 200 and 300), moderate (P/F ratio between 200 and 100), and severe (P/F ratio lower than 100). Importantly, these stages are correlated with mortality[27] (confidence interval [CI] 24% to 30%) in patients with mild ARDS, 32% (CI 29% to 34%) in patients with moderate ARDS, and 45% (CI 42% to 48%) in patients with severe ARDS ($P < 0,10$).[108,109]

Although in the past ARDS was considered rare,[110] a recent population-based study showed an age-adjusted incidence of 86.2 per 100,000 persons per year.[111] Mortality resulting from ARDS has been reported to decline from 60% to 70% in the late 1980s to 30% to 40% over the last 2 decades with improved management.[112-114] Risk factors linked to increased mortality in ARDS include advanced age, low PaO_2/FiO_2 ratio, septic shock, high APACHE II score, high Sequential Organ Failure Assessment (SOFA) score, low Glasgow Coma Scale score, and chronic liver disease.[115] The most common long-term impairments are muscle wasting and weakness, significant neurocognitive and emotional morbidity, and decreased quality of life even after 2 years from hospital discharge, whereas pulmonary function generally returns to normal by 6 months, with the exception of a persistent reduction in carbon monoxide diffusion capacity[116,117] (see also Chapter 101).

The inciting factors for lung injury can be divided in those associated with direct insult to the lungs, such as pneumonia or aspiration, or an indirect cause in the setting of a systemic process, such as sepsis or severe trauma (Fig. 103-13). This "first hit" to the lungs incites

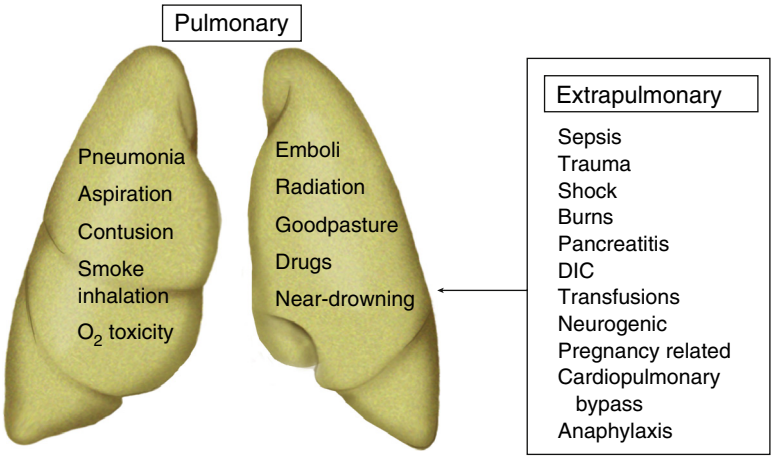

Figure 103-13. Pulmonary (primitive) and extrapulmonary (secondary) triggers of acute respiratory distress syndrome. *DIC,* Disseminated intravascular coagulation.

a pulmonary inflammatory response, which may lead to worsening of the pathologic manifestations of ARDS if coupled with injurious mechanical ventilation.[75,83] Clinical studies suggest increased mortality in patients who continue to manifest elevated bronchoalveolar lavage (BAL) concentrations of interleukin-6 (IL-6), IL-8, IL-1, and tumor necrosis factor cytokine levels during their clinical course, precluding resolution of the pulmonary and systemic inflammatory processes.[112,118,119] An important source of these inflammatory mediators are the neutrophils, which play a pivotal role in the pathogenesis and progression of ARDS,[120] although it may develop in patients with profound neutropenia, suggesting that several parallel and interacting mechanisms are involved.[121]

As previously discussed, ARDS is characterized by abnormal mechanical properties of the respiratory system with hallmark features of a reduction in FRC and a reduction in static compliance of the respiratory system.[122]

In the past, mechanical ventilation with large V_Ts of 10 to 15 mL/kg of body weight was recommended to guarantee a normal pH and $Paco_2$.[123] The use of large V_Ts leads to shear stress injury resulting from overdistention and local and systemic inflammatory response. The multicenter randomized controlled trial performed by the ARDS Network and funded by the National Heart, Lung and Blood Institute of the National Institutes of Health included 10 academic centers with 75 ICUs and enrolled patients with ARDS to compare a control ventilatory strategy using a V_T of 12 mL/kg (based on predicted body weight [PBW]) versus a lung-protective strategy using a V_T of 6 mL/kg PBW.[112] The study intended to enroll up to 1000 patients, but accrual was stopped at 861 patients when an interim analysis revealed that the mortality rate in the lung-protective group was 22% less frequent than in the control group. These beneficial results apply to a wide spectrum of patients, including patients with and without sepsis and those with different degrees of lung dysfunction as assessed by respiratory system compliance. The ARDS Network study protective ventilatory strategy set PEEP and FiO_2 according to traditional criteria, using a standardized PEEP-FiO_2 combination table prescribing simultaneous increases in PEEP and FiO_2 to achieve a certain oxygenation target. Moreover, the ARDS Network study protective ventilatory strategy aggressively maintained $Paco_2$ relatively close to the normal range, employing more frequent respiratory rates and more liberal use of bicarbonate. The study is important from a clinical perspective because for the first time it was demonstrated that a specific intervention (the reduction of V_T) was able to improve outcome in these patients. Recent investigations testing the effects on mortality of higher PEEP titration criteria did not show any improvement in terms of survival rate.[67,124,125] At present the optimal level of PEEP and best method used to set PEEP have not been definitively established.[125]

Acquired Respiratory Distress Syndrome and Refractory Hypoxemia

According to recent reports, severe hypoxemia affects 7% to 26% of patients with ARDS[67,125] whereas the majority of patients are safely oxygenated by the gold standard ARDS Network lung protective strategy. The rescue treatment flow chart for patients who are difficult to ventilate because of developing severe hypoxemia when submitted to the ARDS Network ventilatory protocol includes both ventilatory and nonventilatory strategies[50,126] and will be briefly reviewed.

The first step is defining severe and refractory hypoxemia. Unfortunately, guidelines on this crucial topic are lacking (see also Chapter 102). In the expiratory pressure study EXPRESS, Mercat and associates[67] indirectly defined patients with severe hypoxemia as those receiving rescue ventilatory and nonventilatory strategies, whereas in the Lung Open Ventilation Study (LOVS) Meade and associates[125] defined refractory hypoxemia as a PaO_2 lower than 60 mm Hg for at least 1 hour while receiving an FiO_2 of 1.0. According to the available data on extracorporeal membrane oxygenation (ECMO) as a rescue treatment for ARDS coming from case series,[127-134] one randomized clinical trial,[135] and the Extracorporeal Life Support Organization guidelines, the critical PaO_2/FiO_2 ratio threshold is between 50 and 80, despite the use of high PEEP levels, mean airway pressure ($P_{AO,mean}$) and $P_{AO,plat}$. In a recent review, Esan and associates[50] proposed an alternative definition of severe hypoxemia: (1) PaO_2/FiO_2 ratio of less than 100 or $P_{AO,plat}$ greater than 30 cm H_2O despite the

use of V_T as low as 4 mL/kg PBW or (2) an oxygenation index (OI) higher than 30. The OI is defined as:

$$OI = (P_{AO,\,mean} \times FiO_2 \times 100)/PaO_2$$

Rescue Ventilatory Approaches to Refractory Hypoxemia

According to clinical experience the first rescue strategy is based on nonconventional ventilatory approaches. The first step is defining the potential for further alveolar recruitment. This is a crucial issue because it may change the clinical history of a patient; if considered to have a low potential for recruitment, a patient is a candidate for invasive rescue nonventilatory strategies, mainly ECMO (see later discussion). If, on the contrary, lung recruitment is possible, the potential for rescue using an open lung ventilatory approach is high.

The potential for lung recruitment (i.e., the percentage of nonaerated lung tissue at minimal lung distending pressure that can be reopened by a lung recruitment maneuver) varies, depending on the method used to recruit the lung. De Matos and co-authors[136] studied an aggressive open lung approach using high inspiratory opening pressures to fully recruit the lung (up to 55 to 60 mm Hg) followed by a decremental PEEP trial. They found a median potential for recruitment of 45% (interquartile range 25% to 53%). In an older study, Gattinoni and colleagues,[137] applying a lung distending pressure of only 45 cm H_2O, reported a significantly lower potential for recruitment (13% ± 11%). Because very high recruiting pressures may expose patients to risks (barotrauma, hemodynamic compromise), the debate between aggressive and conservative recruiters is ongoing.

One important issue is considering the role of impaired chest wall mechanics in lung recruitment. If chest wall elastance is higher than normal, as occurs in some patients with ARDS, the distending pressure applied at the airway opening largely affects the chest wall and the resulting P_L (i.e., the real lung distending pressure) will be lower than expected. Titrating the open lung strategy according to the elastance-derived P_L in conditions of impaired chest wall elastance allows reproduction of the same elastance-derived end-inspiratory P_L that would have been obtained with normal chest wall elastance.[68] Recently, a rescue open lung strategy targeting a P_L of 26 cm H_2O was able to reverse hypoxemia refractory to the conventional open lung approach in 7 of 14 patients with influenza A H1N1–induced ARDS; these patients were candidates for ECMO for refractory hypoxemia.[69]

Rescue Nonventilatory Approaches to Refractory Hypoxemia

Prone positioning is an established rescue therapy for refractory hypoxemia.[137,138] Recent meta-analysis suggest that it can inprove mortality in patients with severe ARDS also without refractory hypoxemia.[138a]

Inhaled nitric oxide (iNO) is a selective pulmonary vasodilator without systemic effects. iNO may improve gas exchange and reduce pulmonary hypertension, optimizing the $\dot{V}/\dot{Q}$ matching (see also Chapter 104). Nevertheless, despite the improvement in oxygenation, no effect on clinical outcomes was demonstrated.[139] Thus, iNO cannot be recommended for the routine treatment of ALI and ARDS, but it may be useful as a rescue therapy in patients with refractory hypoxemia.

The use of neuromuscular blockade in patients with severe ARDS can improve critically compromised oxygenation[126] (see also Chapter 34). In a large cohort of patients with early severe ARDS, the use of a neuromuscular blocking drug (cisatracurium) significantly enhanced survival.[140] Whether neuromuscular blockade should be used in patients with severe but early ARDS for the first 48 hours of treatment in all patients with moderate and severe ARDS is questionable.

Extracorporeal Support for Refractory Hypoxemia

The technologic implementation of extracorporeal circuits, artificial lungs, and catheters provides a continuous therapeutic spectrum that extends from ECMO to minimally invasive extracorporeal CO_2 removal (ECCO2R) techniques.[141,142]

Venovenous ECMO was originally proposed to restore normal gas exchange working in series with the native lung in patients with ARDS.[141] Venous blood is drawn through a large-diameter cannula (24 to 32 Fr) usually positioned in the inferior vena cava and forced by a pump to circulate through an artificial lung, then returns to the venous circulation through a smaller reinfusion venous cannula. During ECMO, blood oxygenation is determined by the interplay among several variables, including the quantity of blood flow through the ECMO circuit, cardiac output, residual lung function of the native lung, and FiO_2 of the sweep gas flow into the ECMO oxygenator.[141] The technique was almost abandoned in the early 1980s, after that a randomized clinical trial did not show a decrease in mortality.[143] It then has been recently "resuscitated" for two important reasons: the technologic improvement (improved biocompatibility) of the ECMO circuits, blood pumps, and oxygenators and the use of protective ventilatory techniques to ventilate the native lung during ECMO.

At variance with the past, ECMO is now used to maintain the lung at rest while providing acceptable gas exchange. The target is no longer to normalize gas exchange but to provide ultraprotective ventilation of the native lung and use ECMO to deliver sufficient O_2 to maintain tissue homeostasis. A randomized clinical trial (the Conventional Ventilation or ECMO for Severe Adult Respiratory Failure [CESAR] trial) documented an improved survival of patients centralized to tertiary care facilities offering a complete rescue treatment strategy, including ECMO, compared with patients managed with conventional ventilation in individual hospitals.[135] More recently, attention has been focused on management of the most severe cases of ARDS, perhaps because of the increasing number of patients with ARDS secondary to influenza A (H1N1) and its refractory hypoxemia.[144-146] ECMO has gained a definite role as a rescue therapy for patients failing to respond to less invasive rescue strategies.[128,147]

Extracorporeal Carbon Dioxide Removal for Acute Respiratory Distress Syndrome

The rationale for protecting the diseased lung by "disconnecting" oxygenation (achieved though appropriate levels of CPAP and FiO_2) from CO_2 clearance (using ECCO2R and reduced minute ventilation) was proposed 40 years ago—by Kolobow and Gattinoni.[148] They tested the effects of apneic oxygenation (PEEP 15 to 25 cm H_2O with 3 to 5 superimposed positive-pressure sighs at peak inspiratory pressures of 35 to 45 cm H_2O) plus ECCO2R (pump-driven venovenous device with a blood flow between 20% and 30% of cardiac output) in patients with ARDS.[149] The first ECCO2R devices were relatively invasive; they required blood flows up to 2 L/minute and therefore also required wide-bore drainage and reinfusion catheters. Furthermore, the priming volume was 1.5 to 2 L. Also, the first gas-permeable silicone-rubber membrane lungs created an interface between blood and air, activating the inflammatory and procoagulative blood pathways.[142]

In the last 10 years, arteriovenous pumpless devices that use the arteriovenous pressure gradients to force blood through a very low-resistance heparinized circuit have been used.[150] Their main advantages are lower anticoagulation requirements, smaller priming volumes, less mechanical damage to blood components, and absence of recirculation. On the other hand, the blood flow through these devices depends on patient hemodynamic status. They also increase the left-to-right shunt and, because they require arterial cannulation with relatively large-bore catheters (16 to 19 Fr), may lead to lower limb ischemia.

The latest innovation in the ECCO2R field is minimally invasive low-flow (300 to 450 mL/minute) venovenous pump-driven technique. These devices take advantage of highly efficient and biocompatible polypropylene or poly-4-methyl-1-pentene hollow fiber oxygenators[142] with smaller catheters (8 to 12 Fr) or coaxial double-lumen catheters similar to those used for continuous renal replacement therapies; they also use a smaller priming volume and require a smaller heparin dose.[151]

The venovenous low-flow devices allow the use of ultraprotective V_T, very low respiratory rates, or both. In a pilot observational clinical study, the Ranieri group showed that reducing V_T to 3 to 4 mL/kg further mitigates VILI compared with the ARDS Net protocol.[152] While waiting for confirmatory clinical trials, minimally invasive ECCO2R in ARDS is important because hypercapnia is a major reason for the failure of lung-protective protocols.[142]

CHRONIC OBSTRUCTIVE PULMONARY DISEASE

COPD is a syndrome of chronic lung inflammation characterized by chronic, not fully reversible, airflow limitation (see also Chapters 101 and 102).[153] COPD is the fourth leading cause of death in the world. Its prevalence is approximately 9 in 1000 in men and 7 in 1000 in women, though prevalence of the disease in developed countries may be similar in the two genders.[154,155] Severe $\dot{V}/\dot{Q}$ mismatch, which is found in advanced cases of COPD, leads to chronic CO_2 retention, hypoxemia, and compensatory polycythemia. These conditions, together with an extensive destruction and remodeling of pulmonary vasculature, lead to pulmonary hypertension and chronic cor pulmonale.[156] Emphysema critically impairs lung elastic recoil and alters the alveolar attachments of small airways, compromising their stability. Reduced alveolar driving pressure, susceptibility to dynamic expiratory collapse, or both generates the phenomenon of expiratory flow limitation.[94]

Acute exacerbations of COPD are defined as worsening of dyspnea and increase in sputum purulence and volume.[157] Most COPD exacerbations are caused by tracheobronchial infections, exposure to air pollution and concomitant diseases, and unknown causes.[158] The exacerbation-induced increase in airways obstruction and worsening of dynamic hyperinflation acutely limits the ability of respiratory muscle to maintain minute ventilation. As a consequence, acute-onset chronic hypercapnia, hypoxemia, and hemodynamic impairment develop. Severe, life-threatening COPD exacerbations are characterized by a pH less than 7.30 and a PaO_2 less than 60 mm Hg (while breathing room air) and requires intensive O_2 supplementation and pharmacologic and ventilatory treatments. The target of O_2 supplementation is to maintain PaO_2 slightly more than the threshold of 60 mm Hg, because a moderate hypoxic stimulus is useful to stimulate the ventilatory drive in the presence of chronic hypercapnia.

Noninvasive PSV unloads inspiratory muscles and increases V_T. When applied early in the beginning of COPD exacerbations, the tracheal intubation rate, frequency of complications, and in-hospital mortality and length of stay can be reduced.[159,160] Experience with other noninvasive positive-pressure ventilation (NIPPV) modalities (e.g., PAV or NAVA), though encouraging, are limited to physiologic studies.[161,162] Although CPAP improves acute COPD exacerbation, no specific clinical indication for it exists.[163] If controlled mechanical ventilation needs to be used, targeting minute ventilation to the predecompensation CO_2 level is important to minimize alveolar hyperinflation and avoid rebound respiratory acidosis at the reinstitution of spontaneous breathing. In this context, measuring PEEPi and trying to minimize it by selecting the appropriate ventilatory pattern (small V_T, slow respiratory rate, and longer expiratory time) is of prime importance.[164]

The use of ECCO2R techniques can replace the need for endotracheal intubation in patients with COPD exacerbation failing noninvasive ventilation[165]; hopefully, this approach will prove to be clinically important.

ACUTE CARDIOGENIC PULMONARY EDEMA

Acute cardiogenic pulmonary edema (ACPE) results from any pathologic condition leading to the inability of the left ventricle to handle the pulmonary venous return. The resulting increase in hydrostatic pressure at the capillary level causes a leakage of fluid (with the characteristics of transudate) in the interstitium and subsequently in the alveolar space. Both interstitial and alveolar edema lead to surfactant inactivation and thickening of the walls

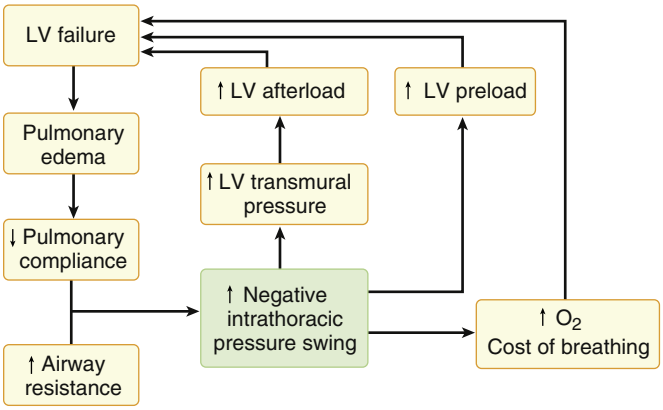

Figure 103-14. The vicious cycle of cardiopulmonary interactions during left ventricular (*LV*) failure leading to acute cardiogenic pulmonary edema (see text for further details).

of small airways, resulting in increased lung elastance, increased airway resistance (cardiac asthma), and hypoxemia. A positive feedback develops, because hypoxemia and increased WOB increase a stress response, which in turn increases left ventricle workload and possibly induces left ventricular ischemia, further limiting the ability of the left ventricle to manage venous return.[166] Moreover, the stiffer edematous lung requires the patient to develop wider negative pleural pressure swings, increasing venous return and promoting further capillary fluid leakage. Finally, the more negative the pleural pressure is during inspiration, the more transmural left ventricular pressure increases, leading to an increased left ventricular afterload[32] (Fig. 103-14).

Noninvasive techniques—both CPAP and NIPPV—reduce the need for tracheal intubation and improve outcome in patients with ACPE.[167-170] However, a small clinical trial raised serious warnings on the risk for myocardial ischemic events when patients with ACPE are treated with bilevel positive airway pressure (BiPAP, a form of PSV) compared to CPAP.[171] Recently, two meta-analyses showed that both CPAP and NPPV significantly reduce the need for endotracheal intubation, CPAP improves mortality whereas NIPPV is associated with a strong but nonsignificant trend toward better survival.[172,173] The same meta-analysis did not show significant differences in myocardial ischemic events between CPAP and NIPPV. Overall, perhaps CPAP should be first-line treatment in patients with ACPE because it is less expensive, easier to implement, and as efficacious as NIPPV.[173]

Several questions regarding noninvasive ventilation in patients with ACPE remain unresolved. (1) Does the mechanism leading to ACPE (systolic versus diastolic heart failure)[174] influence the response to noninvasive ventilation? (2) To what extent is the use of CPAP or NIPPV advisable in patients with acute myocardial infarction? (3) Do differential indications exist for CPAP or NIPPV in subgroups of patients? For example, does a preferential indication for NIPPV exist in hypercapnic patients with ACPE?[170] Furthermore, the optimal setting for CPAP and NPPV in patients with ACPE needs better definition.

Chapter 104

Nitric Oxide and Other Inhaled Pulmonary Vasodilators

FUMITO ICHINOSE • WARREN M. ZAPOL

Key Points

- Endogenous nitric oxide (NO) is produced from oxygen and L-arginine by a group of enzymes called *nitric oxide synthases* with L-citrulline as a by-product.
- Most of the effects of NO in the cardiovascular system are mediated by the activation of the enzyme soluble guanylate cyclase, which catalyzes the formation of the second messenger cyclic guanosine monophosphate (cGMP) from guanosine-5′-triphosphate. NO may directly modulate other signaling systems. For example, inhaled NO may be directly involved in posttranslational protein modification, including nitrosylation of proteins.
- NO can be safely inhaled when delivered by facemask, nasal cannula, or endotracheal tube.
- The intrapulmonary distribution of blood flow and ventilation (ventilation-perfusion distribution) is a major determinant of the efficiency of transpulmonary oxygenation and determines the partial pressure of oxygen in arterial blood. In contrast to intravenously administered vasodilators, inhaled NO selectively improves the perfusion of ventilated regions, thereby reducing intrapulmonary shunting and improving arterial oxygenation.
- Inhaled NO therapy is approved by U.S. Food and Drug Administration for the treatment of hypoxic respiratory failure associated with clinical or echocardiographic evidence of pulmonary hypertension in newborns (also see Chapter 95).
- Inhaled NO therapy may decrease the incidence of bronchopulmonary dysplasia and increase survival in prematurely born infants with a birth weight of at least 1000 g[50] (also see Chapter 95). Inhaled NO is widely used in cardiac catheterization laboratories as a safe and effective agent to determine the pulmonary circulation's capacity for vasodilation in pediatric and adult patients with pulmonary hypertension[68] (also see Chapter 67).
- Several clinical trials of inhaled NO in patients with acute respiratory distress syndrome (ARDS) demonstrated no effect on mortality or the duration of mechanical ventilation; however, a long-term follow-up at 6 months after treatment revealed that patients with ARDS who survived after treatment with low-dose inhaled NO had significantly better values for selected pulmonary function tests[83] (also see Chapter 101).
- The vasodilatory response to inhaled NO is variable in patients with valvular heart disease. The variability of dilator response is likely to be related to the balance of pulmonary vascular remodeling and active vasoconstriction.[89]
- Although inhaled NO does not appear to affect systemic vascular resistance, inhaled NO exerts a variety of systemic effects. Inhaled NO inhibits platelet function,[54] attenuates ischemia-reperfusion injury of extrapulmonary organs,[125] and reverses the adverse effects of free hemoglobin in the circulation.
- Inhaled epoprostenol has been used as a selective pulmonary vasodilator in adult and pediatric patients.[164] The efficacy and safety profile of inhaled epoprostenol have not been established. No general consensus exists as to when and how to use these inhaled vasodilators.

INTRODUCTION

Pulmonary hypertension often complicates patient care in the surgical units and intensive care units (ICUs). Severe acute pulmonary hypertension may produce right ventricular (RV) failure. Pulmonary hypertension and RV failure may reduce left ventricular (LV) filling, decrease cardiac output, and lead to systemic hypotension. Decreased arterial blood pressure may compromise RV coronary perfusion at a time when RV end-diastolic pressures and RV myocardial oxygen consumption are increased as a result of increased RV wall tension, thereby leading to RV ischemia.[1] RV ischemia will exacerbate RV failure, causing a further reduction in cardiac output and blood pressure (Fig. 104-1). This vicious cycle may continue unless the pulmonary artery pressure (PAP) is reduced, permitting an increased RV ejection fraction. Unfortunately, treatment of pulmonary hypertension with intravenous vasodilators may worsen the systemic hypotension. Inhalation of nitric oxide (NO) produces selective pulmonary vasodilation without reducing the systemic arterial pressure in patients with acute or chronic pulmonary hypertension. Additionally, a number of other inhaled pulmonary vasodilators are now described in the literature, which might provide potential alternatives to inhaled NO. In this chapter, the theoretic background, current uses, and future therapeutic potential of inhaled NO and other inhaled pulmonary vasodilators are discussed.

INHALED NITRIC OXIDE

Since the recognition of NO as a key endothelial-derived vasodilator molecule in 1987, the field of NO research has expanded to encompass many areas of biomedical research. NO is an important signaling molecule throughout the body. Endogenous NO is produced from oxygen and L-arginine by a group of enzymes called *nitric oxide synthases* (NOSs) with L-citrulline as a by-product. Most of the effects of NO in the cardiovascular system are mediated by the activation of the enzyme soluble guanylate cyclase (sGC), which catalyzes the formation of the second messenger cyclic guanosine monophosphate (cGMP) from guanosine-5′-triphosphate (GTP). NO may directly modulate other signaling systems. For example, NO is directly involved in posttranslational protein modification, including nitrosylation of proteins (Fig. 104-2).

In 1991, Frostell and colleagues demonstrated a therapeutic potential for inhaled NO to act as a selective pulmonary vasodilator; they showed that breathing NO gas produced rapid and profound pulmonary vasodilation in an awake lamb model of pulmonary hypertension produced by the infusion of a stable thromboxane analogue[2] (Fig. 104-3). Because NO rapidly binds to hemoglobin (Hb) with a high affinity, the vasodilatory effect of inhaled NO is limited to the lung, which is in sharp contrast to intravenously infused vasodilators that often cause systemic vasodilation and can lead to systemic arterial hypotension. This unique ability of inhaled NO to cause highly selective pulmonary vasodilation has prompted a large number of preclinical and clinical studies. The early pilot studies also demonstrated that inhaled NO therapy rapidly improves oxygenation without causing systemic hypotension in newborns who are critically ill with acute pulmonary hypertension.[3,4] Subsequently, the efforts of many research groups studying animals and patients led to the approval of inhaled NO by the U.S. Food and Drug Administration in 1999, by the European Medicine Evaluation Agency and European Commission in 2001, and by the Ministry of Health, Labour and Welfare in Japan in 2008.[5-8]

Inhaled NO may play an important role in treating pulmonary hypertension in pediatric and adult patients with respiratory and cardiac failure, in determining the vasodilatory capacity of the pulmonary vascular bed, and, perhaps, in preventing the development of chronic lung disease in infants with lung injury (also see Chapter 95).

PHYSICAL PROPERTIES, METHODS OF ADMINISTRATION, AND MECHANISM OF ACTION

Chemistry of Nitric Oxide Gas

NO is a colorless and odorless gas that is only slightly soluble in water.[9] Atmospheric concentrations of NO usually range between 10 and 500 parts per billion (ppb)

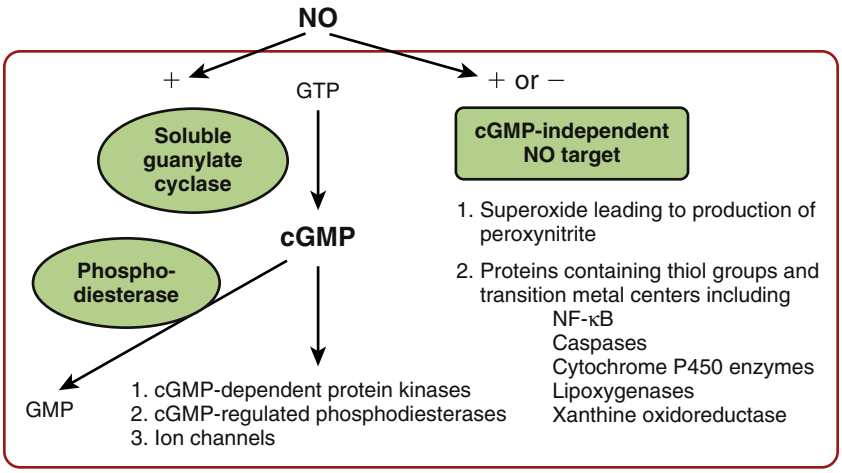

Figure 104-2. Nitric oxide (NO) signaling pathway. *cGMP*, Cyclic guanosine monophosphate; *GMP*, guanosine monophosphate; *GTP*, guanosine-5′-triphosphate; *NF-κB*, nuclear factor kappa–B.

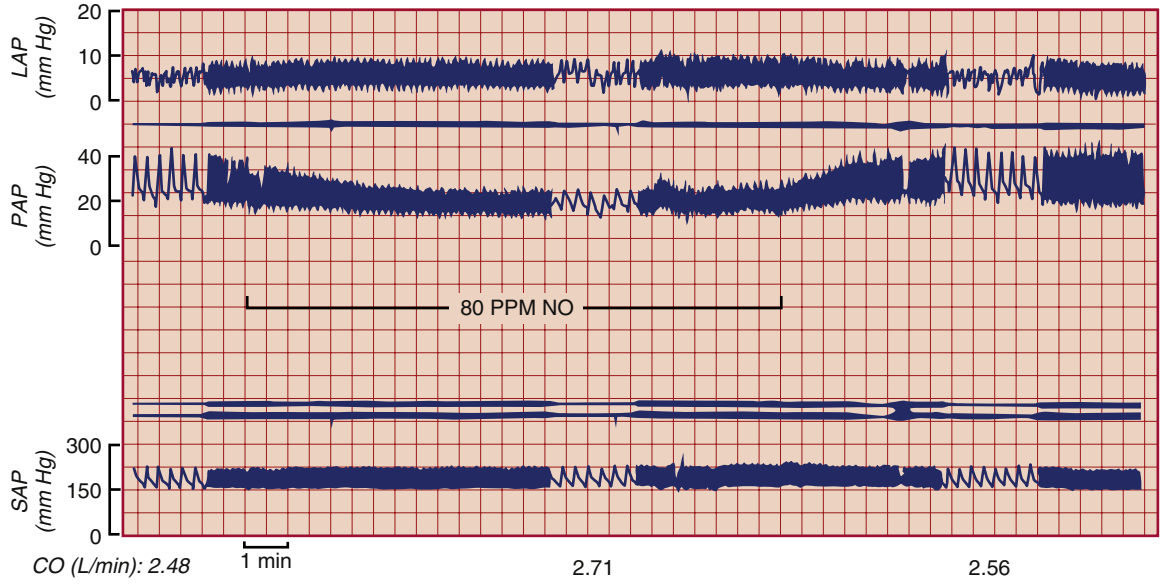

Figure 104-3. Effects of inhaling nitric oxide (NO) at 80 parts per million (PPM) in a lamb with pulmonary hypertension induced by an infusion of U46619, a stable thromboxane analogue. Inhaling NO decreases the pulmonary artery pressure (PAP) without affecting the left atrial pressure (LAP) or the systemic arterial pressure (SAP). *CO*, Cardiac output. *(From Frostell C, Fratacci MD, Wain JC, et al: Inhaled nitric oxide. A selective pulmonary vasodilator reversing hypoxic pulmonary vasoconstriction,* Circulation *83:2038-2047, 1991. Used with permission.)*

by volume but can exceed 1.5 parts per million (ppm) in areas of heavy traffic or lightning.[10] In the inhaled smoke of a burning cigarette, NO is produced by the oxidation of nitrogen from the atmosphere and nitrogen-containing compounds in the tobacco and can reach levels of 1000 ppm.[11] NO is unstable in air and undergoes spontaneous oxidation to form the more toxic nitrogen oxides (NO_2, N_2O_4). NO is therefore stored in cylinders and diluted in an inert gas, usually nitrogen.

Delivery and Monitoring of Inhaled Nitric Oxide

NO can be safely inhaled when delivered by facemask, nasal cannula, or endotracheal tube. Carefully regulating the concentration of NO and its exposure time to oxygen is important, which can be achieved using several commercially available systems. Although NO and NO_2 are more accurately measured by chemiluminescence devices, electrochemical detectors have proved adequate for the measurement of inhaled NO and are integrated components of several clinical delivery systems. Inhaled NO has also been administered long term via pulsed nasal delivery in clinical trials.[12] Although a concern existed that workers in ICUs would passively inhale NO, this has not become a problem because the levels of NO in the ICU air remain quite low.[13]

Nitric Oxide/Cyclic Guanosine Monophosphate Signal Transduction System

After inhalation, NO rapidly diffuses across the alveolar-capillary membrane into the subjacent smooth muscle of pulmonary vessels (Fig. 104-4). NO stimulates sGC to synthesize cGMP that, in turn, activates cGMP-dependent protein kinase G (PKG), leading to vascular relaxation. The physiologic actions of cGMP are limited by its hydrolysis to guanosine monophosphate (GMP)

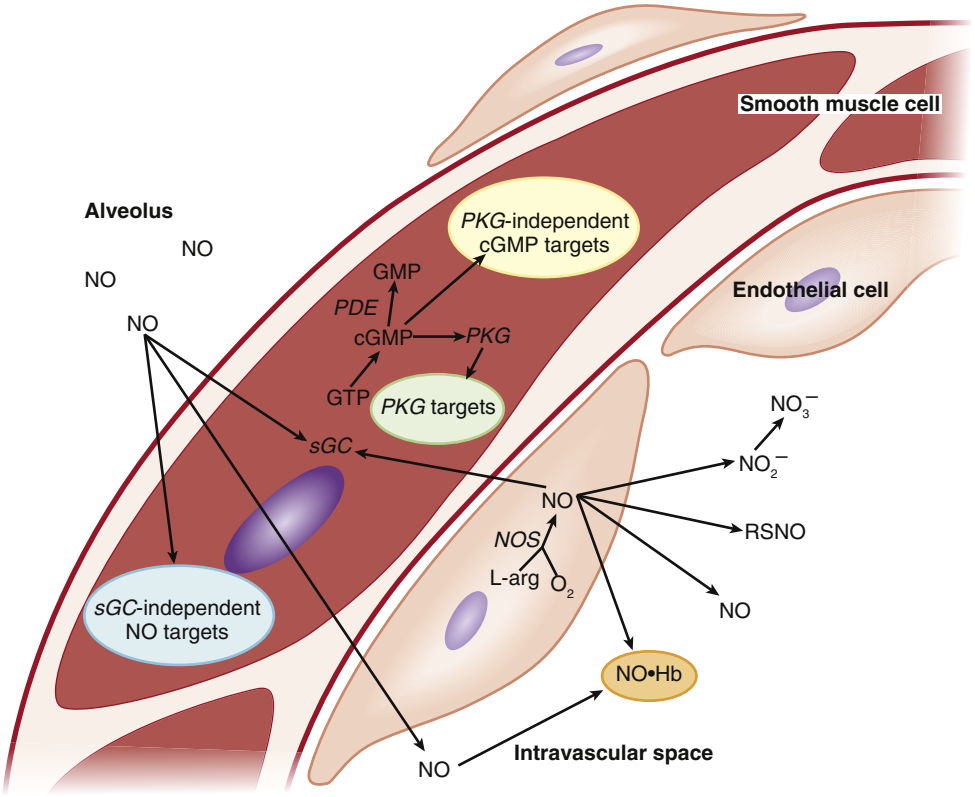

Figure 104-4. Schematic of the nitric oxide (NO) signaling pathway in the lung. NO, formed by endothelial cells or administered by inhalation, diffuses to vascular smooth muscle cells. Numerous targets of NO contribute to the wide variety of effects of this molecule on the cardiovascular system. One of the primary targets for NO is soluble guanylate cyclase (sGC). NO binds to the heme moiety of sGC and stimulates the synthesis of the intracellular second messenger cyclic guanosine monophosphate (cGMP). cGMP interacts with a variety of targets, including ion channels, cGMP-regulated phosphodiesterases (PDEs), and cGMP-dependent protein kinases G (PKG). PKGs have been shown to phosphorylate various proteins in vascular smooth muscle cells. PDEs metabolize cGMP to GMP. On arrival in the bloodstream, the majority of NO rapidly binds to hemoglobin with high affinity, whereas small amounts of NO may remain to react with other molecules, including proteins. *GMP*, Guanosine monophosphate; *GTP*, guanosine-5′-triphosphate; *Hb*, hemoglobin; *L-arg*, L-arginine; NO_2^-, nitrite; NO_3^-, nitrate; *NOS*, nitric oxide synthase; O_2, oxygen; *RSNO, S-nitrosothiol. and by export from the cell. A family of cyclic nucleotide phosphodiesterases (PDEs) is known to hydrolyze cyclic nucleotides. Of the 11 reported PDE isozymes, PDE type 5 is considered to be the most active cGMP, hydrolyzing PDE in smooth muscle.[14] PDE type 5 has a high affinity for cGMP and is selectively inhibited by PDE inhibitors, such as Zaprinast, sildenafil, and vardenafil. In addition to its pulmonary vasodilating effects, inhaled NO has several other effects in the lung. For instance, inhaled NO causes bronchodilation[15,16] and possesses antiinflammatory[17] and antiproliferative[18] effects. NO can also elicit effects via cGMP-independent mechanisms, including interactions with heme-containing molecules (in addition to sGC) and proteins containing reactive thiol groups.[19] NO interacts with the superoxide radical (O_2^-), thereby limiting NO bioavailability and resulting in the formation of the potent oxidant peroxynitrite ($ONOO^-$). In the presence of oxygenated Hb, NO is rapidly metabolized to nitrate with the formation of methemoglobin (metHb). Within red blood cells, electron donors rapidly convert metHb back to ferrous Hb.

Enhancement of Ventilation-Perfusion Matching by Nitric Oxide Inhalation

The intrapulmonary distribution of blood flow and ventilation (ventilation-perfusion [$\dot{V}/\dot{Q}$] distribution) is a major determinant of the efficiency of transpulmonary oxygenation and determines the partial arterial pressure of oxygen (PaO_2). In the normal, healthy lung, the majority of ventilated areas are well perfused. The shunt from the right to the left side of the circulation is mainly extrapulmonary (e.g., bronchial veins) and is less than 5% to 8% of cardiac output.[20] In the normal lung, local alveolar hypoxia constricts the vascular bed adjacent to hypoxic regions and redistributes blood flow toward lung regions with better ventilation and a higher intraalveolar partial pressure of oxygen (PO_2). Inhaled NO may amplify this mechanism by increasing blood flow to well-ventilated lung areas, which may, in some diseases, have an increased vasomotor tone. This inhaled vasodilatory effect is in marked contrast to the effect of intravenously administered vasodilators, which produce diffuse dilation of the pulmonary vasculature, thereby increasing blood flow to areas of nonventilated lung and

Figure 104-5. increasing intrapulmonary shunting and reducing the PaO_2. In contrast, inhaled NO should selectively improve the perfusion of ventilated regions, thereby reducing intrapulmonary shunting and improving arterial oxygenation (Fig. 104-5). These beneficial effects of inhaled NO on intrapulmonary shunting and oxygenation have been demonstrated in some adult and pediatric patients with acute respiratory distress syndrome (ARDS).[21,22] Unfortunately, this effect can, at times, be transient.[23]

CLINICAL USE OF INHALED NITRIC OXIDE

Perinatal and Pediatric Uses of Inhaled Nitric Oxide

Nitric Oxide Is an Important Regulatory Molecule in the Perinatal Lung. Several studies indicate that NO plays an important role in modulating the pulmonary vascular resistance (PVR) at birth. For example, in the developing lungs of several animals, NOS and sGC expression levels and signaling increase late in gestation, are maximal in the postnatal period, and decrease in the adult.[24-26] Moreover, because NOS inhibitors attenuate the reduction of PVR at birth,[27,28] NO signaling likely plays a critical role in the transition from the fetal to the newborn pulmonary circulatory system.

Many forms of newborn and infant lung disease are associated with endothelial cell injury and decreased NO/cGMP signaling. Studies in newborns suggest that premature constriction of the ductus arteriosus, septic mediators, and meconium aspiration all cause pulmonary endothelial cell injury. For example, in utero ligation of the ductus arteriosus in the fetal lamb causes flow-induced endothelial cell dysfunction and decreases the expression of endothelial NOS (NOS3)[29] and vasorelaxation caused by NO.[30] Moreover, cardiac lesions, such as atrial and ventricular septal defects, atrioventricular canals, persistent ductus arteriosus, and transposition of the great vessels without a ventricular septal defect, cause endothelial cell injury, decrease NO-mediated pulmonary vasorelaxant activity, and lead to pulmonary hypertension.[31]

NO/cGMP signaling plays an important role in regulating lung development. For example, in mildly hypoxemic NOS3-deficient newborn mice, alveolar development is severely inhibited in a manner that can be improved by NO inhalation.[32,33] Moreover, in perinatal models of pulmonary vascular disease, in which NO activity has been observed to be decreased, inhaled NO improves the development of peripheral pulmonary arteries.[34]

Experimental Studies of the Selective Pulmonary Vasodilator Effects of Inhaled Nitric Oxide in the Newborn. Several investigations using newborn animals have demonstrated that inhaled NO decreases pulmonary hypertension. For example, in fetal lambs with an intact placental circulation, inhaled NO decreased the PVR.[35] Similarly, in newborn lambs with pulmonary vasoconstriction associated with hypoxemia, inhaled NO was observed to decrease the PVR and increase lung cGMP levels in a manner that was not modified by acidosis.[36] Importantly, in the latter study, inhaled NO did not cause systemic vasodilation; breathing up to 80 ppm NO did not decrease either systemic vascular resistance or blood pressure. Inhaled NO also reversed vasoconstriction in newborn animals with pulmonary vascular remodeling. In newborn lambs with pulmonary vascular disease induced by premature ligation of the ductus arteriosus and associated with muscularization of peripheral arteries in the lung periphery, inhaled NO caused dose-dependent vasodilation and improved systemic oxygenation and the survival rate.[37,38]

Inhaled Nitric Oxide Can Attenuate Pulmonary Disease in Newborn Animals. In newborn rats, lung injury as a result of sustained hypoxia or exposure to endothelial toxins, for example, causes pulmonary artery muscularization and hypertension that is similar to that observed in patients with pulmonary artery hypertension (PAH) and many forms of congenital heart disease. In these models, prolonged NO inhalation has been reported to attenuate pulmonary vascular remodeling and RV hypertrophy in the newborn who is chronically hypoxic.[34] Importantly, it appears that breathing NO can inhibit pulmonary vascular remodeling even in the absence of pulmonary hypertension. Roberts and colleagues reported that in newborn rats with monocrotaline-induced endothelial injury, inhaled NO decreased the abnormal proliferation of cells in the walls of the pulmonary arteries

and prevented abnormal pulmonary vascular remodeling even before the development of pulmonary hypertension.[18] These findings suggest that inhaled NO may play an important role in modifying the abnormal vascular development and secondary pulmonary hypertension of the injured newborn lung.

Lung injury decreases alveolar and pulmonary microvascular development in premature lambs and baboons and in newborn mice and rats.[39] Inhaled NO probably promotes the development of the injured maturing lung. For example, prolonged NO inhalation increases alveologenesis in chronically ventilated premature baboons[40] and lambs.[41] Moreover, inhaled NO improves alveolar development in mice after hyperoxic lung injury.[42] The mechanisms responsible for the protective effects of inhaled NO in alveologenesis are unknown. The pulmonary vasculature regulates alveolar development,[43] and inhaled NO protects the newborn lung vessels from injury.[34] Further, inhaled NO possibly protects the lung via its effects on the microvasculature. The observation that inhaled NO improves alveolarization in rat pups that have decreased microvascular development supports this concept.[44] However, NO may regulate the homeostasis of other cells or may modulate other signaling systems, thereby regulating or contributing to lung development

Inhaled Nitric Oxide Increases Systemic Oxygenation in Hypoxemic Newborns With Pulmonary Hypertension. Pilot studies revealed that inhalation of NO increases systemic oxygenation in newborns with pulmonary hypertension and severe hypoxemia.[3,4] The ability of inhaled NO to increase systemic oxygen levels was confirmed in several multicenter randomized controlled studies of term and near-term infants with hypoxemia and pulmonary hypertension.[6,8] In one study, systemic oxygenation increased in nearly one-half of the patients with severe persistent pulmonary hypertension of the newborn (PPHN) and who received inhaled NO.[6] Importantly, the magnitude of the increase in oxygen levels in newborns treated with inhaled NO was directly proportional to the degree of hypoxia before NO inhalation, and the increased systemic oxygenation of the NO-breathing infants was maintained in 75% of the patients. In another study, the optimal concentration of inhaled NO level was investigated.[45] Although the maximum increase in systemic oxygenation was observed in infants breathing 80 ppm NO, as little as 5 to 20 ppm NO increased the arterial oxygen levels above those measured in newborns not breathing NO. Inhaled NO decreases the need for extracorporeal membrane oxygenation (ECMO), an invasive procedure requiring systemic heparinization.[6,8]

Inhaled Nitric Oxide in Bronchopulmonary Dysplasia. Bronchopulmonary dysplasia (BPD) is an important chronic lung disease of prematurely born infants that results, in part, from the inhibition or disruption of normal pulmonary alveolar and microvascular development as a result of oxygen- and ventilator-induced lung injury.[46] Although an early study suggested that inhaled NO did not decrease the incidence of BPD,[47] a subsequent single-center trial involving 207 premature infants conducted by Schreiber and colleagues suggested that inhaled NO decreases the incidence of BPD and death in prematurely born infants.[48] These observations were supported by the results from a later multicenter trial during which inhaled NO was noted to decrease the rate of BPD and death in premature infants with a birth weight greater than 1000 g.[49] In a more recent study of 793 newborns who were 34 weeks' gestational age or younger, Kinsella and colleagues reported that inhaled NO decreased the incidence of BPD in the subset of 129 infants with a birth weight of at least 1000 g.[50] Moreover, in another randomized multicenter study of 582 premature infants with a birth weight of 1250 g or less, during which inhaled NO was commenced 7 to 21 days after birth, Ballard and co-workers reported that NO inhalation improved survival and reduced the incidence of BPD.[51] Although these results are encouraging when considered together, additional studies need to be performed before the role of inhaled NO in preventing BPD can be defined.

Safety of Inhaled Nitric Oxide in the Newborn. Although studies in newborns and infants suggest that prolonged inhalation of NO is safe,[52] the long-term pulmonary and extrapulmonary effects of inhaled NO are unknown. In particular, the effects of chronic NO inhalation on normal pulmonary cell proliferation and differentiation, as well as on alveolar and microvascular development, are unknown.

NO can increase cGMP levels in platelets and inhibit their function.[53] The potential of inhaled NO to alter platelet function[54] is of particular concern for immature infants, since abnormal hemostatic activity might increase the incidence or evolution of intraventricular hemorrhage (IVH) and associated neurologic injury. In one study, breathing NO was associated with increased mortality and rates of IVH in infants weighing 1000 g or less.[49] Nevertheless, inhaled NO exposure does not increase the incidence or severity of IVH in premature babies.[47,48,51] In fact, in one large study of premature infants, inhaled NO was reported to decrease the frequency of IVH and its sequelae.[52]

It is uncertain whether an improvement in pulmonary disease in some premature babies who breathed NO is associated with an improved neurologic development. In a European multicenter trial of nearly 100 premature infants, inhaled NO was not observed to affect the incidence of death or severe disability at 1 year corrected for postnatal age.[55] In a follow-up study of the randomized multicenter trial of inhaled NO in premature infants previously mentioned, inhaled NO had no adverse neurodevelopmental effects at 2 years of age.[56] On the other hand, a more rigorous evaluation of older premature infants treated in another trial suggests that inhaled NO can improve neurologic outcomes[57] (also see Chapter 95).

Uses of Inhaled Nitric Oxide in Adult Patients With Cardiopulmonary Diseases

Pulmonary Vasoreactivity Testing in the Cardiac Catheterization Laboratory. Demonstration of a positive response to vasodilating agents in patients with pulmonary hypertension correlates with an improved long-term clinical outcome and has been used to guide medical therapy.[58] Whereas a number of vasodilators,

including intravenous prostacyclin and calcium channel blockers, have been used for diagnostic testing during cardiac catheterization, such circulating agents produce systemic vasodilation and increase the intrapulmonary right-to-left shunt.[59] In contrast, inhaled NO is a safe and effective agent to determine the pulmonary circulation's capacity for vasodilation in pediatric[60,61] and adult patients[62,63] with pulmonary hypertension; doses of 20 to 80 ppm for 5 to 10 minutes are typically used. In these patients, selective pulmonary vasodilation during NO breathing correlates with a subsequent response to oral and systemically active vasodilators.[64,65] A preoperative hemodynamic evaluation with oxygen and inhaled NO, as opposed to a test with oxygen alone, is suggested to identify more accurately those patients with pulmonary hypertension who will be the most appropriate candidates for corrective cardiac surgery or transplantation.[66] In 1998, inhaled NO was the primary vasodilator used to test pulmonary vascular responsiveness in 32% of U.S. tertiary hospitals.[67] According to a survey in 2000, 94% of pediatric cardiologists consider inhaled NO to be a clinically proven agent to test pulmonary vasoreactivity in the cardiac catheterization laboratory[68] (also see Chapter 67).

Treatment of Chronic Pulmonary Hypertension With Inhaled Nitric Oxide. Current treatment approach for chronic pulmonary hypertension includes prostacyclin (prostaglandin I_2 [PGI_2]) and its analogues, endothelin receptor–1 antagonists (ERAs), and PDE type 5 inhibitors.[69,70] Although the continuous administration of intravenous prostacyclin (epoprostenol) is associated with improved survival and exercise tolerance,[71] indwelling central venous catheters carry the risk of bacteremia. The feasibility of an ambulatory NO delivery system has been reported in a small number of patients with persistent pulmonary hypertension (PPH).[72,73] The safety and efficacy of long-term domiciliary NO inhalation requires investigation in larger patient populations.[69,74-76] Although PGI_2 analogues, ERAs, and PDE type 5 inhibitors are the mainstays of the current treatment for pulmonary hypertension, all have systemic effects in addition to their pulmonary effects that can cause unfortunate side effects. In patients who do not tolerate systemic effects of these orally active medications, long-term therapy with inhaled NO may be considered.

Treatment of Cardiogenic Shock as a Result of Right Ventricular Myocardial Infarction. RV injury and dysfunction may complicate inferior myocardial infarction (MI) as a result of right coronary artery occlusion. If coronary revascularization is delayed, then cardiogenic shock may develop, despite preserved LV function, and is associated with a high frequency of mortality. In a small series of patients with cardiogenic shock as a result of right ventricular myocardial infarction (RVMI), Inglessis and colleagues reported that unloading the RV by breathing NO 80 ppm acutely improved cardiac index by approximately 25%.[77] In patients with RVMI and a patent foramen ovale, treatment with inhaled NO significantly reduced the right-to-left shunt and improved systemic oxygenation. Further studies are required to determine whether NO inhalation will decrease morbidity and mortality associated with RVMI.

Acute Respiratory Distress Syndrome in Adults. In clinical studies of patients with severe ARDS, inhaled NO produced selective pulmonary vasodilation,[21] decreased pulmonary capillary pressure[78] and pulmonary transvascular albumin flux,[79] and improved oxygenation.[21] Although these clinical studies, as well as a number of studies in animal models of acute lung injury (ALI), have demonstrated a physiologic benefit of inhaled NO therapy, subsequent clinical trials reported disappointing outcome results. A randomized, double-blinded, placebo-controlled trial of 177 patients (average entry PaO_2/fraction of inspired oxygen concentration [FiO] ~129 mm Hg) treated with various concentrations of inhaled NO (1.25 to 80 ppm) versus a placebo failed to find a difference in either the mortality rate or the number of days alive and off mechanical ventilation.[80] A prospective, randomized, unblinded European multicenter trial of inhaled NO in patients with ALI (n = 286, average entry PaO_2/FiO_2 ~105 mm Hg) also demonstrated no effect on mortality or the duration of mechanical ventilation; however, the frequency of development of severe respiratory failure from milder respiratory failure was decreased with inhaled NO.[81] Subsequently, a large-scale, randomized, blinded, placebo-controlled study carried out in the ICUs of 46 U.S. hospitals evaluated the efficacy of low-dose (5 ppm) inhaled NO in 385 patients with moderately severe ALI (also see Chapter 101). Results of an intent-to-treat analysis revealed that inhaled NO had no significant benefit versus control (nitrogen gas) as it related to mortality (23% versus 20%, respectively), days alive and off assisted breathing (mean, 10.7 versus 10.6 days), or days alive and meeting oxygenation criteria for extubation (mean, 16.7 versus 17.0 days). Treatment, however, resulted in a significant increase ($P < .05$) in PaO_2 during the initial 24 hours of treatment, with improvement resolved by 48 hours.[82] Interestingly, a long-term follow-up at 6 months after treatment revealed that patients with ARDs who survived after treatment with low-dose inhaled NO had significantly better values for selected pulmonary function tests (e.g., total lung capacity [TLC], forced expiratory volume in 1 second [FEV_1], forced vital capacity [FVC], FEV_1/FVC) at 6 months after treatment than patients treated with placebo.[83] Further trials may be warranted to determine the effects of inhaled NO on chronic lung function in survivors of ARDS, a factor in long-term morbidity and quality of life in this population.

Chronic Obstructive Pulmonary Disease. Pulmonary hypertension and hypoxemia frequently complicate severe chronic obstructive pulmonary disease (COPD). Primarily, $\dot{V}/\dot{Q}$ mismatching causes systemic hypoxemia in COPD, not intrapulmonary right-to-left shunting as in ARDS. Hypoxic pulmonary vasoconstriction diverts venous blood flow to better-ventilated lung regions, thereby improving arterial oxygenation. Although inhaled NO is a more potent pulmonary vasodilator than oxygen in COPD, breathing inhaled NO admixed with air may produce vasodilation of poorly ventilated regions of the obstructed lung without receiving sufficient oxygen

replenishment. Increasing blood flow with inhaled NO to these hypoventilated lung areas can reduce the transcutaneous arterial oxygen tension[84] and PaO_2.[85] However, when NO gas is inhaled in combination with modest oxygen enrichment (1 L/min via facemask),[86] the PaO_2 is increased to a greater extent than with oxygen therapy alone. Along these lines, a recent controlled prospective randomized trial demonstrated that the combined use of supplemental oxygen and inhaled NO for 3 months via a portable inspiratory pulsing device caused a greater improvement of pulmonary hemodynamics than supplemental oxygen alone and did not worsen the oxygenation of patients with COPD.[87] Further studies are needed to determine the effect of long-term ambulatory breathing of pulsed NO and oxygen on the quality of life and mortality rate of patients with severe COPD.

Treatment of Perioperative Pulmonary Hypertension With Inhaled Nitric Oxide

Coronary Artery Bypass Grafting. Pulmonary hypertension often complicates the management of patients during and after cardiopulmonary bypass (CPB) surgery (also see Chapter 67). A number of uncontrolled studies have demonstrated that 20 to 40 ppm inhaled NO effectively decreases the PAP after coronary artery bypass grafting (CABG), even in patients without significant preoperative pulmonary hypertension.[88-90] Although these results suggest a role for inhaled NO in treating transient pulmonary hypertension after CPB surgery, whether inhaled NO can improve the clinically important outcomes of patients undergoing CABG is unknown. A large prospective randomized trial would be needed to define a role for inhaled NO in this patient population.

Congenital Heart Disease. Postoperative pulmonary hypertensive crises are an important cause of morbidity and mortality after congenital heart surgery[91,92] and may be precipitated by diminished NO bioavailability as a result of endothelial dysfunction.[31,93] PAH and subsequent heart failure is associated with certain types of congenital heart defects, particularly those with increased pulmonary blood flow (e.g., ventricular septal defect and atrioventricular [AV] canal). Inhaled NO ameliorates the postoperative pulmonary hypertension of congenital heart disease[94,95] and decreases the need for postoperative ECMO.[96] In a randomized double-blind study, Miller and colleagues examined the effects of the prophylactic use of inhaled NO in high-risk infants undergoing congenital heart surgery[97] (also see Chapter 94). In this study, 124 patients were randomized before surgery, and inclusion in the study did not depend on the presence of pulmonary hypertension. They reported that, as compared with a placebo, infants who continuously inhaled 10 ppm NO from after surgery until just before extubation had fewer pulmonary hypertensive crises and a shorter time to eligibility for extubation. These studies indicate that inhaled NO safely decreases postoperative pulmonary hypertension in patients after surgery for congenital heart disease. Further studies are needed to test whether inhaled NO should be used after CPB surgery in all patients with congenital heart disease to decrease their perioperative morbidity and mortality.

Valvular Heart Disease. Patients with chronic mitral valve disease may have preoperative pulmonary hypertension caused by retrograde transmission of an elevated left atrial pressure (also see Chapter 67). After mitral valve repair or replacement, pulmonary vascular remodeling and vasoconstriction may persist or slowly decrease. It has been reported that the vasodilatory response to inhaled NO is variable in patients with valvular heart disease.[89,98] The variability of dilator response is likely to be related to the balance of pulmonary vascular remodeling and active vasoconstriction. Treatment with inhaled NO after repair of valvular heart disease can relieve the vasoconstrictor component of pulmonary hypertension in these patients.[99] Whether inhaled NO can alter the clinical outcome of patients after valvular heart surgery is unknown.

Cardiac Transplantation. Pulmonary hypertension in the recipient undergoing cardiac transplantation is a major cause of right heart failure and early death. Goals in the management of acute RV failure include the preservation of coronary perfusion through the maintenance of systemic blood pressure and reducing RV afterload by decreasing the PVR.[100] In contrast to therapy with intravenous vasodilators that often cause systemic hypotension, inhaled NO has been shown using a small group of patients to selectively reduce PVR and enhance RV stroke work after cardiac transplantation.[101] A positive pulmonary vasodilator response to NO inhalation has been used as a criterion to select patients for cardiac transplantation.[102]

Insertion of Left Ventricular Assist Device. RV dysfunction occurs in 20% to 50% of patients after insertion of a left ventricular assist device (LVAD).[103] The ability of the RV to pump sufficient quantities of blood to the LVAD is critically related to the intrinsic contractility of the RV and the RV afterload, which is influenced by the PVR. The PVR is usually elevated in long-standing congestive heart failure and can be further increased in the early postoperative period by the effects of CPB surgery. Inhaled NO has been shown to decrease the PVR effectively in the setting of RV dysfunction after LVAD insertion.[104] A trial of inhaled NO is recommended before considering implantation of a RV assist device, as this invasive procedure may be avoided if the response to inhaled NO is salutary[105] (also see Chapter 67). Although a small randomized, double-blinded trial demonstrated the hemodynamic benefits of inhaled NO (decreased PAP and increased LVAD flow) in patients with pulmonary hypertension who received an LVAD,[106] a recent larger clinical trial failed to show beneficial effects of NO inhalation after LVAD insertion.[107]

Treatment of Pulmonary Ischemia-Reperfusion Injury. Ischemia-reperfusion (I-R) injury is one of the major causes of early graft failure after lung transplantation. Adhesion and sequestration of activated leukocytes by activated pulmonary endothelium are believed to be important mechanisms of I-R injury. NO possesses antiinflammatory properties, and inhaled NO has been shown to attenuate pulmonary I-R injury in preclinical studies.[108] Although two uncontrolled clinical studies suggested that

inhaled NO may prevent lung I-R injury,[109,110] a small randomized, placebo-controlled study demonstrated that inhaling 20 ppm NO commencing 10 minutes after reperfusion did not affect the physiologic or clinical outcome of patients after lung transplantation.[111] Additional studies are required to define the therapeutic role of inhaled NO in patients who have developed an I-R injury after lung transplantation.

EXTRAPULMONARY EFFECTS OF BREATHING NITRIC OXIDE

Because breathing NO decreased the PVR without altering systemic blood pressure, an initial proposal suggested that the action of inhaled NO was limited to the lungs. It was hypothesized that any NO reaching the bloodstream would be rapidly scavenged by oxygenated Hb, leading to the production of nitrate and metHb.[2] However, as early as 1993, evidence began to accumulate that NO inhalation could inhibit platelet function.[54] Subsequently, studies describing a wide range of systemic effects of breathing NO were published, as summarized recently by McMahon and Doctor[112] and highlighted in Table 104-1. In this section, the ability of NO inhalation to decrease I-R injury is reviewed, and the circumstances during which breathing NO can modulate systemic vascular tone are discussed. In addition, potential mechanisms by which inhaled NO may exert its systemic effects are outlined.

Inhaled Nitric Oxide and Platelet Function

The ability of NO-donor compounds to inhibit platelet function is well known, but systemic hypotension limits the therapeutic application of their antithrombotic effects. In 1993, Hogman and colleagues first reported that breathing NO (30 ppm) could prolong the bleeding time in rabbits and healthy human subjects.[54] Subsequent reports from multiple research groups presented conflicting data with some investigators reporting that breathing NO increased bleeding time in neonates and adults and others reporting that NO inhalation did not alter either bleeding time nor platelet function. A recent randomized controlled blinded crossover study showed that inhaled NO, when administered with heparin, exhibited no significant additive effects on activated clotting time, prothrombin time, activated prothrombin time, bleeding time, or platelet aggregation.[113] On the other hand, the observation that breathing NO could decrease platelet function led other investigators to examine in animal models whether NO inhalation could be used to treat vascular diseases associated with platelet activation. For example, Semigran and

colleagues reported that in a canine model of coronary thrombosis after thrombolysis, breathing 20 and 80 ppm NO decreased platelet-mediated thrombosis,[114] an effect that was augmented by the co-administration of PDE inhibitors.[115,116] Breathing NO did not prolong the bleeding time or cause systemic hypotension in these studies.

Inhaled Nitric Oxide and Ischemia-Reperfusion Injury of Extrapulmonary Organs

Observations that NO can form stable, biologically active adducts with protein thiol groups led Kubes and colleagues to examine whether inhaled NO could be used to deliver NO to peripheral tissues.[117] Studying postcapillary venules from cats subjected to intestinal ischemia and reperfusion, these investigators observed that breathing 80, not 20, ppm NO prevented the reduction of blood flow, the increase in leukocyte activation (i.e., rolling, adherence, migration), and vascular leakage. The investigators also observed that breathing NO prevented the arteriolar constriction and neutrophil activation induced by the administration of L-NG-nitroarginine methyl ester (L-NAME), a NOS inhibitor. Interestingly, inhaled NO did not alter neutrophil activation or vascular leakage in endotoxin-challenged cats, leading the investigators to propose that inhaled NO does not affect peripheral tissues with abundant NO (produced by inducible NOS). In contrast, Neviere and associates reported that breathing 10 ppm NO decreased the adhesion of leukocytes to mesenteric venular endothelium of endotoxin-challenged rats.[118] Moreover, breathing NO prevented endotoxin-induced cardiac dysfunction and leukocyte accumulation. In a subsequent report, Kubes and colleagues reported that, in contrast to NO-donor compounds, inhaled NO did not prevent the increase in mucosal permeability induced by intestinal I-R and suggested that the effects of breathing NO were limited to the vascular compartment.[119]

Based on these observations, Guery and colleagues evaluated the ability of breathing NO to preserve cardiac function after myocardial I-R injury.[120] Hearts from rats that had breathed air with or without 10 ppm NO for 4 hours were isolated and perfused. Coronary perfusion was stopped for 30 minutes, followed by reperfusion for 40 minutes. The investigators observed that pretreatment with inhaled NO led to improved systolic and diastolic function after I-R. These findings were extended by Hataishi and colleagues who examined the ability of breathing NO to decrease cardiac I-R injury in intact mice.[121] They observed that breathing NO for the final 20 minutes of ischemia and for 24 hours after reperfusion decreased MI size and improved systolic and diastolic function. Breathing 80 ppm NO decreased MI size similarly after 30, 60, or 120 minutes of ischemia. Breathing 40 and 80 ppm NO equally decreased myocardial I-R injury, but 20 ppm was not effective. Breathing NO decreased cardiac neutrophil accumulation and leukocyte depletion prevented the beneficial effects of NO on MI size. Observations in rodents have recently been extended to a clinically relevant porcine model of cardiac I-R injury. Janssens and colleagues reported that breathing 80 ppm NO decreased MI size and improved myocardial perfusion in pigs subjected to 50 minutes of cardiac ischemia and 4 hours of reperfusion.[122] The ability of inhaled NO to decrease I-R injury of extrapulmonary organs is further suggested in a small series of patients undergoing CPB surgery,[123] patients after limb I-R,[124] and patients undergoing liver transplantation.[125] Based on these considerations, a randomized clinical trial has been initiated to test whether breathing 80 ppm can decrease MI size in patients with an ST-segment elevation MI.

Inhaled Nitric Oxide and Systemic Vascular Tone

Whether breathing NO can modulate systemic vascular tone remains controversial. Clinically significant systemic hypotension has not been observed in adults and infants with a wide variety of disorders treated with concentrations up to 80 ppm NO. However, breathing 80 ppm NO attenuates the ability of L-NAME to increase arterial blood pressure in cats.[119] Cannon and colleagues reported that breathing 80 ppm NO increased forearm blood flow in healthy patients treated with an intrabrachial artery infusion of the NOS inhibitor L-NG-monomethylarginine acetate salt (L-NMMA).[126] In contrast, Hataishi and colleagues observed that breathing NO did not decrease systemic vascular resistance in L-NAME–treated mice or in mice congenitally deficient of NOS3.[127]

The ability of inhaled NO to decrease systemic vascular resistance is perhaps clearest in the case of the endothelial dysfunction associated with hemolysis, such as that observed during vasoocclusive pain crisis (VOC) of sickle cell disease (SCD). Presence of Hb in the plasma may likely induce systemic vasoconstriction via scavenging of endothelium-derived NO.[128] Preclinical studies and small clinical series suggest beneficial effects of NO inhalation on VOC of SCD.[129,130] Nonetheless, a recent prospective, multicenter, double-blind, randomized, placebo-controlled clinical trial for up to 72 hours of inhaled NO versus inhaled nitrogen placebo in 150 participants with vasoocclusive pain crisis of SCD showed that the use of inhaled NO compared with placebo did not improve time-to-crisis resolution.[131]

Preclinical studies have also shown beneficial effects of inhaled NO against systemic vasoconstriction and inflammation associated with transfusion of Hb-based oxygen carrier (HBOC),[132] packed red blood cells stored for a prolong period (40 days),[133] and cerebral malaria.[134] Several clinical trials are underway to determine the efficacy of NO inhalation in various disease states associated with cell-free Hb.

Protecting the Brain Using Inhaled Nitric Oxide

Although NO-dependent signaling exerts multifaceted protection against I-R injury, the vasodilating effects of systemically administered NO-donor compounds preclude their use in patients with unstable arterial blood pressure, which is especially true for patients resuscitated from sudden cardiac arrest (also see Chapter 108). Sudden cardiac arrest remains a leading cause of death worldwide. Despite advances in cardiopulmonary resuscitation (CPR) methods, including the introduction of the automatic external defibrillator (AED) and therapeutic hypothermia (TH), only approximately10% of those who have adult out-of-hospital cardiac arrest (OHCA) survive to hospital

discharge, and up to 60% of survivors have moderate-to-severe cognitive deficits 3 months after resuscitation. No pharmacologic agent is available to improve the outcome from cardiac arrest and CPR.

In a recent preclinical study, Minamishima and colleagues evaluated the impact of breathing NO on outcomes in mice subjected to cardiac arrest and CPR. These authors reported that breathing 40 ppm NO starting 1 hour after return of spontaneous circulation (ROSC) and continuing for 23 hours (1) improved neurologic and myocardial function and the survival rate in mice at 10 days, (2) attenuated water diffusion abnormality and blood-brain barrier leakage at 24 hours (as demonstrated by magnetic resonance imaging [MRI] in live mice), (3) prevented apoptotic cell death and glial activation in the brain 4 days after cardiac arrest, and (4) attenuated inflammatory cytokine induction in the brain and heart 1 and 4 days, respectively, after cardiac arrest.[135] The protective effects of NO breathing after CPR, if extrapolated to human beings, is highly clinically relevant, because NO inhalation can be started after patients are transferred to the hospital and informed consent is obtained.

Subsequent preclinical studies supported the effects of inhaled NO. Terpolilli and colleagues showed that NO inhalation prevented ischemic brain injury induced by middle cerebral artery occlusion in mice and sheep by selective dilation of collateral arterioles.[136] Similarly, inhaled NO was found to reduce brain damage by collateral recruitment in a neonatal stroke model in rat pups.[137] Clinical trials are underway to investigate the neuroprotective effects of NO inhalation.

How Does Inhaled Nitric Oxide Exert its Systemic Effects?

With the exception of the case of hemolysis, the mechanisms by which NO, once inhaled, are able to induce responses in the periphery remains incompletely understood. One hypothesis is that during NO inhalation, blood cells, including white blood cells and platelets, are exposed to NO before the scavenging of the gas by red blood cells, and NO-exposed blood cells are responsible for the systemic effects of inhaled NO (Fig. 104-6). For example, exposure of platelets to NO in the pulmonary circulation may inhibit their activation at the site of vascular injury. However, this hypothesis does not fully account for the dilator effects of breathing NO observed in some vascular beds or the observations of Fox-Robichaud and associates,[117] who reported that inhaled NO did not alter the ability of feline blood leukocytes to bind to immobilized platelet monomers ex vivo.

An alternate hypothesis is that some of the inhaled NO escapes scavenging by Hb and is carried in a stable, bioavailable form to the periphery (see Fig. 104-6). Loscalzo and colleagues proposed that endogenously synthesized NO reacts with low- and high-molecular-weight thiols in blood, including serum albumin.[138,139] These *S*-nitrosothiols can deliver NO to tissues distant from the site of its synthesis. Stamler and colleagues observed that NO reacts with the thiol group on Cys^{93} of the Hb β chain; the *S*-nitrosylation of Hb (SNO-Hb) is dependent on the oxygen tension, enabling erythrocytes to load Hb in the oxygen-rich environment of the lungs and to release low-molecular-weight *S*-nitrosothiols in the relatively hypoxic periphery.[112] NO can be oxidized in blood to nitrite, which regenerates NO in the presence of nitrite reductases including deoxyhemoglobin.[140] Erythrocyte SNO-Hb and nitrite have both been implicated as potential mediators of the systemic vasodilation induced by tissue hypoxia. NO may also react with other plasma species that are subsequently capable of regenerating NO, including *N*-nitrosamines, iron-nitrosyls, and nitrated lipids.

Even before it was appreciated that breathing NO could selectively dilate the pulmonary vasculature, several research groups examined the metabolic fate of inhaled NO. In 1975, Oda and colleagues reported NO inhalation led to the formation of nitrosyl-Hb in the blood of mice, rats, and rabbits.[141] In 1987, Yoshida and Kasama reported that breathing ^{15}NO (145 ppm for 123 minutes)

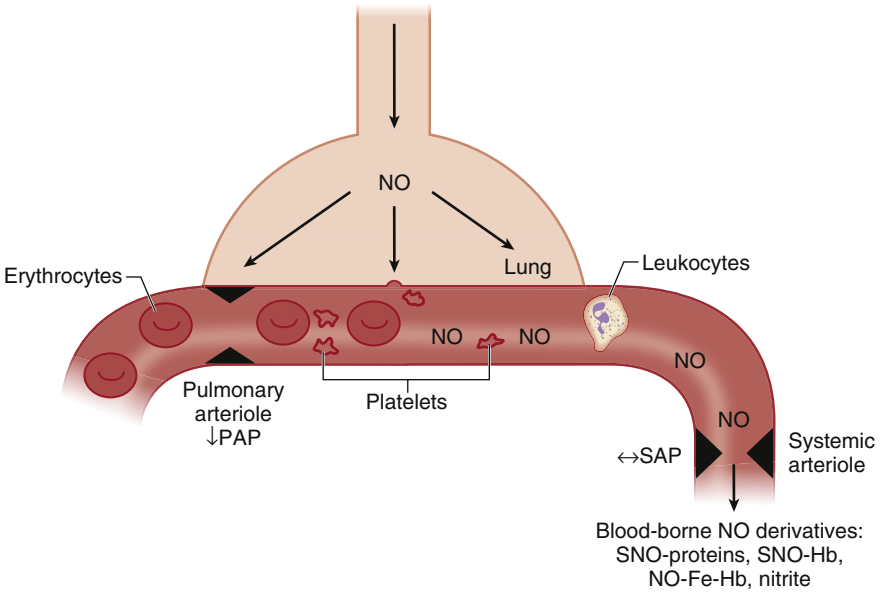

Figure 104-6. Inhaled nitric oxide (NO) is a selective pulmonary vasodilator with actions on the systemic vasculature. A schematic of an alveolar-capillary unit is presented, highlighting the ability of inhaled NO to dilate pulmonary arterioles and reduce pulmonary artery pressure (PAP). Although inhaled NO does not dilate systemic arterioles or alter systemic arterial pressure (SAP) under normal conditions, inhaled NO has systemic effects that are described in the text and may be mediated by circulating cells exposed to NO in the lungs and bloodborne NO derivatives: SNO-proteins or *S*-nitroso proteins including SNO-albumin; SNO-Hb or *S*-nitrosylation of hemoglobin (nitrosylated on Cys^{93} of the β chain); NO-Fe-Hb or nitrosyl-hemoglobin; and nitrite. *(From Bloch KD, Ichinose F, Robert JD, Zapol WM: Inhaled NO as a therapeutic agent,* Cardiovasc Res *75:339-348, 2007. Used with permission).*

led to the formation of nitrosyl-Hb, nitrite, and nitrate.[142] More recently, Cannon and associates found that nitrosyl-Hb concentrations significantly increased in healthy adults breathing 80 ppm NO, whereas nitrite modestly increased.[126] Arterial concentrations of both products were greater than venous levels, suggesting consumption in peripheral tissues. Cannon and colleagues did not detect an increase in plasma *S*-nitrosothiols or SNO-Hb. In contrast, Ng and colleagues reported that plasma levels of both *S*-nitroso-albumin and nitrite increased in cats breathing 80 ppm NO; both were further increased in the setting of intestinal I-R.[143] Arterial levels of *S*-nitroso-albumin were higher than venous levels, whereas the converse was true for nitrite levels, which suggested that *S*-nitroso-albumin was consumed in the periphery and nitrite was generated.

The potential importance of nitrite as a mediator of inhaled NO's impact on I-R injury was highlighted in recent studies of Duranski and colleagues.[144] They observed that small increases in blood nitrite levels were sufficient to decrease I-R injury in the liver and heart. Moreover, in studies of murine I-R injury, Hataishi and colleagues[121] reported that breathing NO increased nitrite concentrations in plasma and blood to levels similar to those demonstrated to be effective by Duranski and associates. More recently, Nagasaka and colleagues demonstrated that breathing NO leads to the rapid accumulation of a variety of NO metabolites in blood and tissues, contributing to the ability of brief periods of NO inhalation to provide cardioprotection against I-R injury.[145]

SAFETY ISSUES AND METHOD OF ADMINISTRATION

Prolonged inhalation of low levels of NO appears to be safe. The major clinical toxicity is due to the formation of NO_2 and methemoglobinemia. Nitrogen dioxide is rapidly converted to nitric acid in aqueous solution (e.g., acid rain) and is highly toxic to the respiratory tract. Increased airway reactivity in humans occurs after exposures to as low as 1.5 ppm NO_2.[146] At higher inhaled NO_2 doses, pulmonary edema is the major toxicologic effect[147] and can result in rapid death after inhalation exposure.[148]

Inhaled NO can combine with Hb to form nitrosyl-Hb, which is rapidly oxidized to metHb. The rates of uptake and release of NO from ferrous (Fe^{2+}) Hb are 10^5- to 10^6-fold greater than those of oxygen. Tissue hypoxia can be produced at excessive circulating metHb concentrations. In general, cyanosis does not appear until metHb levels approach 15% to 20%, and clinical symptoms of hypoxia (e.g., fatigue, dyspnea) become significant at metHb levels above 30% of the Hb concentration.[149] The enzyme metHb reductase rapidly converts metHb to Hb in the red blood cell. Because neonates have reduced activity of this enzyme, they are at greater risk than adults for developing significant methemoglobinemia after inhaling high levels of NO for a prolonged period.[149] Blood metHb concentrations and inspired NO_2 concentrations were frequently monitored in clinical trials of inhaled NO in both adults and neonates.[5-7, 80] In a large number of adult (n = 120) and newborn patients (n = 351) pooled from several clinical trials, significant methemoglobinemia or NO_2 formation was uncommon in patients breathing NO at doses ranging from 1.25 to 80 ppm. (See summary table in a study by Steudel and others.[20]) If metHb or NO_2 levels increased above predetermined limits, then the concentration of inhaled NO was decreased. Discontinuation of NO administration because of excessive NO_2 or metHb formation was necessary in only 3 of 471 patients (0.6%).

Inhaled NO is a selective pulmonary vasodilator in patients with heart failure, although breathing NO can be accompanied by an elevation of LV filling pressure in patients with severe LV dysfunction.[59,150] Taken together with the in vitro experimental evidence of a direct negative inotropic action of NO,[151,152] these clinical observations led to the concern that inhaled NO may clinically exert important negative inotropic effects in patients with impaired LV function. However, investigators learned that the elevation in LV filling pressure that occurs with NO breathing is due to the augmentation of filling into a relatively noncompliant LV and is not caused by a negative inotropic effect.[153] An observation in patients with heart failure who received mechanical LV assistance supported the concept that inhaled NO increases LV filling pressure only when cardiac output is not assisted.[154] Nonetheless, being aware of the possibility that inhaled NO can produce pulmonary vasodilation and may overwhelm a failing LV, thereby producing pulmonary edema, is important.

OTHER INHALED PULMONARY VASODILATORS

BACKGROUND

The successful clinical use of inhaled NO as a selective pulmonary vasodilator prompted the search for other alternatives, at least, in part, as a result of the significant cost of inhaled NO therapy (e.g., $3000 per day with a $12,000 monthly cap) in the United States.[155] A wide variety of intravenous vasodilators were clinically tested via the inhaled route. These vasodilators include prostacyclin (PGI_2)[156]; milrinone[157]; nitroglycerine[158]; sodium nitroprusside[159]; prostaglandin E_1[160] and a stable analogue of PGI_2, epoprostenol[161]; and iloprost.[162] It was expected that inhalation of intravenous vasodilators would maximize drug levels in the lung while minimizing their systemic effects (see Fig. 104-5). Although some studies have reported encouraging results in the perioperative off-label use of these drugs via off-label route of administration (i.e., inhalation), especially with inhaled epoprostenol,[161,163,164] at the time of this writing, efficacy and the safety profile of these inhaled vasodilators have not been established. As a result, no general consensus exists as to when and how to use these inhaled vasodilators. (The use of epoprostenol at the author's institution is described in the next section as an example.)

INHALED EPOPROSTENOL

At Massachusetts General Hospital, epoprostenol (Flolan) has been used to treat intraoperative pulmonary hypertension during cardiac surgery and postoperative

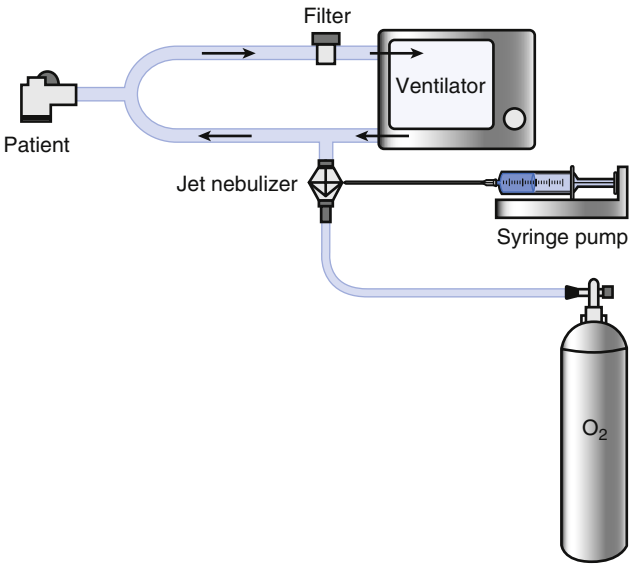

Figure 104-7. Diagram illustrating a sample setup of inhaled administration of epoprostenol in patients on ventilation. O_2, Oxygen.

pulmonary hypertension, RV dysfunction, or refractory hypoxemia in the ICUs in adult and pediatric patients. In adults, inhaled epoprostenol (30,000 ng/mL) is administered using a syringe pump and jet nebulizer connected to the inspiratory limb of the ventilator[163] (Fig. 104-7). The usual starting dose is 30 ng/kg/min and can be increased up to 50 ng/kg/min. In pediatric patients, drug concentration and air flow is adjusted accordingly.

Limitation: Although a brief exposure to inhaled PGI_2 or its analogues decreases PVR similar to inhaled NO,[165,166] PGI_2 and its analogues are known to cause systemic hypotension when large doses are inhaled.[166] The plasma half-life of epoprostenol is sufficiently long (~6 minutes) to allow for systemic effects, and systemic arterial levels of an active metabolite have been measured during inhalation of even small doses of epoprostenol. Furthermore, epoprostenol must be dissolved in a highly viscous and basic glycine diluent (pH = 10.5) that is associated with tracheitis,[167] interstitial pneumonia,[168] and ventilator valve malfunction.[169] Replacement of the ventilator filter every 2 hours is recommended to avoid possible valve malfunction. Last, although the drug cost associated with inhaled epoprostenol is claimed to be smaller than that of inhaled NO, a robust cost comparison taking into account the impact of prolonged therapy on the overall cost has not been made. For example, if one therapy reduced ICU stay by 1 day or the need for a RV assist device or ECMO perfusion, then the difference in drug cost would be incidental. Further studies appropriately designed to address these issues are needed to better define the role of other *less selective* inhaled pulmonary vasodilators.

CONCLUSIONS

Inhaled NO is the first vasodilator to produce truly selective pulmonary vasodilation. It is characterized by pulmonary vasoselectivity, and it also increases arterial oxygenation and enhances pulmonary $\dot{V}/\dot{Q}$ matching by increasing blood flow to ventilated regions of the lung. A large number of laboratory and clinical research studies have been performed to delineate its biochemistry, physiologic characteristics, side effects, and clinical efficacy in various diseases of children and adults. Nearly simultaneously, the clinical use of inhaled NO has become widespread. An estimated 20,000 patients are treated with inhaled NO annually in the United States. During the past 16 years, inhaled NO has been used to treat pulmonary hypertension and hypoxemia in over 100,000 pediatric and adult patients worldwide. For many, inhaled NO is lifesaving. The experimental use of inhaled NO continues to be a unique and fascinating approach to studying and treating diseases as diverse as acute rejection of the transplanted lung and sickle cell crisis. It is critical that a single study of a particular disease state not influence an evaluation of this complex field. As with most medical advances, the accumulation of a wide-ranging body of clinical research will eventually determine the place of NO inhalation therapy in the therapeutic armamentarium for many diseases.

Chapter 105

Neurocritical Care

MICHAEL J. SOUTER • ARTHUR M. LAM

Key Points

- Critical care of the nervous system is based on support of cerebral and spinal cord physiology and the prevention of secondary insults. This goal, in turn, depends on the comprehensive maintenance and adequacy of cardiopulmonary, gastrointestinal, renal, and endocrine function.
- Cerebral function is critically dependent on perfusion and oxygenation matching metabolism. Increased intracranial volume beyond the capacity of compensatory mechanism increases intracranial pressure (ICP) and may diminish perfusion adversely. The resulting cellular energy failure both initiates and propagates edema and inflammation.
- The resolution of cerebral edema depends on hydrostatic and osmolar forces applied to the blood-brain barrier. Excesses of perfusion pressure or intravascular hypotonicity worsen edema and must be avoided. Blood-brain barrier disruption varies over time and by pathologic process, and it affects the ability of hypertonic agents to exert an osmotic effect.
- Fever is frequently overlooked in the neurocritical care unit, but it significantly affects patient outcomes across a range of pathologic processes.
- Neurologic monitoring comprises placement of appropriate monitoring devices, as well as prompt response and institution of therapy to changes detected. The goal is to optimize the physiologic environment, despite the current lack of level 1 evidence to support the majority of monitors in common use. Clinical examination of neurologic function remains a crucial part of monitoring and care.
- The incidence of traumatic brain injury has declined, but this disorder remains a disease of the young, with enormous long-term socioeconomic impact. Prompt surgical appraisal is mandatory. Decompressive craniectomy after diffuse injury is not currently recommended. Hypothermia may still offer benefit in refractory intracranial hypertension. Corticosteroids are contraindicated.
- After the initial hemorrhage, mortality and morbidity from subarachnoid hemorrhage (SAH) arise from cerebral ischemia. Medical therapy for this complication involves augmentation of perfusion pressure, maintenance of blood volume, and optimization of oxygen delivery. Endovascular therapy with angioplasty with or without chemical vasodilation plays an important role in treating vasospasm. SAH may be accompanied by significant pulmonary, cardiovascular, or endocrine effects.
- Successful therapy for ischemic stroke is contingent on a time window of viability. Urgent appraisal and rapid treatment are crucial to a good outcome. Endovascular therapy and ultrasound are going to play an increasing role in conjunction with advances in magnetic resonance imaging.
- Injury to the spinal cord necessitates careful observation of respiratory adequacy because conditions may deteriorate before any observed improvement occurs. Fatigue is frequently a factor.
- Infectious disease of the central nervous system demands an aggressive approach to resuscitation, cerebrospinal fluid sampling, and early empiric antibiotic therapy, similar to that for sepsis.

Critical care of the central nervous system (CNS) involves collaboration among several disciplines—neurosurgery, neuroanesthesia, neurology, neuroradiology, and electrophysiology. Each discipline offers unique contributions, which, in partnership, provide optimal care not only to the injured brain but also to the cardiopulmonary, endocrine, gastrointestinal, and renal systems that support cerebral physiology. Integration of the complex goals of this care relies on the physician specializing in neurocritical care, which increasingly is recognized as an important subspecialty.[1]

The use of a neurocritical care team, rather than single specialty care, has been associated with reduced in-hospital mortality and length of stay.[2] Although the brain has a certain preeminence among the organs of the body, it relies on a stable platform of organ function elsewhere to enable homeostatic control and mechanisms of repair and recovery. Injury to the brain is associated with and precipitates a wide spectrum of dysfunction of other organ systems (Box 105-1). Although other specialists can train to be neurointensivists, anesthesiologists with training in neuroanesthesia and critical care are particularly well suited to demonstrate the combination of airway and cardiovascular support skills that, together with an understanding of the physiology and pharmacology of the nervous system, may improve outcome.

BOX 105-1 ***Potential Systemic Complications Associated with Serious Brain Injury***

Global	Pyrexia
	Inflammatory activation
Cardiovascular	Arrhythmia: bradycardia, tachycardia, atrial fibrillation
	Hypertension
	Hypotension
	Left ventricular dysfunction
Respiratory	Apnea
	Pneumonia: aspiration, hypostatic, ventilator associated
	Pulmonary edema
	ARDS
Gastrointestinal	Gastric erosion
	Ileus
	Constipation
	Perforation
	Malabsorption
Renal	Dehydration
	Acute renal failure
	Urinary tract infection
Hematologic	Anemia
	Leukocytosis
	Coagulopathy, disseminated intravascular coagulation
	Deep venous thrombosis, pulmonary embolism
Metabolic or endocrine	Hyponatremia, hypernatremia
	Hyperglycemia, hypoglycemia
	Hypokalemia, hyperkalemia
	Hypomagnesemia
	Hypophosphatemia
	Catabolic azotemia
	Rhabdomyolysis

ARDS, Acute respiratory distress syndrome.

INTRACRANIAL PHYSIOLOGY AND CEREBRAL AUTOREGULATION

The cerebrovascular circulation is constrained by a rigid perimeter of bone (see also Chapter 17). After exhaustion of limited compensatory mechanisms, the bony confines of the skull mandate increasing intracranial pressure (ICP) consequent to increasing intracranial volume. The change in ICP with change in intracranial volume is often referred to as the intracranial compliance curve, but it is more appropriately termed the *intracranial elastance curve* (Fig. 105-1).

Thus, an increase in elastance implies poor compliance, and a small change in volume can lead to an inordinate increase in pressure. These changes in volume arise from increments in intracranial tissue or fluid content (i.e., blood, interstitial fluid, or cerebrospinal fluid [CSF]). Tissue content is relevant insofar as mass lesions reduce intracerebral compliance and accentuate the effects of fluid changes.

Small increases in volume can be accommodated by an outflow of CSF from the cranial cavity into the spinal canal that produces the exponential pressure-volume relationship (see Fig. 105-1).

The cranial vault is compartmentalized by the falx cerebri and tentorium cerebelli, which creates the possibility of internal pressure gradients (Fig. 105-2). This may induce physical protrusion of brain tissue through the "apertures" of the compartments—herniation. Brain tissue may be injured directly but also indirectly by deforming and compressing vasculature adjacent to the dural margin.[3] This is typically seen in severe lateral herniation ("midline shift") when the anterior cerebral vasculature may be obstructed, thus producing frontal lobe infarction.

Pressure gradients are initially hydraulically equilibrated, with CSF moving between ventricular chambers and to the extracranial spinal space. The compensation achieved is limited by the CSF volume available to be displaced; ultimately, changes in volume will induce tissue displacement. This displacement may also contribute to impedance of CSF drainage either by occlusion of the foramina of Monro in the case of lateral herniation or by occlusion of the third ventricle and aqueduct by supratentorial herniation through the tentorial gap. This situation typically gives rise to clinical features of midbrain structure compression. Unilateral papillary dilation, ipsilateral or even contralateral paralysis (the Kernohan notch phenomenon), and abnormalities of respiration are apparent in the spontaneously breathing patient. If the herniation continues, it will result in cerebellar descent through the foramen magnum with consequent compression of the brainstem, thus producing bilateral papillary fixation, either tachycardia or bradycardia, and systemic hypertension.[4] Changes in cerebral mass secondary to increase in venous blood volume also arise from obstruction to

venous drainage by compression of the easily susceptible bridging veins draining from cortex to venous sinuses. Once an individual threshold of compliance is crossed, changes in volume exert a mass effect on the draining veins, which act as Starling resistors. This effect decreases drainage, which, in turn, amplifies and prolongs pressure increases. Blood volume increases may be extravascular (i.e., hemorrhage) or intravascular (i.e., accumulation within a predominantly venous capacitance circulation). Venous circulation comprises approximately 75% of the cranial blood volume, whereas approximately 25% of vessels are arteries, arterioles, and capillaries.

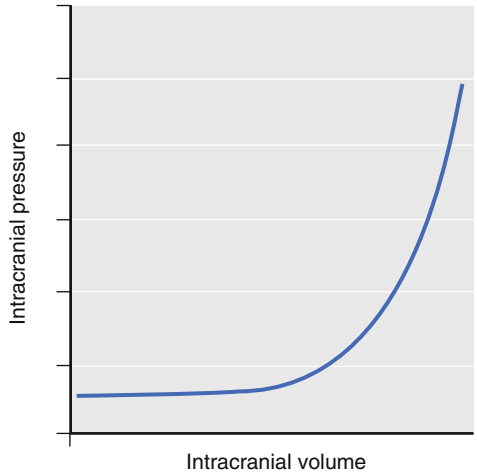

Figure 105-1. Intracranial pressure-volume relationship.

The other main fluid mass effect is through edema, either cytotoxic or vasogenic.[5,6] Cytotoxic edema results from hypoxia, with swelling of the intracellular compartment, whereas vasogenic edema in the interstitium usually develops from a breach of the blood-brain barrier, often in response to high blood pressure.[7]

Thus, changes in the control of cerebral blood volume may have significant effects on ICP. The cerebral vasculature responds to changes in arterial pressure, arterial partial pressure of carbon dioxide ($Paco_2$), or partial pressure of oxygen (PO_2), by dynamically altering arteriolar caliber to maintain a constantly matched cerebral blood flow (CBF) sufficient to meet metabolic demands (Fig. 105-3). The pH, $Paco_2$, potassium, and adenosine are among many purported metabolic mediators of flow.[8]

CBF control may be directly compromised by brain injury or by abnormalities of respiration and arterial blood pressure. In turn, this may increase venous volume by allowing an excessive arterial inflow that venous

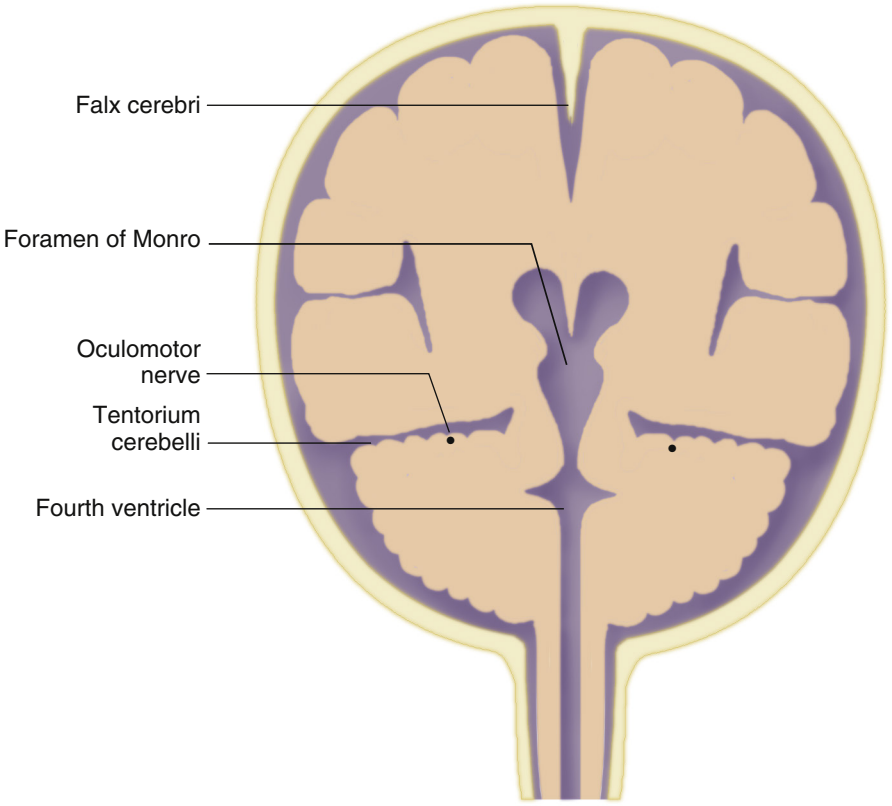

Figure 105-2. Schematic of intracranial compartments: coronal section.

drainage cannot match, thereby increasing ICP. Consequently, untoward events, including hypotension, airway obstruction, fever, and seizures, produce what is termed a *secondary physiologic insult*. This has been demonstrated to induce further harm to the vulnerable brain and, in so doing, worsen outcome.[6,9]

A reduction in substrate delivery (i.e., oxygen and nutrients) to less than the threshold necessary to maintain cellular viability produces cell injury with cytokine and chemokine release. This inflammatory amplification expands the injury,[10] disrupts the blood-brain barrier function, and may directly lead to apoptosis. The disruption of the blood-brain barrier creates vasogenic edema and allows serum proteins to cross into brain parenchyma, with prolonged effects. This process is more evident in the more metabolically active gray matter than in white matter.[5] Most changes peak in the first 48 hours, but one study identified up to 25% of ICP peak increases occurring after day 5.[11]

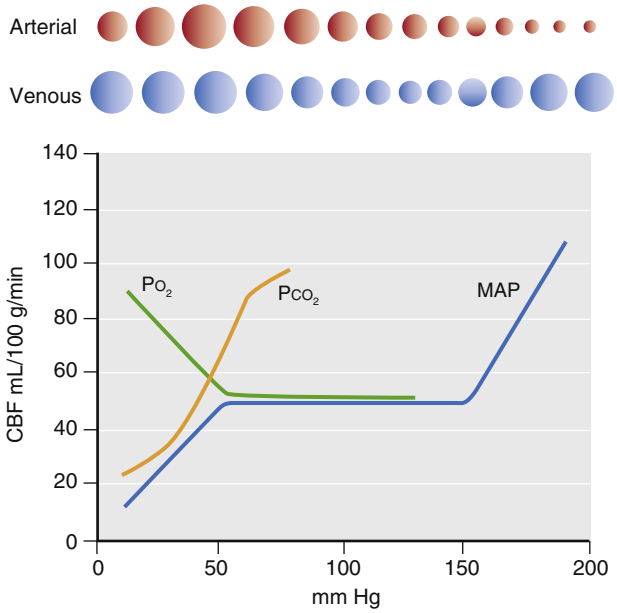

Figure 105-3. The influence of changes in mean arterial pressure (MAP), arterial partial pressure of oxygen (PO_2), and arterial partial pressure of carbon dioxide (P_{CO_2}) upon cerebral blood flow (CBF). Vascular diameter changes shown are in response to MAP.

GENERAL CARDIOPULMONARY CONSIDERATIONS

Any deterioration in ventilatory efficacy may adversely affect cerebral compliance (elastance) through carbon dioxide–induced vasodilation. Concerns have been expressed about the effect of positive end-expiratory pressure (PEEP) in this situation, but the decreased pulmonary compliance necessitating the PEEP also limits intrathoracic pressure transmission to the cerebral circulation.[12] The net benefit of improved ventilatory efficacy from PEEP outweighs any mild disadvantages from its use. However, injudicious use of PEEP in circumstances of hypovolemia may reduce functional venous return and hence reduce cardiac output, with consequent effects on cerebral perfusion.[12]

Reductions in cardiac output and arterial blood pressure can initiate reflex cerebral vasodilation, which is the brain's attempt to preserve CBF. Hypotension is a well-documented source of worsened morbidity,[13,14] whether the decrease in blood pressure results from underresuscitation or iatrogenic mechanisms. This vasodilation increases venous blood volume and further diminishes cerebral perfusion pressure (CPP).[15]

Hypoxemia can cause direct as well as indirect injury to the brain. Hypoxemia less than 60 mm Hg is a significant contributor to secondary insult from vasodilatory ICP effects, in addition to the reduction in the oxygen gradient to the cell. The resultant reduction in cerebral perfusion, irrespective of primary cause, may cause further deterioration by depressing the level of consciousness, in turn leading to airway compromise, hypoventilation, and further decrease in oxygenation (Fig. 105-4). Consequently, pulmonary compromise is often seen in neurologic patients with altered mental status, as a result of impaired airway reflexes and repeated aspiration episodes, culminating in a significant incidence of pneumonia, irrespective of the initiating pathologic process.[16]

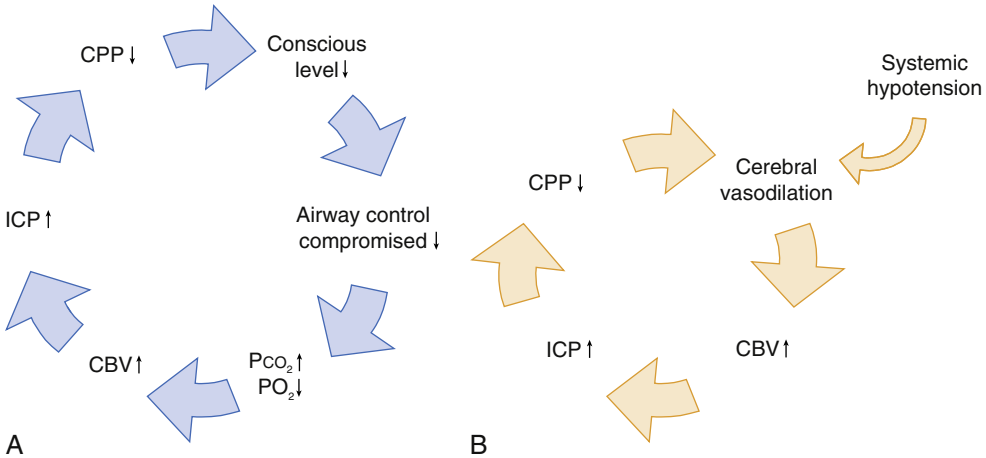

Figure 105-4. A, Ventilatory-neurologic circle of dysfunction. Induced changes in partial pressure of carbon dioxide (P_{CO_2}) and partial pressure of oxygen (PO_2) produce changes in cerebral blood volume (CBV), intracranial pressure (ICP), and cerebral perfusion pressure (CPP). This, in turn, impairs ventilatory control. **B,** Hemodynamic-neurologic circle of dysfunction. Similar to the diagram in **A**, systemic hypotension induces cerebral vasodilation, with increased CBV, increased ICP, and reduced CPP, which, in turn, increases vasodilation.

Another potential mechanism is the release of cytokines from the brain in response to the inflammatory process triggered by an injury; this release may be sufficient to induce acute respiratory distress syndrome (ARDS) and systemic inflammatory response syndrome (SIRS).[17,18] Moreover, the large tidal volume ventilation delivered during initial hyperventilation can enhance the development of ARDS[19] (see also Chapters 101 to 103). This may create a therapeutic dilemma in the presence of cerebral pathophysiology. However, the "open lung" concept (i.e., small tidal volumes, high frequencies, and high PEEP) developed to minimize alveolar distention and reduce lung injury appears to be feasible in neurosurgical patients despite theoretic concerns for adverse effects on ICP.[20]

The relationship between $Paco_2$ and CBF can be exploited in examining the response of ventilated patients to tests of spontaneous breathing. Restoring $Paco_2$ to normal may increase ICP, a finding indicating limited craniovascular compliance. Understanding this situation may guide subsequent therapy and ventilatory strategy, and ICP effects should be considered during any weaning process.

FLUIDS AND ELECTROLYTES

Normally, capillary fluid shift is a function of hydrostatic pressure pushing fluid out and the balance of osmotic forces retaining fluid within[21]:

$$Jv = Kf\,([Pc - Pi) - \sigma\,[\pi c - \pi i])$$

where Jv is the net fluid movement between compartments, Pc is the capillary hydrostatic pressure, Pi is the interstitial hydrostatic pressure, πc is the capillary osmotic pressure, πi is the interstitial osmotic pressure, Kf is the filtration coefficient (this is a product of surface area and hydraulic conductivity), and σ is the reflection coefficient (the membrane impermeability toward osmotically active particles). In extracranial capillaries, these osmotic forces derive from oncotic pressure because smaller solutes can cross the capillary basement membrane following concentration gradients and only large protein molecules remain to exert effect.

However, in the brain, because of the presence of tight junctions in the endothelium, this intact blood-brain barrier reflects smaller solutes (e.g., sodium and chloride ions), and this relative impermeability renders cerebral capillary fluid shift a function of hydrostatic and *total* osmolar forces, with the oncotic pressure playing a very small part and the fluid shift most dependent on the osmolar gradient. In the absence of externally administered osmotically active substances (e.g., mannitol), this gradient is largely determined by sodium concentration, as serum osmolality.

$$\text{Serum osmolality} = (\text{serum Na}) \times 2 + \text{glucose}/18 + \text{BUN}/2.8$$

where Na is sodium and BUN is blood urea nitrogen.

Thus, in general, hypotonic solutions should not be used in the neurosurgical patient when edema is a significant consideration. The osmolalities of commonly used solutions are listed in Table 105-1.

At the same time, the tighter endothelial connections and lipid bilayers also serve to reduce water permeability and hence the filtration coefficient. This physiologically limits the water shift across the vascular bed in response to changes in tonicity; otherwise, the brain volume would be significantly reduced by the large osmotic forces created by changes of only a few milliosmoles per kilogram. Net fluid shift across the blood-brain barrier therefore depends on water permeability, as defined by the filtration coefficient, and solute permeability, as defined by the reflection coefficient. This process permits osmotic diuresis, in which substances reflected by the blood-brain barrier can exert a significant effect on brain water (e.g., mannitol and hypertonic saline).

Inadequate perfusion and supply of substrate, whether relative or absolute, induces energy failure. This process translates into real effects on the integrity and function of the blood-brain barrier, which is an energy-dependent physiologic construct, as opposed to a purely anatomic structure. Ischemia and rapid reperfusion are associated with the generation of matrix metalloproteinases that directly attack the proteins sealing the connections between the endothelial processes that make up the blood-brain barrier.[22] This condition creates a loss of integrity and increased porosity of the blood-brain barrier that pathologically affect the permeability and reflection coefficients. This acute blood-brain barrier disruption may allow solute shifts into the parenchyma and result in brain swelling, the extent of which depends on the "leakiness" of the blood-brain barrier, as well as the size and concentration of the osmotically active molecules on either side of the barrier.

Hence, intravascular fluid therapy must be carefully considered under circumstances of cerebral ischemia and inflammation. The brain exerts homeostatic control on metabolic and endocrine activity, and neurologic dysfunction can manifest as untoward changes in fluid and electrolyte balance. Diabetes insipidus is a florid example of this, with polyuria, subsequent hypovolemia, and, if the disorder is left untreated, systemic hypotension. Iatrogenic causes may also include the use of osmotic diuretics, sedation, and analgesics. Sympathetic denervation as

TABLE 105-1 SODIUM CONTENT, OSMOLALITY, AND ONCOTIC PRESSURE OF COMMONLY USED INTRAVENOUS FLUIDS

a consequence of brainstem or spinal cord injury may also contribute to reductions in venous return as a result of increased vasodilatation and peripheral venous pooling.[23]

The increased sympathetic discharge commonly accompanying cerebral insults can also manifest as extracerebral stress on the entire body with increased incidence of gastric stress erosion, hypercatabolism, hyperglycemia, and impaired glucose tolerance.[24]

Nutrition requirements are often increased after brain injury, and evidence suggests improved outcome with the early use of enteral nutrition (see Chapter 106).[25]

Hyperglycemia is a potent aggravator of cerebral insult.[26] However, tight glycemic control with aggressive insulin therapy worsens the outcome of critical care patients in general and may worsen cerebral metabolic stress (see also Chapter 39).[27,28] Moderate glycemic control is advocated.

FEVER AND INFECTION

More than 50% of patients in neurologic intensive care units (ICUs) develop fever.[29] This condition is an often overlooked insult to the compromised brain, thus increasing oxygen utilization and metabolic stress.[29] Patients within the ICU have multiple risk factors for infection and sepsis, including the presence of a variety of indwelling catheters (e.g., arterial, venous, CSF). Other potential causes of fever include intracranial hemorrhage and idiosyncratic drug effects (e.g., the anticonvulsant phenytoin).[29,30] Fever is associated with a worsened outcome after neurologic injury, including intracranial hemorrhage, subarachnoid hemorrhage (SAH), and stroke. A meta-analysis of available studies demonstrated an increase in neurologic morbidity and mortality associated with fever.[31]

Although hypothermia has not proven to be a successful intervention for patients with traumatic brain injury (TBI)[32] or SAH,[33] this finding does not equate to a lack of beneficial effect of normothermia compared with hyperthermia, and many clinicians are increasingly aggressive in preventing and treating fever.[34]

To provide appropriate treatment for fever, it is necessary to perform daily reappraisal to delineate the source of fever, given the large number of potential causes. However, in many cases a cause cannot be determined, and empiric treatment including scheduled administration of acetaminophen, application of cooling blankets, and, increasingly, more invasive methods of cooling are required.

MONITORING

The avoidance or correction of secondary physiologic insults necessitates the aggressive use of physiologic monitors (see Chapter 49 and Fig. 105-5). This monitoring does not obviate the need for regular clinical examination

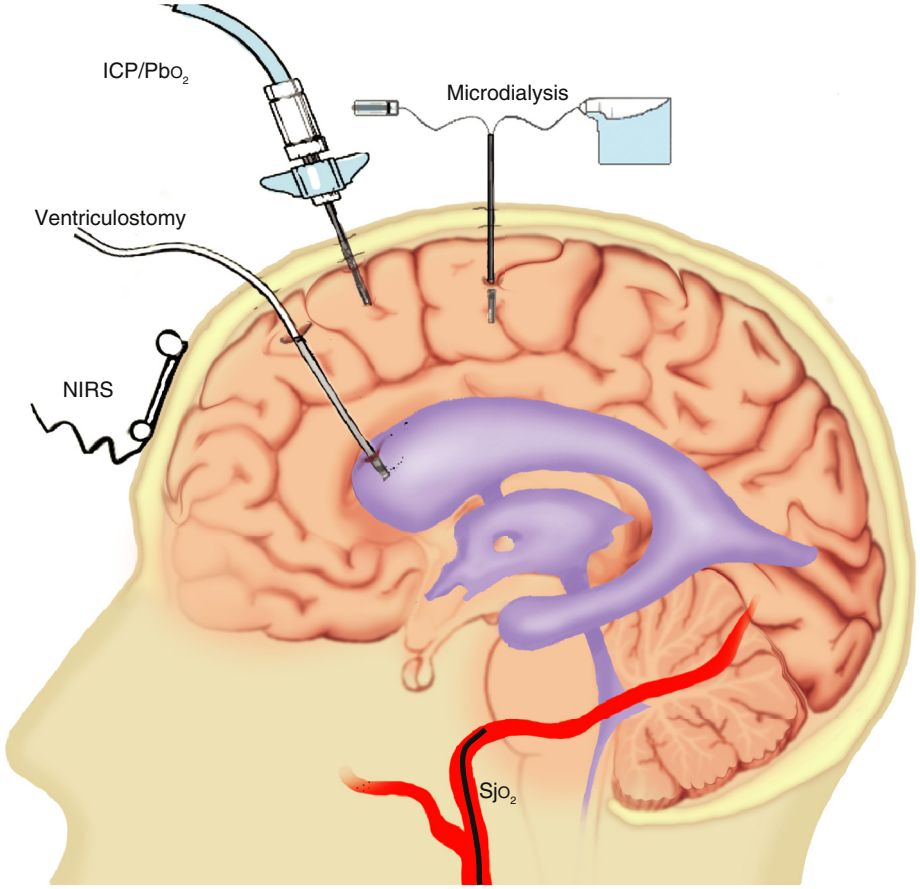

Figure 105-5. Schematic of available intracranial monitoring, with near-infrared oximetry (NIRS), intracranial pressure (ICP, either by ventriculostomy or parenchymal probe), brain tissue oximetry (Pbo_2), microdialysis, and jugular venous oximetry (Sjo_2).

of the CNS, with observation of the response to stimuli. Monitors (e.g., processed electrical activity, cerebral oxygenation, and ICP) are merely surrogates of actual cerebral function. Similarly, attention should be paid to the basics of fluid volume status, respiratory rate, cardiovascular stability, and metabolic consumption.

INTRACRANIAL PRESSURE

ICP monitoring quickly became a standard of care after its introduction to clinical use in the 1970s, thereby making subsequent determinations of utility and effectiveness difficult. Nevertheless, a NIH sponsored randomized controlled trial has been performed in Latin America, demonstrating no overt benefit of ICP monitoring.[36] Noninvasive monitors have not established sufficient reliability and remain the subject of research. While recent data suggests that ICP monitoring has minimal effect on outcome,[35] monitoring must guide therapy to be effective and ICP data should remain as one of the components influencing but not replacing clinical appraisal. Most neurosurgical centers still insert such devices routinely in the management of patients with TBI and SAH, by using defined thresholds (e.g., ICP > 25 mm Hg) to trigger treatment interventions, including osmotic agents (e.g., mannitol or hypertonic saline) or operative treatments (e.g., decompressive craniotomy or CSF drainage).

ICP sensors may represent only the compartment pressure where they were placed (see Fig. 105-2), and they may not be sensitive to acute transients in pressure on the other side of the falx or tentorium.[37] Intraparenchymal fiberoptic devices are less invasive and easier to place, but they may be calibrated only ex vivo and cannot drain CSF. Thus, provided the ventricles are accessible, ventricular catheters remain the "gold standard" of measurement, albeit at the expense of an increased risk of infection of approximately 6%.[38]

When the ventricles are small, this monitoring becomes technically difficult, and the risks of hemorrhage and contusion are increased.

ICP devices can be quickly placed with a minimum of morbidity in experienced hands and, provided suitable attention is paid to the issue of potential drift from calibration,[39] generally offer useful insights to guide therapeutic interventions. However, placement of these devices is contraindicated in the presence of coagulopathy or platelet dysfunction.

Observation of ICP monitoring trends reveals characteristic patterns that may have prognostic implications (e.g., the Lundberg "A" or "plateau" ICP wave indicating critical cerebral compliance[40] and impending herniation).

CEREBRAL BLOOD FLOW

Important threshold values for function were identified by Symon and others (Table 105-2).[41] The initial methods of quantitative CBF measurements were laborious and time consuming and did not offer accurate regional estimates.[42] These methods were replaced by the use of isotopic tracers that allow basic regional flow measurement (e.g., inhaled or intravascular xenon-133) or a combination of imaging and qualitative assessment (i.e., single photon emission computed tomography [SPECT]). Calibrated imaging techniques such as positron emission tomography (PET) and stable xenon or contrast computed tomography (CT) perfusion[42] have become standard in many centers. Magnetic resonance imaging (MRI) of perfusion is rapidly evolving and may provide quantitative flow measurement in the near future.

TABLE 105-2 **FUNCTIONAL THRESHOLDS OF CEREBRAL BLOOD FLOW**

CBF (mL/100 g/min)	Result
50	Normal
20	EEG slowing
15	Isoelectric EEG
6-15	Ischemic penumbra
<6	Neuronal death

CBF, Cerebral blood flow; *EEG,* electroencephalogram.

Although providing potentially useful information on regional perfusion, these methods often involve transporting the patient outside the ICU, a maneuver that may be clinically inappropriate in unstable circumstances.

Thermodilution is a focal technique in which small thermocouples are placed cortically. Blood flow is related to temperature diffusion at the probe.[43] An alternative approach has been to use jugular venous temperature diffusion to assess flow. Whether this measure reflects CBF reproducibly may depend on the ratio of jugular venous drainage to overall cerebral venous flow.[44] It remains to be seen whether these devices can be developed into reliable and consistent monitoring tools.

TRANSCRANIAL DOPPLER MONITORING

Transcranial Doppler monitoring uses the Doppler shift effect to assess flow velocity in insonated arteries (see also Chapter 49).[45] This method is often used as a surrogate of flow for examining accessible vessels and, in skilled hands, offers considerable insights into dynamic flow. This technique has the advantage of being a bedside, relatively speedy, and noninvasive monitor of flow within the main components of the circle of Willis through the ophthalmic, temporal, and foramen magnum acoustic windows. It has excellent temporal resolution and, being noninvasive, allows repetitive measurements with little or no risk. In a small proportion of patients, predominantly older women and black patients, temporal bone thickness may prevent monitoring.[46] Extrapolation of velocity to flow relies on an assumption of relatively constant diameter of the large conductance vessels. Under different circumstances, changes in velocity can be used to assess alterations of vascular caliber (e.g., arterial vasospasm after SAH)[47] or intracranial stenosis (Fig. 105-6). For the middle cerebral artery, vasospasm can be distinguished from hyperemia by examining the ratio between the intracranial flow velocity and the extracranial carotid artery flow velocity (the Lindegaard index). A ratio greater than 3 is generally indicative of vasospasm, whereas a ratio less than 3 is consistent with hyperemia.[48] A similar ratio has been developed for the posterior circulation by comparing the flow velocity in the basilar artery with that of the extracranial vertebral artery. A value greater

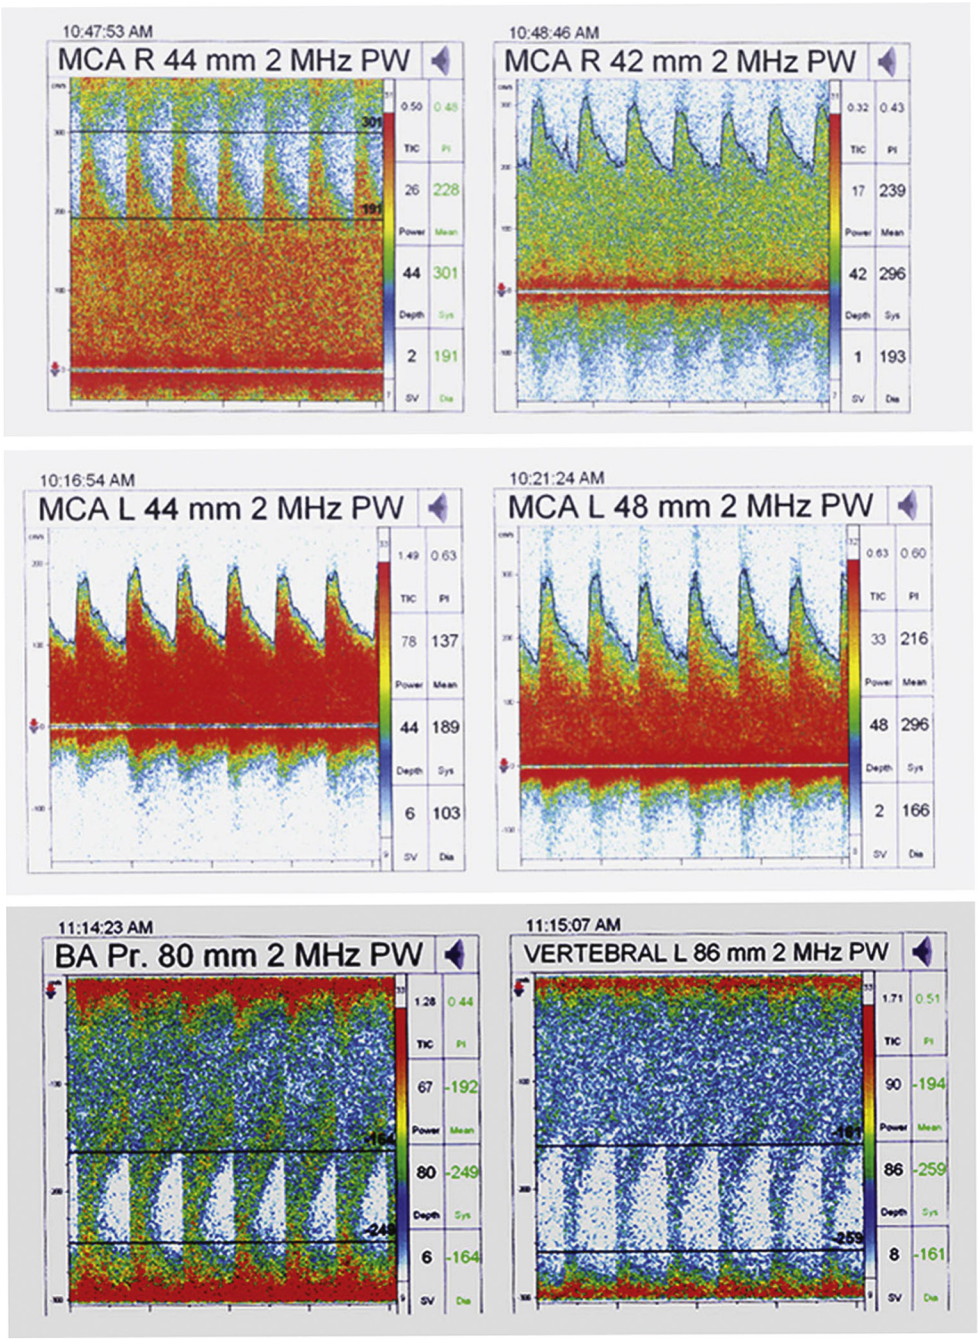

Figure 105-6. Transcranial Doppler images of elevated cerebral blood flow velocities in the middle cerebral and vertebrobasilar vessels.

than 2 with an elevated flow velocity in the basilar artery is reportedly consistent with vasospasm,[49] although this finding has been questioned by concurrent angiographic comparisons.[50]

AUTOREGULATION AND VASOMOTOR REACTIVITY

Monitors of CBF can assess the response of the cerebral vasculature to changing circumstances of metabolism and blood pressure (i.e., autoregulation).[51,52] Static cerebral autoregulation can be determined with sustained manipulation of blood pressure by using either a tilt test or a direct vasopressor as clinically appropriate, whereas dynamic autoregulation can be assessed using rapid deflation of previously inflated thigh cuffs above systolic blood pressure. Alternatively, autoregulation can be assessed by monitoring CBF velocity through transcranial Doppler in response to spontaneous fluctuation of blood pressure by using transfer function analysis, although these techniques are likely to be less reliable than the stimulus-response paradigm.[53] The presence or lack of autoregulation may guide subsequent treatment and prognosis because frequently the loss of autoregulation is associated with a poor outcome.[54,55] Cerebrovascular reserve or vasomotor reactivity, as determined by CBF response to changes in $Paco_2$, can be assessed either with rebreathing or addition of carbon

dioxide to the breathing circuit or with administration of acetazolamide.[53]

JUGULAR BULB OXIMETRY

The Fick principle may be reversed to examine the venous oxygen saturation which, assuming a constant hematocrit and metabolism, can offer an assessment of the adequacy of CBF and associated oxygen delivery relative to cerebral oxygen consumption:

$$\text{If } AVDo_2 = (CMRo_2/CBF), \text{ then } Cao_2 - Cjvo_2 = (CMRo_2/CBF)$$

Ignoring the contribution of dissolved oxygen, then:

$$(Sao_2 - Sjvo_2) \times Hgb \times 1.34 = (CMRo_2/CBF)$$

where $AVDo_2$ is the arteriovenous oxygen content difference; $CMRo_2$ is the cerebral oxygen metabolic rate; Cao_2, $Cjvo_2$, Sao_2, and $Sjvo_2$ are the arterial oxygen and jugular venous oxygen contents and saturations, respectively; Hgb is the hemoglobin concentration; and 1.34 is the oxygen affinity constant.

In vivo, catheters are placed in retrograde fashion through the internal jugular vein to its jugular bulb at the foramen or even beyond, to the large sinuses (Fig. 105-7).[56,57]

These catheters provide information related to both perfusion and oxygen consumption, in a manner analogous to the use of mixed venous oximetry for shock management. Both desaturation (<50%, suggesting inadequate delivery or excess consumption) and abnormally high saturation (>75%, suggesting hyperemia or stroke) have been associated with poor outcome.[58,59] The derivable arteriovenous oxygen content difference is possibly a more accurate assessment of the adequacy of flow and is related to outcome.[60] Jugular venous oximetry has been criticized as being insensitive to focal changes because it reflects the averaged global cerebral venous oxygen saturation from the confluence of hemispheric venous drainage. Consequently, some authors have suggested using oxygen consumption in combination with the cerebral arteriovenous gradient of lactate to make stoichiometric assessments of aerobic versus anaerobic metabolism.[61] These authors use metabolically directed management strategies, as opposed to management of cerebral hemodynamics,[62] that is, goal-directed therapy based on metabolic indices (jugular venous oxygen saturation), rather than on hemodynamic indices (ICP and CPP).

BRAIN TISSUE OXYGEN TENSION

In conceptually similar assessments of in vivo oxygenation, miniaturized Clark electrodes have been developed and combined with ICP catheters to provide simultaneous estimations of tissue oxygen tension and ICP. Pathologic levels are thought to be lower than 15 mm Hg with normal values in the 20- to 45-mm Hg range.[63] These brain tissue O_2 tension (Pbo_2) devices have been used in a variety of pathologic conditions, thus guiding therapy and providing insight into the adequacy of cerebral perfusion,[63] although Pbo_2 may alert to poor outcomes independent of CPP.[64] However, many concerns remain regarding measurement errors, calibration drifts, and uncertainty of the generalizability of the local measurement.[65] Nevertheless, in patients without focal lesions, important physiologic feedback is provided in response to therapeutic manipulations of arterial blood pressure and oxygenation.[66] The hope is that these questions will be addressed by ongoing clinical trials of Pbo_2-guided treatment protocols.[67]

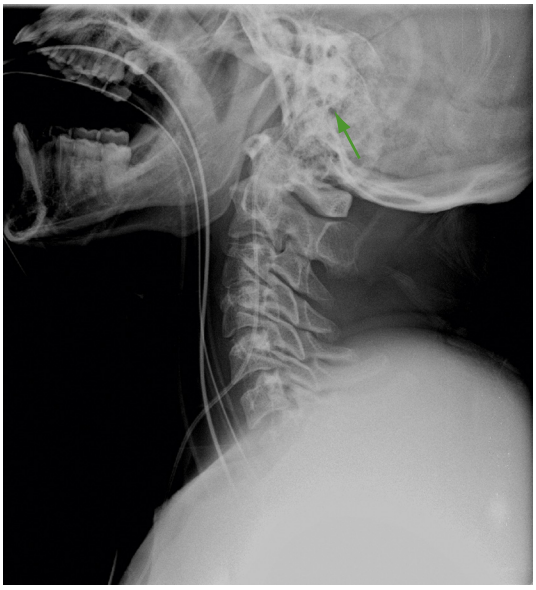

Figure 105-7. Lateral cervical spine radiograph showing appropriate positioning of the jugular venous oximetry (Sjo_2) catheter above the lower border of the C1 vertebra (the *arrow tip* is actually within the jugular foramen).

CEREBRAL MICRODIALYSIS

Interest in the use of cerebral microdialysis probes to assess the biochemical milieu of the brain is significant. These probes are placed through a burr hole and cycle small volumes of dialysate through the catheter to an extracranial collection system. Consequently, various substances can diffuse across the semipermeable membrane (e.g., lactate. pyruvate, glucose, glycerol, glutamate),[68] for collection and subsequent analysis using a bedside high-pressure liquid chromatography device. This device gives graphic and numeric displays of trended concentrations for the preceding collection interval (usually 1 hour). This information then relates to the in vivo biochemistry of the brain. Although this technique is intuitively attractive, unresolved questions have hampered its wider implementation, not the least of which is the question of the optimal site of placement, in relation both to disease and to anatomic region of gray matter versus white matter.[68]

These issues were addressed by a consensus statement on placement of microdialysis catheters, with the aims of improving accuracy in the comparison of results and allowing generalization from accumulated experience.[69] Improvements in membrane technology now permit larger molecules to cross into dialysate, thus creating the possibility of research into microvascular peptidomics.[68]

ELECTROENCEPHALOGRAPHY

The electroencephalogram (EEG) records electrical activity generated and detected by appropriately placed electrodes in a radial and axial array, as defined by the 10/20 system, an internationally standardized system of recording (see also Chapter 49). The consequent waveforms are displayed and recorded. The spectrum of component frequencies, together with amplitude and power, can be quantified and analyzed in a variety of fashions by what are termed *processed EEG monitors*. These devices can provide important diagnostic information in patients in the neurocritical care unit who cannot be otherwise assessed. The EEG tends to be used in a diagnostic snapshot mode for isolated assessments, and it is underused as a continuous monitor within the ICU. This underuse is a function of the difficulty involved in its application and interpretation, which necessitate dedicated equipment and personnel. A 24-hour continuous recording of EEG is, in general, more fruitful than a snapshot recording.

Moreover, both in TBI and in SAH, significant numbers of patients develop nonconvulsive status epilepticus,[70,71] a condition that constitutes a regularly overlooked but significant source of morbidity and stress on the brain. Whereas the EEG is a difficult monitor to use, definite indications exist for its deployment, and the neurocritical care physician should be familiar with the basic principles of its function and use.

Some related devices have also been developed from processed EEG to monitor the depth of anesthesia. Although these devices have been used to monitor the level of sedation in critically ill patients, they are not designed for—and should not be used to—monitor neurologic integrity or seizure activity.

NEAR-INFRARED SPECTROSCOPY

The idea of pulse oximetry for the brain, as conceptualized in the early 1990s, is attractive. It relies on the principle of reflectance spectroscopy, in which near-infrared light traverses bone transparently, to be scattered and reflected to a degree inversely proportional to the concentration of light-absorbing materials in tissue (e.g., hemoglobin and other tissue chromophores). The surface detector is constructed and calibrated to detect light that has ostensibly traversed down to cerebral cortex and back. An adjacent detector is positioned to detect a signal from superficial tissues, and both signals are then used in an algorithm to derive an estimated tissue saturation. However, the devices employed have been troubled by issues of reliability, specificity, and cross contamination from other cytochrome-containing tissues.[72,73] Slightly more enthusiasm exists for their role as trend monitors of flow, especially in children and patients with extracranial carotid artery disease.[74,75]

RADIOLOGIC IMAGING

Imaging can be employed as a monitoring technique, albeit on a protracted time scale.[76] The two major modalities are CT and MRI. CT is by far the most useful and commonly used technique because it is the most efficient method. MRI, although more time consuming, is more sensitive for brainstem lesions, as well as for axonal injuries. Both CT and MRI can provide information on the vascular tree, but conventional contrast angiography remains the gold standard. Assessment of intracranial masses, diffuse injury, or hemorrhage can be subsequently used to guide therapy, triage, and prognosis.[77]

To provide meaningful comparison of therapeutic modalities in clinical trials, it is important to standardize and categorize CT images. The Marshall scale has been used in TBI to stratify degrees of hemorrhage and contusion within the cranial vault, and it correlates with outcome (Table 105-3).[78,79] The Fisher scale assesses the volume of subarachnoid blood after a diagnosis of SAH.[80] There again, it has strong relationship with outcome regarding the development of vasospasm (Box 105-2A),[81] the correlation of which was further improved by the modified Fisher scale (Box 105-2B). [82] These scales rely on experienced interpretation for accuracy. Inconsistent application of the Marshall scale has been reported, a finding suggesting an urgent continued need for standardization.[83]

A more recent and exciting development in CT scanning is the capacity to estimate specific gravity of tissue (eSG), thus delivering insight into cerebral edema and tissue swelling. Such measurements taken from the first CT scan (average 4 hours from injury) have performed well as predictors of outcome at 6 months, and they also correlate with ICU length of stay and time spent ventilated.

TABLE 105-3 MARSHALL SCALE: COMPUTED TOMOGRAPHY CATEGORIES FOR HEAD INJURY

Category	Definition
Diffuse injury I	No visible intracranial pathologic process
Diffuse injury II	Cisterns are present with midline shift of 0-5 mm and/or lesion densities present; no high- or mixed-density lesions at >25 mL
Diffuse injury III	Cisterns compressed or absent, with midline shift of 0-5 mm; no high- or mixed-density lesions of >25 mL
Diffuse injury IV	Midline shift of >5 mm; no high- or mixed-density lesion of >25 mL
Evacuated mass lesion (V)	Any lesion surgically evacuated
Nonevacuated mass lesion (VI)	High- or mixed-density lesion of >25 mL; not surgically evacuated

BOX 105-2A ***Fisher Scale (Computed Tomography Scan Appearance)***

Grade 1	No blood detected
Grade 2	Diffuse deposition of subarachnoid blood, no clots, and no layers of blood >1 mm
Grade 3	Localized clots and/or vertical layers of blood ≥1 mm in thickness
Grade 4	Diffuse or no subarachnoid blood, but intracerebral or intraventricular clots present

The relative objectivity and quantitative nature of this method may offer advantages over other scoring systems.[84]

CLINICAL EXAMINATION

Comprehensive neurocritical care encompasses the ability to perform a competent neurologic examination. Reproducible and objective assessment of neurologic function is as important a monitor as some of the sophisticated technology mentioned earlier, with the advantage that it offers better insight into global function of the nervous system and allows integration of information in an inherently complex dynamic system. One of the most basic yet important examinations is the pupillary light reflex, the unilateral absence of which may indicate midbrain compression from uncal herniation and neurologic emergency. Bilaterally absent papillary reflexes signify imminent or established cerebellar herniation, but this may be reversible with rapid efficacious treatment.

Clinical scales have been devised for common neurologic settings. The Glasgow Coma Scale (GCS) is a well-known, universally if inconstantly applied scale (Table 105-4). It relies on independent assessment of eye opening, speech, and best motor movement in response to progressive trials of command, voice, and noxious stimuli.[85] The Hunt and Hess scale (Table 105-5), when applied to patients with SAH, offers classification and prognostication of mortality.[86] The World Federation of Neurologic Surgeons (WFNS) scale is the preferable rating because it uses the more prevalent GCS but with a modifying component of focal deficit (Box 105-3).[87] Knowing and using these scales are crucial to understanding the terminology and practice of neurocritical care.

BOX 105-2B *Modified Fisher Scale (Computed Tomography Scan Appearance)*

Grade 0	No blood detected
Grade 1	Thin* subarachnoid blood, no intraventricular hemorrhage
Grade 2	Thin subarachnoid blood, with intraventricular hemorrhage
Grade 3	Thick subarachnoid blood, no intraventricular hemorrhage
Grade 4	Thick subarachnoid blood, with intraventricular hemorrhage

*Vertical thickness of 1 mm separates thin from thick subarachnoid hemorrhage.

MULTIMODALITY MONITORING

No single monitor credibly and reliably offers insight into the functioning physiology of the brain. Instead, various surrogates of function are offered. Many criticisms can be directed at each individually, but an interesting concept is that of multimodality monitoring, which uses a combination of parameters to improve on accuracy of diagnosis and guidance to management.[88] Although it is an attractive concept, the precise implementation of this idea is still in its early days, with little methodologic standardization; this standardization may be facilitated by rapidly approaching commercial development.

COMMON DISEASES IN THE NEUROCRITICAL CARE UNIT

HEAD INJURY

The treatment of TBI was one of the initial emphases of neurocritical care (see also Chapter 81). Changes in road traffic legislation and enhancements in passenger protection have led to a decline in the incidence of TBI in the United States, to the degree that motor vehicle accidents have been replaced by falls as the chief cause of injury.[89] These causes, together with assaults and off-road and sporting injuries, still contribute to what is referred to as a silent epidemic,[89] accentuated by ongoing military conflicts and their hallmark blast injuries,[90] as well as a prevalence consequent on concentration in a predominantly youthful population. Outside of wartime, these causes usually share a common factor in the contribution from alcohol consumption.[91,92]

In all circumstances, brain structure is deformed by the transmission of kinetic energy. The distribution of this damage covers a wide spectrum from localized contusion to diffusely scattered foci, varying with the circumstances of the incident and the architecture of the victim's brain. Typically, cerebral contusions are located at the bony prominences of the skull, at the sphenoid wing and petrous ridge.[93] This variability in inflicted

TABLE 105-4 **GLASGOW COMA SCALE**

Grade 5	GCS score of 3-6, motor deficit absent or present

GCS, Glasgow Coma Scale.

pathologic features introduces significant heterogeneity in presentation and behavior, and it confounds some broader assumptions on time course and care. A patient with a temporal lobe injury may behave very differently from a patient with a posterior fossa lesion.

TBI may also be classified according to whether it is blunt or penetrating. Penetrating injury may again have widely varying consequences depending on site, depth, and energy, but is generally fatal if it bilaterally traverses the midbrain.[94] Although initial mortality from penetrating injury is higher, outcome in survivors is similar to that for nonpenetrating injury.[95]

Vascular injury may affect more superficial arterial blood vessels, as seen in the middle meningeal artery injury typical of pterional fracture. This injury commonly results in an extradural hematoma.[96] These rapidly expanding collections can result in swift neurologic deterioration and devastating results, if not treated quickly. The mortality is between 15% and 20%.[97] Alternatively, cortical bridging veins between cortex and the dural venous sinuses are often torn by rotational or acceleration-deceleration forces to produce an accumulating subdural hematoma. This may manifest slowly and may even be unaccompanied by signs of external trauma. In the time taken for the venous hematoma to develop, symptoms may be subtle and, unfortunately, may be disregarded. The slow expansion exerts a cumulatively damaging effect, which by the time severe signs eventually manifest may be just as or even more destructive than a rapidly expansile lesion.[98] This injury is prevalent in older patients, in whom the process of senile cerebral atrophy results in greater tension on the bridging veins crossing an increasing distance, thus rendering these vessels all the more susceptible to rupture.

In all these scenarios, the primary pathologic process is accentuated by secondary features of elevated ICP, diminution of arterial inflow, and consequent reduction in CPP, with resulting tissue hypoxia and cell death, as previously described in discussion of the intracranial pressure-volume relationship (see Fig. 105-1).

This process can also be modified adversely by loss of autoregulation, which may result in further increases in ICP. This condition is often seen in diffuse injury, in which although individual foci may be small, they additively combine to produce a total burden of inflammatory change sufficient to overwhelm autoregulation.[99]

Traumatic SAH (tSAH) is seen in up to 60% of admissions for TBI.[100] Some variability of detection and reporting exists, but despite this, tSAH has a substantial effect on outcome.[101] Prolongation of the QTc interval is seen in 67% of patients with tSAH, and QTc prolongation is seemingly proportional to severity.[102] Approximately 20% of patients with tSAH may also develop vasospasm, which can lead to secondary ischemic insult. The diagnosis and management of the vasospasm are facilitated by the use of transcranial Doppler monitoring. Vasospasm is also being recognized as a feature in the pathologic process of blast injury.[90]

Management of TBI in the ICU should include comprehensive examination and assessment using such principles as outlined in Advanced Trauma and Life Support (ATLS) because occult injuries can escape initial screening yet subsequently exert a delayed physiologic compromise on the arrival of the patient in the ICU, or worse, in the CT scanner. These injuries may accentuate the primary brain injury by contributing to secondary physiologic insult.[14]

Overall, the common goal of treatment of TBI is to maintain cerebral perfusion. In patients with mass lesions resulting in anatomic distortion with mass effect, surgical removal of lesions is indicated. Early decompressive craniectomy for patients with diffuse injury has not proven useful and may have worsened outcome,[103] although results of a larger trial are awaited. Medical management may be required both before and after surgical intervention or as an alternative in circumstances of diffuse injury. Such treatment strategies within the ICU revolve around the reduction of ICP and the maintenance of cerebral perfusion, which may not be compatible goals. Although therapeutic resolution of ICP with osmotic diuresis is a logical approach, it may have unintended consequences on central vascular volume and myocardial function.[104] After an initially beneficial effect in reducing intracerebral volume, mannitol then leaves the vasculature through the kidney. This process also reduces cardiovascular volume, thus diminishing cardiac output and arterial blood pressure and possibly replacing one physiologic insult for another.

Mannitol has diminished in popularity, to be supplanted by hypertonic saline.[105] This solution demonstrates a good resuscitation profile, with none of the delayed hypotension observed with mannitol.[106] Some of

the same concerns with the use of mannitol also apply to the use of hypertonic saline (i.e., diffusion of osmotically active particles into the brain interstitium in circumstances of injury or compromise of the blood-brain barrier).[107] This approach may create rebound effects on reduction of plasma osmolarity as hypertonic saline administration is reduced, with an increase in brain water. This finding has been observed with differential effects in contused versus noncontused brain.[108] Although bolus usage of hypertonic saline has been shown to be useful, it remains to be seen whether sustained infusions or the practice of persistent-induced hypernatremia offer any improvement in outcome.

Although the choice of resuscitation fluid does not have any effect in a large study of trauma victims,[109] a post hoc analysis of subgroup data demonstrated increased mortality associated with the use of albumin in TBI.[110] This finding is somewhat at odds with the demonstration of potential benefit in stroke,[111] and a prospective trial is needed.

Control of the vascular blood volume may also be regulated by manipulation of the partial pressure of carbon dioxide (Pco_2), which most frequently requires intubation of the trachea and mechanical ventilation.

Controlled hyperventilation is frequently practiced to reduce blood volume and hence ICP.[112] Studies have demonstrated adverse consequences of aggressive hyperventilation, and most authorities agree on limiting the reduction in Pco_2 to avoid ischemia.[113]

The Brain Trauma Foundation publishes guidelines on the management of brain trauma, which are regularly updated. These guidelines concentrate on the principles outlined previously, namely, reduction of ICP while preserving perfusion pressure.[114] They also provide statements of consensus on the merits of these strategies. They recommend a target Pco_2 of between 30 and 35 mm Hg,[108] with a CPP of 60 to 70 mm Hg. Higher CPP values have no benefit and may worsen outcome.[115,116]

Hypertension in excess of autoregulatory control can induce both excess blood volume and the formation of vasogenic edema across a compromised blood-brain barrier.[7] This concept underpins the Lund group protocol, which gives priority to limiting the Starling forces across the capillary bed to avoid the formation of edema.[117] These investigators recommend a CPP of 50 mm Hg using β-blockers as required, the reduction of metabolic demand with barbiturates, and intravenous colloid administration.[118]

Any evidence of comparative effectiveness was restricted to case series, offering outcomes similar to those with CPP-oriented management.[119] However, a more recent small randomized controlled trial suggested that a modified Lund approach (to include mannitol), guided by microdialysis monitoring, had less mortality than an aggressive CPP-oriented approach (70 to 80 mm Hg) in a patient group equally distributed between TBI and SAH.[120] Although the study design had significant flaws, the possible benefit is worthy of further exploration. Some subsets of disorders may possibly respond differentially to each approach, determined in part by lesion volume, inflammatory burden, and blood-brain barrier integrity.

Currently, ICP/Pbo_2 and ventriculostomy are frequently used in the management of patients with severe TBI. However, these invasive monitors are contraindicated if coagulopathy is present. The occurrence of coagulopathy in TBI is associated with a poor prognosis and should be vigorously treated with clotting factors, fresh frozen plasma, and platelets.

Hyperglycemia is associated with poor outcome in multiple retrospective studies.[26] Meta-analysis of tight glycemic control on outcome in patients with TBI indicates no benefit,[121] whereas Vespa and associates, in a crossover study, demonstrated increased metabolic crisis associated with its use.[28] More moderate targets seem prudent.

Corticosteroids had an adverse effect on mortality and morbidity in a multicenter evaluation of more than 10,000 patients with brain injury, and these drugs cannot be recommended for use.[122]

Hypothermia still may have a role in controlling ICP in patients withTBI.[123] Early prophylactic use may also be beneficial.[124] Finally, after an initial failure to improve outcome, subsequent reanalysis of previous multicenter studies suggested a differential benefit of modest hypothermia in those patients undergoing surgical evacuation of a mass lesion, as compared with those without hypothermia.[125]

The timing of prophylaxis against deep vein thrombosis (DVT) has been an issue of controversy. Investigators generally agree on the need for prophylaxis because up to 25% of patients with isolated TBI develop DVT,[126] and most clinicians agree with implementation of prophylaxis 48 hours after injury. The immediate postoperative use of heparin prophylaxis is probably safe and does not confer additional risk of bleeding.[127]

SUBARACHNOID HEMORRHAGE

Most cases of SAH are aneurysmal in origin (aSAH). The incidence of aSAH in the United States has been estimated at 9.7 per 100,000 per year, but it may be as high as 14.5 per 100,000.[128] As much as a 10-fold variability by ethnicity and geography is noted, with the incidence in Finland and Japan more than double that in the United States.[129] Women have a greater risk than men by a factor of 1.24.[129] Most aneurysms occur in persons who are more than 50 years old, but gender differences exist, with peaks in men aged 25 to 45 years, women aged 55 to 85 years, and men older than 85 years.[129] aSAH has a relatively severe morbidity and mortality. Between 12% and 15% of patients will die before hospitalization, and 25% will die within the first 48 hours, with initial hemorrhage the primary cause of death, followed by rebleeding.[128,130] Subsequent morbidity and death are attributable to neurologic deficits secondary to ischemia.[128]

Significant improvements in mortality and morbidity have occurred in recent decades.[129] This finding suggests that further reductions may be achievable with continued changes in surgical practice and further concentration of expertise in regional centers. Paralleling this has been the development of neuroimaging and endovascular technologies, which have played a large part in improved outcome.[131,132]

Early Versus Late Treatment

Mortality and morbidity from SAH in those who survived the initial hemorrhage are mostly secondary to rebleeding of unsecured aneurysms or onset of delayed cerebral ischemia. Delayed cerebral ischemia has long been considered secondary to vasospasm, but some emerging evidence indicates dissociation between vasospasm and final ischemic deficit, a finding suggesting other etiologies of ischemia (e.g., microthrombosis).[133] This information has discouraged the use of vasospasm as an independent outcome measure in clinical trials,[127] but vasospasm remains an important cause of ischemia. Rebleeding peaks within the first 24 hours after the initial hemorrhage and declines progressively thereafter, reaching a plateau of 2% by 6 months.[130] In contrast, vasospasm tends to develop by the third day, peaks between 5 and 7 days, and generally wanes by 14 days. This pattern led to some debate on the timing of treatment—in which rebleeding may be averted by early intervention but at a risk of an increased risk of vasospasm, which may induce devastating neurologic ischemic deficit. Surgically, early treatment is also associated with less optimal brain relaxation conditions. Although no difference in outcome was reported, aggressive vasopressor therapy and endovascular support have tipped the balance in the favor of early clipping in the first 72 hours after bleeding.[134] Since publication of the International Subarachnoid Aneurysm Trial, endovascular coiling is increasingly the treatment of choice, particularly in posterior fossa aneurysms and in patients in poor medical condition.[135]

In addition to rebleeding and vasospasm, acute hydrocephalus develops in 25% to 30% of patients after SAH, and emergency ventriculostomy may be lifesaving as well as offering a more accurate prognosis.[136]

Antifibrinolytics

Although antifibrinolytics were previously associated with increased incidence of stroke,[137] their transient use before clipping may offer some advantage, and although some concern exists for increased rates of hydrocephalus, studies are under way.[138] Many clinicians, however, control arterial blood pressure with the use of vasoactive infusions (e.g., nicardipine) to reduce the risk of rebleeding until the aneurysm is secured.[139]

Vasospasm

Vasospasm is thought to derive from the attenuation of nitric oxide–induced vasodilation, with an associated enhanced production of endothelin production and consequent vasoconstriction. The extravascular heme molecule is the leading candidate in a long list of possible culprits.[140] Seventy percent of patients with SAH develop angiographic vasospasm, although only 30% to 40% of patients will become symptomatic. Patients with a large amount of subarachnoid blood are at higher risk for the development of vasospasm. The Fisher grade is frequently used clinically to prognosticate the risk of vasospasm,[80] and the highest incidence of vasospasm is observed in patients with modified Fisher grade 4.[82] A meta-analysis of treatment techniques suggested no difference in the incidence of vasospasm among treatment modalities,[141] whereas more recent studies suggested that the incidence and severity of vasospasm are less following endovascular treatment compared with surgical clipping, but that difference had little effect on outcome.[142,143]

The components of "triple H" therapy (hypervolemia, hypertension, and hemodilution) have been advocated in varying forms for the treatment of vasospasm since the 1950s and as a consistent package since the 1980s.[144] Despite a significant anecdotal history of effect, little evidence of benefit has been noted in randomized control trials and meta-analysis.[145,146] Triple H therapy may also be associated with an increased frequency of complications,[147] probably because of the use of hypervolemia.[146,148]

Current recommendations center on augmentation of arterial blood pressure with vasopressors, in the context of euvolemia rather than hypervolemia.[128,129]

Hemodilution is largely a passive result of hypervolemia, thus reducing its relevance; more importantly, a higher admission hemoglobin level is associated with less cerebral infarction and better outcome.[149] The use of deliberate transfusion to increase oxygen delivery is controversial, however, with some evidence of increased vasospasm and poor outcome to counter assertions of benefit.[149,150] The general critical care literature reinforces these deleterious effects of transfusion.[151] A prospective trial is awaited.

Studies on the use of nimodipine provide the only level 1 evidence from randomized control trials in SAH. This agent, when administered prophylactically from diagnosis for 21 days, offers modest improvement in outcome with reduction in the incidence of ischemic deficit.[128,130] It does not have a readily apparent effect on the incidence of angiographic vasospasm,[152] thereby lending weight to the argument for alternative explanation of its beneficial effects.[133] Nimodipine is known to have fibrinolytic activity that may be of benefit in microthrombosis.[153]

Management of vasospasm is facilitated by the appropriate use of imaging, including the use of transcranial Doppler monitoring, SPECT, and cerebral angiography when indicated. Institution of triple H therapy necessitates the use of invasive monitoring, including that for arterial blood pressure and central venous pressure (or other indices of preload).

The use of mechanical balloon dilation of blood vessels—angioplasty—has added a major weapon to the armamentarium against vasospasm.[154,155] Angioplasty is limited by the caliber of blood vessels, as well as their accessibility, and it carries a risk of catastrophic rupture.[155]

Pharmacologic angioplasty with intraarterial injection of a vasodilator is an accepted technique. First established using papaverine, the use of calcium channel blockers such as nicardipine and verapamil is being increasingly reported and has fewer adverse effects. All current agents are limited by the transient nature of their effects (<24 hours).[156] Vasodilators may be used in vessels too small to be accessible by balloons.

Other therapeutic approaches have proven disappointing to date. Trials of endothelin antagonists and statins provided further evidence of some dissociation between vasospasm and clinical outcomes, but neither drug class showed any effect on outcome despite a decrease in the incidence of vasospasm.[157,158]

Cardiac Dysfunction

Significant autonomic disturbance may arise with SAH, thus resulting in changes in the electrocardiogram and myocardial performance. Electrocardiographic changes are frequent but do not appear to relate to outcome.[159] However, one series described a 32% incidence of abnormal perfusion scans, independent of the clinical history, electrocardiogram pattern, or neurologic condition.[160]

Abnormal echocardiography has been described in up to 8% of patients with SAH, mostly in patients with blood in basal cisterns, frequently accompanied by hypotension and pulmonary edema; this feature is associated with a poor neurologic grade. A typical pattern of symmetric T-wave inversion and severe QTc prolongation was described, although multiple electrocardiographic patterns had been observed.[161]

The phenomenon of neurogenic stunned myocardium is a definite clinical entity, with what can be a severe limitation of cardiac contractility. It is, however, a reversible condition, in contrast to myocardial infarction, and it has a good recovery profile. Obvious abnormalities of function start to recede within 72 hours, but when stunning is severe, endovascular management rather than surgical treatment may be indicated (if the aneurysm is suitable). Cardiac dysfunction may complicate and limit the active treatment options for vasospasm and may render early mechanical angioplasty more appropriate.[162] Unlike atherosclerotic ischemic cardiac myopathy, stunned myocardium often exhibits apical sparing on echocardiographic examination.[163] Conversely, patients with SAH develop cardiac dysfunction similar to takotsubo cardiomyopathy, which is an acute transient dysfunction resulting from sympathetic overactivity in postmenopausal women.[164] Troponins are frequently increased in acute SAH, and high levels are associated with increased hemorrhage, hemodynamic manipulations, and worse outcomes.[165] Whether this release of troponin represents a frank cardiac injury or a "myocardial leak" remains unknown. Adrenoreceptor polymorphism was implicated in myocardial stunning, in which different receptor genotypes denoted an increased sensitivity to and release of catecholamines, in turn associated with a 3- to 4.8-fold increase in risk of cardiac injury and dysfunction.[166]

A typical strategy for cardiovascular management is given in Box 105-4. Comprehensive consensus guidelines have been published.[128,130]

BOX 105-4 ***Suggested Cardiovascular Management Strategies in Subarachnoid Hemorrhage***

GENERAL

1. Manage hypertension in unsecured aneurysms (with nicardipine titrated to systolic BP < 140 mm Hg.
2. Maintain euvolemia prophylactically; no role for prophylactic hypervolemia.
3. Administer nimodipine (possibly statins).

CARDIOVASCULAR INSTABILITY

1. BP and cardiac output goals will alter as aneurysm is secured.
2. ECG

If abnormal (QTc prolongation, ST-segment changes): check troponins.

If troponins elevated: perform echocardiography.

3. Perform echocardiography if any manifested hypotension or heart failure is suspected.
4. Monitor cardiac output.
5. Support on dobutamine for cardiac output and norepinephrine for blood pressure.
6. Consider coiling as soon as practicable.
7. Reserve coronary catheterization for isolated wall motion deficit and rising troponins (coil first if possible).
8. Avoid β-blockers unless the patient has active coronary artery disease.
9. Vasospasm: treat with euvolemia/mild hypervolemia, pressors, and cardiac output monitoring: adjust targets as perfusion tests suggest.
10. Transfusion: maintain hematocrit >25%. Avoid use of stored blood if possible.

BP, Blood pressure; *ECG*, electrocardiogram.

Respiratory Dysfunction

Pulmonary injury is a frequent complication in the clinical course of the patient with SAH; nearly 17% of patients will experience severe dysfunction. This finding is associated with a poor neurologic outcome.[167] Blood transfusion can increase the risk of lung injury (transfusion-related acute lung injury [TRALI]), which, in turn, affects mortality[168] (see Chapter 61). Acute pulmonary edema can also occur in patients with poor-grade SAH, and this edema can be either neurogenic or cardiogenic.

Endocrine and Metabolic Derangements

Hyperglycemia is a risk factor for poor outcome, especially in SAH.[169,170] However, aggressive glucose control is not useful in SAH and may worsen outcome.[171] As in TBI, no basis exists for the use of corticosteroids.[172]

Hyponatremia is observed in 30% to 40% of patients with SAH.[173] Whether cerebral salt-wasting syndrome (CSWS) or the syndrome of inappropriate secretion of antidiuretic hormone (SIADH) is the dominant mechanism is debated.[174]

In CSWS, sodium is actively excreted from the body in high concentration, and accompanying diuresis occurs despite ongoing hyponatremia.[175] Berendes and colleagues demonstrated an associated increase in brain natriuretic peptide (BNP) release, thought at that time to derive exclusively from the brain.[176] Given the increasing evidence for the ventricle as the main source of production of BNP, it is unclear whether BNP arises from a stressed ventricle at the time of the hemorrhage and associated sympathetic discharge or from a brain experiencing abnormal perfusion states of homeostatic areas. Hyponatremia is also associated with cerebral infarction,[177] in keeping with the clinical observation that hyponatremia predicts the onset of vasospasm by approximately 24 hours.[178]

SIADH is the more common etiology of hyponatremia in general, but it should not induce reduction in circulating blood volume. That such a reduction does occur after SAH persuades many (including us) to consider CSWS the

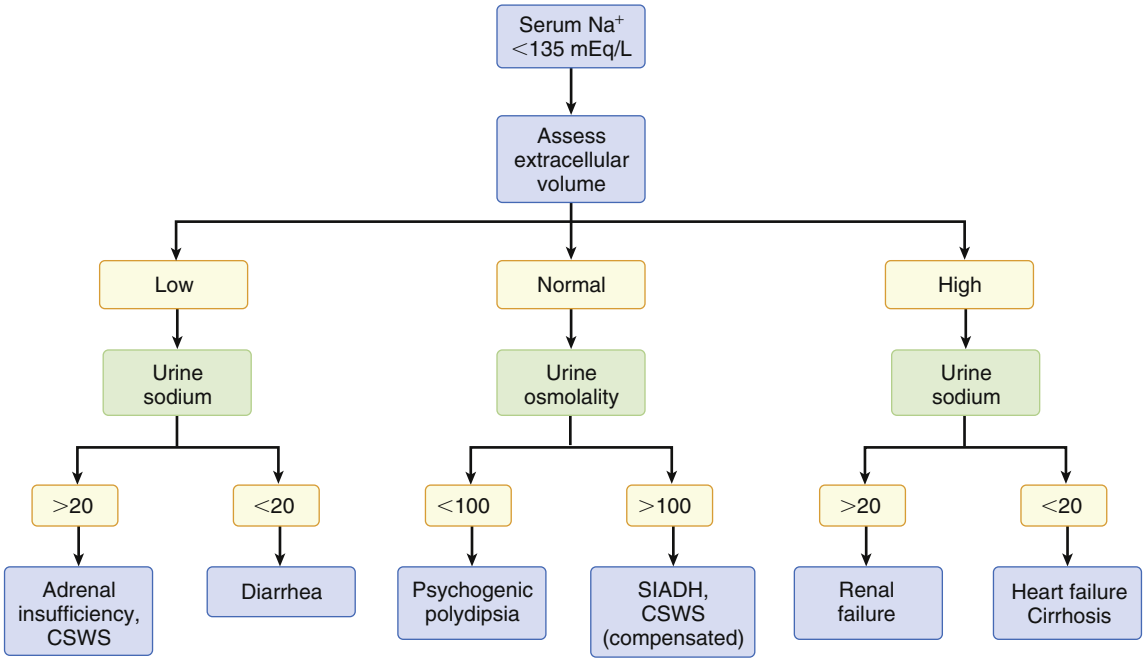

Figure 105-8. Algorithm for the differential diagnosis of hyponatremia in the neurosurgical patient. *CSWS,* Cerebral salt-wasting syndrome; *SIADH,* syndrome of inappropriate secretion of antidiuretic hormone.

more relevant etiology.[179] Profound differences exist in the subsequent management of hyponatremia in these two conditions. CSWS indicates replacement with sodium and fluids, whereas SIADH may indicate fluid restriction, which may aggravate vasospasm and ischemic deficit. The situation is rendered all the more complex by the consideration that volume loading itself induces natriuresis.[180] Both disorders are associated with SAH, and the main distinguishing feature is the state of intravascular volume; CSWS is associated with depletion, whereas SIADH is associated with elevation. Because of the adversely combined effects of hyponatremia and decreased blood volume on delayed ischemic deficits, many clinicians have advocated the use of hypertonic saline as the primary treatment for hyponatremia in patients with SAH. [181] A suggested algorithm for resolving diagnostic uncertainty is given in Figure 105-8.

Feeding and Nutrition

SAH induces a profound stress response in which the hypercatabolic state relates to the severity of the neurologic insult. Resting energy expenditure may reach a peak of 172% that of normal on day 10 after hemorrhage. This change, coupled with the tendency to suffer from headache, nausea, and vomiting, leads to relative hypoalbuminemia that may compound the tendency for hypovolemia.[182]

ISCHEMIC STROKE

Stroke is the fourth leading cause of death in the United States after heart disease, cancer, and chronic lower respiratory disease. It is a major source of disability, with 795,000 cases per year and a prevalence of 3%.[183]

The deprivation of oxygen and nutrients to the brain beyond the combined thresholds of severity and time induces cellular death in neuronal tissue. In complete occlusion, this process starts within minutes. Around the dead tissue, an area of marginally sufficient blood supply exists in which the probability of cell death is related to ischemic time. This is the ischemic penumbra and is potentially salvageable with aggressive intervention. Just as cardiologists say "time is muscle," it can also be said that "time is neurons."

Thus, the goals of treatment have moved away from physiologic stabilization and risk factor avoidance toward accelerated reperfusion and retrieval of threatened brain tissue.

Paralleling aggressive cardiac management in threatened infarction, treatment should start in the emergency department but continue into the ICU. Intravenous thrombolytics were initially deployed, followed by intraarterial and mechanical thrombolysis and, more recently, varying combinations of each modality. Current recommendations for treatment windows are 4.5 hours for intravenous therapy or 8 hours for the intraarterial route, but this regimen may be adjusted in the light of perfusion- and diffusion-weighted MRI mismatch.[184] No evidence suggests the benefit of one strategy over another on the most recent systematic review of anterior circulation stroke. The addition of stents to support subsequent vessel patency is a fast-growing practice with ongoing studies exploring efficacy.[184] Vertebrobasilar occlusion may benefit from the more recent techniques.[185]

Vigorous perfusion should be maintained until thrombolysis has been attempted. Consequently, hypertension should not be treated unless it is inducing myocardial damage or unless intracerebral hemorrhage (ICH) has already occurred (hemorrhagic conversion). This latter circumstance also precludes thrombolysis. Hypotension should be actively avoided.

Once thrombolysis has been attempted, this increases the risks of hemorrhage, and hypertension should be moderated.[186] Unwanted side effects obviously center around hemorrhage, which is associated with higher thrombolytic doses and later treatment.[187] Keen attention should be paid to postprocedural CT scans and any signs of systemic hemorrhage such as lower abdominal pain, which may indicate retroperitoneal bleeding. Areas of brain that cannot be salvaged will swell, causing compressive ischemia in adjacent regions. Just as the effects of TBI and SAH may vary by anatomic site, so, too, will the effects of ischemic stroke vary with the particular vascular area of occlusion.

In addition to control of cerebral volume, interest has revived in the early use of decompressive surgery in circumstances of "malignant" swelling. Edema can induce ICP in excess of 30 mm Hg, with a correspondingly high mortality. Studies to date suggest treatment benefit if decompressive craniectomy is carried out in the first 24 hours after onset of symptoms, with aggressively sized bone flaps.[188] Increasing age and CT hypodensity have adverse effects, but hemispheric dominance is less important. However, efficacy remains a concern because good functional outcomes are in the minority.[189]

POSTOPERATIVE NEUROSURGICAL CARE

Many neurosurgical procedures are lengthy and involve significant insult to the brain (see Chapter 70). Thus, postoperative admission to the ICU for avoidance of secondary insult and a more graduated withdrawal of ventilatory support is common, although most significant events after craniotomy happen in the immediate postoperative period.[190] ICU care particularly entails careful control of arterial blood pressure to minimize edema formation, by taking into account potential compromise of autoregulation and cerebrovascular compliance. However, the importance of neurologic examination cannot be overemphasized, and early withdrawal or intermittent interruption of sedation to allow appropriate clinical examination is a prudent approach to follow these patients.

Patients with vascular lesions such as arteriovenous malformations and vascular tumors predisposed to the development of hyperemia benefit from careful attention to blood pressure management, as do patients undergoing carotid endarterectomy. In both arteriovenous malformation and carotid disease, areas of the brain adjacent to the malformation or ipsilateral to the tight carotid stenosis may have absent autoregulatory control or may autoregulate only at a significantly lesser range of arterial blood pressure. Until the autoregulatory mechanism returns to normal, blood pressure should be carefully and tightly controlled to prevent what has been termed normal pressure perfusion breakthrough. This can be accomplished with intravenous nicardipine or esmolol infusion, or both, to allow titratable adjustment of the blood pressure.

Aneurysmal clipping is not in this category, except in cases of vascular graft bypass procedures, in which attention should be paid to minimum as well as maximum pressure targets. This is known as the *Goldilocks approach*. If arterial blood pressure is maintained too low, then this may risk graft thrombosis. If arterial blood pressure is too high, then the graft may rupture, or hemorrhage may occur. Although the range maintained is arbitrary, and no supporting data are available, systolic blood pressure probably should be maintained in a narrow range between 100 and 120 mm Hg.

Although not common, patients treated with lumbar CSF drainage may develop central herniation syndrome. The diagnosis is not always apparent, and the sudden decline in mental status, with a history of CSF drainage, should prompt appropriate imaging of the brainstem. Treatment is with fluid hydration and maintenance of the patient in the Trendelenburg position.

INTRACEREBRAL HEMORRHAGE

Nontraumatic ICH may arise from ruptured aneurysm, ruptured arteriovenous malformation, hemorrhagic stroke (amyloid angiopathy, hypertension), conversion from ischemic stroke, tumor, substance abuse (alcohol, cocaine, methamphetamines), and the use of warfarin (Coumadin). This wide range of differential diagnoses can swiftly be refined by the CT scan, with accompanying clinical signs aiding localization and the assessment of pathophysiologic effect. Angiography may be required to rule out aneurysmal rupture.

Management is to avoid secondary insult by reducing the incidence of rebleeding, hypoxemia, hypercarbia, or edema.[191,192] Essential care is directed toward the airway and circulation. If the initial CT or MRI appearance suggests arteriovenous malformation, then care should be taken to limit blood pressure to reduce the risk of rebleeding. The addition of ICP monitoring allows one to set the CPP target and provide a more physiologic approach to the management of systemic blood pressure. If the ICH is in the posterior fossa or midbrain, consideration should be given to the insertion of a ventriculostomy to reduce the risk of hydrocephalus. Patients with lesions in these regions are prone to airway and respiratory problems and may need early tracheal intubation to protect their airway and prevent aspiration.

Nimodipine does not have an established role in these circumstances. Corticosteroids are also not indicated. If the patient is receiving warfarin, it should be reversed with fresh frozen plasma and vitamin K.

Most intracranial hematomas expand in volume during the first 24 hours, and the volume of expansion is correlated with outcome. Although recombinant factor VIIa led to a reduction in hemorrhage volume, outcome is not improved. The role of recombinant factor VIIa in ICH is therefore uncertain, although it may be useful for rapid reversal of patients receiving warfarin.

The management of intracranial hemorrhage is generally medical and supportive, with control of arterial blood pressure to less than 180 mm Hg. Ongoing clinical trials are targeting a systolic blood pressure of 140 mm Hg to decrease the risk of ICH volume expansion.[193,194]

Surgery is rarely indicated.[192] However, in patients with cerebellar hemorrhage, and brainstem compression, or in those showing acute neurologic deterioration or obstructive hydrocephalus, surgical evacuation of clots may be indicated.[191,192] Although patients with other types of

stroke have experienced improved morbidity and mortality in recent years, no significant change in outcome after ICH has occurred.

BRAIN INJURY AFTER CARDIAC ARREST

Although the therapeutic cerebroprotective value of induced moderate hypothermia has been disappointing in both TBI and SAH, its efficacy in improving neurologic outcome has been demonstrated in patients who suffered global hypoxia secondary to ventricular fibrillation (see also Chapter 108). Neurologic morbidity is common in those patients experiencing global cerebral ischemia as a consequence of cardiac arrest and is related to the generation of free radicals and cellular injury on reperfusion of the ischemic brain.

Two studies reported improved neurologic outcome and reduced mortality in patients with ventricular fibrillation who were resuscitated but remained in coma and were immediately treated with mild hypothermia in the range of 32° to 34° C.[195,196] These results were confirmed in a wider population, and a regimen of 12 to 24 hours of mild hypothermia is now recommended treatment for all post–cardiac arrest patients with neurologic dysfunction.[197]

Whereas initial studies induced hypothermia using cooled intravenous solutions, more sophisticated methods and devices have since been introduced. These include noninvasive methods such as forced air cooling with limb and trunk blankets, topical adhesive cooling pads, and invasive methods deploying intravascular heat exchange catheters. Water-cooled adhesive pads connected to heat exchange units are the most commonly used methods at present.

Some clinicians consider the use of somatosensory evoked potentials (particularly the N20 and N70 latencies) to be helpful in the prognosis of coma after cardiac arrest.[198]

STATUS EPILEPTICUS

This condition has been defined as "repeated seizures occurring frequently without recovery between attacks" and has a significant morbidity and mortality, with approximately 50,000 deaths per year for an estimated annual incidence of 126,000 to 195,000 cases.[199] Some clinicians have attempted to refine this condition by using a stricter definition of continuous seizure lasting at least 30 minutes. Irrespective of the definition of status epilepticus, prompt treatment of seizure should be instituted because a seizure lasting beyond 5 minutes is unlikely to stop spontaneously. Variants of seizure type are seen, but all may present in status epilepticus, including nonconvulsive types, which present their own particular diagnostic challenges.[200]

Seizure activity may arise from any major insult affecting the cerebral cortex, whether infectious, mechanical, metabolic, or toxic. Even mild insults may provoke status epilepticus in which the seizure threshold is reduced by preexisting parenchymal disease or comorbidity (e.g., alcohol withdrawal). Given the previously outlined emphasis on the avoidance and termination of secondary insult to the brain, the metabolic disadvantage of status epilepticus is readily apparent. Management guidelines have been published.[201] Goals of treatment include seizure termination, physiologic support, and prevention of recurrence. This approach may involve intubation and ventilation, in which long-term paralytic agents should not be used for fear of masking ongoing or recurrent seizure. Electroencephalographic control is highly recommended. Preferred anticonvulsants for acute termination include lorazepam and midazolam, in view of their relatively benign cardiovascular profile. Phenytoin remains a commonly used agent but takes time to administer because it can provoke hypotension and bradycardia if given rapidly. Hypotensive effects may also limit the usefulness of thiopental, pentobarbital, and propofol.[201] In some patients refractory to treatment with usual antiepileptics, inhaled anesthetics have been used with success.[202]

GUILLAIN-BARRÉ SYNDROME

Guillain-Barré syndrome (GBS) occurs at a rate of 1 to 4 cases per 100,000 population per year. The incidence increases with age, and this disorder is one of the most common neurologic causes of admission to critical care units.[203,204]

The classic form of GBS is acute inflammatory demyelinating polyneuropathy that appears as progressively ascending muscle weakness. This can manifest as flaccid paralysis and respiratory failure. Several clustered conditions are associated with the syndrome, including acute inflammatory demyelinating polyneuropathy (AIDP), acute motor axonal neuropathy (AMAN), acute motor-sensory axonal neuropathy (AMSAN), and Miller-Fisher syndrome (MFS), with MFS affecting the cranial nerves first. AIDP is the most common variant seen in the United States, and more than 50% of all patients have a recent history of bacterial or viral infection. *Campylobacter jejuni* is the most frequently observed pathogen, along with cytomegalovirus, Epstein-Barr virus, and herpes simplex. GBS may display sensory and autonomic features, depending on the subtype, and some variation in speed of onset and offset is noted. Commonly, symptoms progress over several days to reach their peak at 2 weeks, with a plateau thereafter. In approximately 5% of patients, GBS progresses more rapidly, with maximal loss of function within 72 hours of symptom onset. At 4 weeks, most have progressed to the limit of their symptoms, and improvement is observed to start soon thereafter. Recovery may be protracted for up to 6 months, however. Whether the speed of onset relates to a slower rate of recovery and outcome limitation is debated.[203,204]

Loss of ventilatory efficacy is the main reason for admission to the ICU. A forced vital capacity of less than 20 mL/kg is a sensitive indicator of need for observation, and 15 mL/kg for probable intubation, along with clinical signs of fatigue and airway compromise. Hypercarbia is a relatively late sign, and the clinician should not rely on it.

Bulbar dysfunction, albeit less common, may appear before ventilatory compromise, particularly in patients with the MFS variant.

Dysautonomia is seen in up to 20% of patients and is a source of morbidity.[205] It should be monitored carefully, because of the significant mortality of arrhythmia in older patients. Dysautonomia can vary from urinary retention to fixed tachycardia to both severe hypotension and paroxysmal hypertension.

Investigations should include electrocardiography, CSF protein (for acellular protein elevation), electromyography (axonal degeneration is associated with poorer recovery), and antibody status or screening for possible causative pathogens and also prognosis. GM_1 antibody is associated with worsened recovery, whereas MFS is associated with anti-GQ1b antibody.[204]

Particular challenges to management are the problems of deafferentation pain and psychiatric depression. The pain can be severe, is truncal in distribution, and may respond to anticonvulsants more than to opiates. It certainly contributes to the frequently observed depression. This pain is often worsened by immobility, boredom, and the limited ability of busy staff to engage actively with a (relatively unusual for the neurocritical care unit) cognitively intact patient. Early tracheostomy in identifiably prolonged cases is appropriate.

Both symptom limitation and recovery from GBS have been improved with the use of plasmapheresis or the intravenous administration of gamma globulin. No advantage is seen with one treatment approach over the other or in combination. However, many physicians try them sequentially in cases of treatment failure. Persistence of foot drop at the conclusion of immunotherapy is an indicator of longer-term ventilation.[206]

Neither interferon nor corticosteroid use has been shown to improve outcome, either alone or in combination with immunotherapy.[203]

SPINAL CORD INJURY

In contrast to GBS, spinal cord injury is much more common (11,000 cases/year), is intractable to treatment, and almost inevitably has permanent effects. The number afflicted in the United States is estimated to exceed 270,000. The degree of dysfunction is similar to GBS in that as the level of injury ascends, the patient has a high level of motor paralysis of the lower limbs, trunk, upper limbs, and diaphragm. Additionally, traumatic sympathectomy also occurs, producing bradycardia, hypotension, and gastrointestinal paralysis. This gastrointestinal aspect is often overlooked, and subsequent abdominal distention can embarrass an already compromised diaphragm into inefficacy. The cardiovascular effects of sympathectomy, particularly above T5, manifest as bradycardia and hypotension.[207] This patient can be supported by fluid and pressor therapy, and the tachycardic effect of dopamine may be a useful attribute. Unopposed vagal stimuli, as well as hypoxia, may induce bradycardia.[207] Resuscitation targets are controversial, with more recent interest in maintaining spinal perfusion analogous to the CPP of TBI. Patients with injuries below T5 may still manifest hypotension but usually only on the provocation of posture, hypovolemia, or comorbidities.

Ventilatory support depends on the level of injury. If the injury is below C5, although the diaphragm remains functional, in the acute stage respiratory embarrassment secondary to abdominal and intercostal paralysis can still occur because flaccidity in these muscles significantly decreases the functional efficiency of the diaphragmatic contraction. Thus, paradoxic respiration with chest indrawing during inspiration occurs. This can be alleviated in part with the use of an abdominal binder. With complete cervical spinal cord injury, acute respiratory failure is common, secondary to the sudden loss of functional residual capacity and the inability of the sternocleidomastoid muscle to stabilize the chest wall. With time, many patients can regain the ability to breathe spontaneously, except those with high cervical lesions. Controversy exists regarding the ventilatory pattern used for spinal patients. Some investigators suggest that a larger tidal volume should be used, with an aim of opening more alveoli, reducing atelectasis, and treating air hunger. No randomized clinical trials are available to support this, and it would seem contrary to more recent insights into lung stretch injury. Air hunger may be more a consequence of disordered proprioception than an indication to hyperventilate.[208]

Lower limb blood flow is reduced with increased arterial and venous pooling. This is associated with a higher incidence of thromboembolic disease, and early prophylaxis with low-molecular-weight heparin is recommended.

As with GBS, the patient with spinal cord injury is commonly aware, and this constitutes an additional burden of psychological stress. Consequently, the best approach taken is truly holistic, tending to psychological needs, as well as to cardiopulmonary, gastrointestinal, renal, and integumentary support. Significant advances have been made in the critical care and rehabilitation support afforded to these patients, and 2-year survival has increased significantly since the 1980s. Unfortunately, this improvement has not translated to increased long-term survival.[209]

MYASTHENIA GRAVIS

Although myasthenia gravis is a relatively uncommon disease (prevalence of 10 to 20 per 100,000), it is relevant to neurocritical care in that patients can present acutely with rapid deterioration of muscle function, predisposing to ventilatory failure—the myasthenic crisis. Myasthenia itself has a strong association with various autoimmune conditions (e.g., thyroid disease, pernicious anemia, rheumatoid arthritis), as well as being linked to women with certain human leukocyte antigen (HLA) types.[210,211]

The myasthenic crisis can be precipitated by a progression in severity of the disease state or often by amplification by another factor. This factor can include infection, recent surgery, or interruption of immunosuppressants. Many drugs can exacerbate myasthenic crisis, including aminoglycosides, fluoroquinolones, anticonvulsants (including phenytoin), steroids, β-blockers, calcium antagonists, ketamine, lidocaine, neuromuscular blockers, and anticholinergic agents.[211]

The diagnosis should exclude GBS, brainstem stroke, organophosphate poisoning, and botulism. Tests should include electrophysiology, CSF protein, edrophonium response, and antibodies to acetylcholine and muscle tyrosine kinase receptors.

The presentation is typically that of acutely worsening weakness of either respiratory or pharyngeal muscles, or both. The patient should be observed closely for signs of impending respiratory failure. Forced vital capacity is again useful with 15 mL/kg being a useful trigger for intubation.[211]

The other mainstay of therapy is by immunomodulation. Typically, intravenous immunoglobulin or plasmapheresis is started quickly to limit progression of symptoms and avert frank crisis. Corticosteroids do have a role in establishing longer-term control of immunosuppression because immunoglobulin G (IgG) and plasmapheresis have limited duration of efficacy. Corticosteroids alone are associated with a transient worsening of symptoms, before improvement, so they are best used concurrently with or immediately after plasmapheresis or IgG.[212]

MENINGITIS

Meningitis is a serious condition producing inflammation of the leptomeninges covering the CNS. The causative pathogens differ among different patient populations. Community infections are frequently caused by *Streptococcus pneumoniae, Haemophilus influenzae, Listeria monocytogenes, Neisseria meningitidis,* and group B streptococci. *N. meningitidis* is particularly evident in teenagers. Since the advent of a childhood vaccination program, *H. influenzae* affects chiefly adults, but the other organisms tend to affect all age groups. Nosocomial infection, in contrast, predominantly arises in the neurosurgical patient, especially with the use of ventricular devices, and the pathogens here comprise gram-negative rods and staphylococci. Diagnostic features include fever almost invariably with the classic nuchal rigidity and change in mental status; less often, photophobia, papilledema, and new-onset seizures may be seen. A rash is typical of meningococcal infection, whereas arthritis occurs in a significant minority. Tests should include CSF Gram stain and culture by lumbar puncture, but any previous antibiotic dosing can diminish sensitivity. Under this circumstance, polymerase chain reaction (PCR) testing is the method of choice, thus displacing the more variable latex agglutination test. A CT scan should delay the lumbar puncture only when the patient's history suggests a previous mass lesion, stroke, or focal infection, recent seizures, or immunocompromise. Similarly, signs of papilledema, depressed level of consciousness, or focal deficit indicate a need for a CT examination to avoid herniation. Cerebral edema not infrequently develops in patients with meningitis and can lead to acute deterioration in mental status. ICP monitoring may be indicated.

Treatment should be delivered swiftly, pausing only to obtain emergency samples for Gram stain and culture. If no identification is possible on Gram stain, empiric antibiotic therapy should be delivered with third-generation cephalosporins (e.g., ceftriaxone or cefotaxime), along with vancomycin until organism and sensitivities are obtained. This approach covers the community-acquired pathogens. Nosocomial or trauma-associated infections can be effectively treated with cefepime and vancomycin. Steroids are useful adjuncts in bacterial meningitis and have been shown to reduce mortality.[213]

The outcome of meningitis is a function of patient-related factors, the pathogenicity of the organism, and the time to effective treatment. An interesting study examined admission hypotension, altered mental status, or seizures for an effect on outcome. A 9% mortality rate occurred when one factor was present, and it increased to 33% for two factors and to 57% for all three.[214]

ENCEPHALITIS

Encephalitis manifests with fever, headache, and alteration of consciousness. Patients may also have delirium, focal deficit, and, commonly, seizures. Nuchal rigidity may be present in a mixed meningoencephalitis picture but should be absent in isolated encephalitis. Accompanying identifiers may be a vesicular rash associated with herpes zoster (although its absence does not remove zoster from suspicion), bilateral paralysis typical of West Nile disease, parotitis if mumps is suspected, and, of course, the hyperactivity, hydrophobia, and pharyngeal spasm of rabies. West Nile neuroinvasive disease has increased its incidence from 62 cases in 1999 to 438 in 2011, over 43 states, with estimates of up to 34,000 non-neurologic infections per year.[215] Many nonviral and noninfectious causes of encephalitis may confound the diagnosis. These include vasculitis, systemic lupus erythematosus, stroke, rickettsial and parasitic infection, and drug-induced meningitis (e.g., IgG). Careful examination of clinical features, history, and laboratory data is necessary. CSF should be drawn for viral DNA polymerase chain reaction, as well as the routine biochemistry, culture, and cell count. MRI is useful in identifying the demyelination and edema that can be difficult to see on CT. Serum serology is helpful for the diagnosis of Epstein-Barr virus, mumps, and West Nile disease as sources of encephalitis. Paired samples are recommended to allow later comparison if CSF PCR is unhelpful. Brain biopsy was considered the gold standard but is now a last option after CSF PCR, culture, and serology have proven negative.

Herpes simplex type 1 infection carries a very poor outlook if it is not treated expeditiously, and a course of intravenous acyclovir is recommended as soon as samples are drawn.

The pathogen remains unidentified more often than not, and outcome usually then depends on classification of the clinical features, with intractable seizure and cerebral edema carrying a poor prognosis. Self-limiting seizure usually indicates a swift recovery.

BRAIN DEATH

It is crucially important that the physician understand the principles of the diagnosis of brain death and be able to apply them assiduously and without compromise (see Chapter 76). Many unfortunate instances of poor understanding have led to imperfect examination, misdiagnosis, and considerable distress to all concerned.

Declaration of brain death was originally codified by the Harvard criteria in 1968, with subsequent modification to allow separation of cerebral death from death of the entire nervous system including the spinal cord.[216]

The diagnosis is built on a solid clinical examination of nervous system function, by examining the reflex response of the brain and cranial nerves to varying stimuli of hypercarbia, pain, light, temperature change, attitudinal change of the middle ear, and detection of the blink, cough, and gag reflexes. The mechanisms for the cause of neurologic dysfunction should be clear. As with the operation of the GCS scale, the examination must be done in circumstances of adequate systemic oxygenation and perfusion. Confounders, such as hypothermia, metabolic or endocrine compromise, and persistent sedative or neuromuscular drugs, should be avoided, corrected, or removed. Although guidelines allow a single examiner in adults,[217] many clinicians believe that two examiners are preferable, and this is mandatory in pediatric cases[218] (see also Chapter 95). At least one of the testing physicians should have had training in neurology, neurosurgery, or neurocritical care. Time between tests is less important for diagnosis than for the opportunity to start communicating with and preparing the family. One of the tests should include an appropriately conducted apnea trial in the presence of the physician, with confirmation of adequate changes in Pco_2. Two apnea trials are required in pediatric cases.[218] If for any reason any test cannot be completed in a safe manner, or to the satisfaction of either physician, then an ancillary test of CBF should be performed.

The hospital should have an institutionally approved protocol for the conduct of these tests and mechanisms in place for review and quality improvement.

ETHICAL CONSIDERATIONS

Ethical issues are frequently encountered in a neurologic ICU setting (see Chapter 10). Unfortunately, as well as the mortality described previously, significant life-altering morbidity occurs, to the extent that many patients and families would not desire aggressive therapy.[219] This can be a difficult concept to accept for the physician, whose aim is to heal and preserve life. However, the ethical imperative in Western culture is to preserve the autonomy of the individual (along with the principles of nonmaleficence, beneficence, and justice), and this has been extended to health care decision making. This situation may lead to uncomfortable choices and communication within the health care team, whose members may have differing opinions on goals, and from there to the patient and relatives, who, again, may think very differently.

Certain strategies can avoid or minimize these difficulties:

- Prognosis should be made on the basis of the best available evidence. This may involve planning and discussion among the team members in advance of meeting with families. The personal anecdote should be avoided, even if solicited.
- The relationship within the team should be open and collegial, with mutual respect given to the principle of open discussion. This approach avoids misperception of goals and attitudes and enables more consistent communication with families, who often find dissonance among members of the ICU team disturbing.
- The presence of an advance directive offers major benefits, and the neurocritical care unit should have an admissions protocol that includes asking all competent, conscious patients to consider making their attitudes or wishes known.
- Regular family and patient conferences allow communication of prognosis as it is appropriate and offer the opportunity for correction of any misconceptions, as well as progressive education of the family to anticipated problems.
- Internal institutional mechanisms for raising concerns and conducting reviews should be in place. This is often facilitated by the presence of an institutional ethics committee, whose members can examine the issues, promote educational discussion, and help achieve a consensus.
- All decision making should be documented carefully and completely.
- Orders for limitation or withdrawal of therapy should be written explicitly, and institutional protocols should be used wherever possible.

Other important areas of possible conflict exist that are not possible to address within the confines of this text, but readers are advised to educate themselves on the following:

- The issues surrounding organ donation from the brain dead and the non–heart-beating donor
- Withdrawal of care for the incompetent patient without family
- Hospital bylaws and state legislation on the certification of death, whether that be by neurologic or cardiovascular criteria

CONCLUSION

Neurocritical care demands a thorough comprehension of the physiology, pharmacology, and pathology of the nervous system, as well as for the organ systems supporting it. The best care is provided in circumstances that allow multidisciplinary collaboration and appropriate attention to detail of often complex and demanding pathologic processes, but integrating them optimally under the direction of the critical care physician.

Chapter 106

Nutrition and Metabolomics

CHARLES WEISSMAN

Key Points

- Sepsis, trauma, and surgery activate complex metabolic and inflammatory responses that affect all body systems.
- Catabolism, hypermetabolism, hyperglycemia (diabetes of injury), and enhanced lipolysis characterize the metabolic response to the stress response.
- The counter-regulatory hormones (e.g., cortisol, glucagon, catecholamines) along with the cytokines (e.g., interleukin 1, tumor necrosis factor) are major mediators of the stress response.
- Certain intraoperative anesthetic and postoperative analgesic techniques can modulate the stress response.
- During the acute phase of illness, patients unable to eat should receive parenteral or enteral nutritional support.
- Nutritional support during the acute phase of critical illness is a supplementary therapy designed to provide patients who are suffering from underlying metabolic disarray with sufficient nutrients to aid cellular biochemical functions and attenuate further loss of body mass.
- Only once the ravages of the stress response have abated can lost lean and fat mass be repleted.
- Overfeeding or aggressive refeeding should be avoided.

Humans are adaptable organisms with many interrelated mechanisms that identify, respond, and neutralize both internal (e.g., infection) and external (e.g., temperature extremes) events (stressors) that threaten or upset homeostasis. Anesthesiologists must be knowledgeable about these mechanisms because they routinely care for patients with acute and chronic homeostatic changes. Moreover, anesthesia and surgery involve significant disruption and manipulation of body physiologic processes, anatomy, and biochemistry, which activate the body's responses to stress.

The stress response evolved as a means for helping organisms react to immediate danger. The outpouring of catecholamines and other hormones increases the outputs of the respiratory, cardiovascular, and metabolic systems, thus enhancing the organism's ability to flee from an enemy and to maintain perfusion to vital organs after blood loss. Metabolic alterations caused by changes in the hormonal milieu increase the availability of certain substrates and reduce the availability of others. The organism thus attempts to improve conditions for wound healing, blood coagulation, and humoral immunity, a response that is beneficial in acute events such as bleeding and infection. Although once regarded positively as the body's defense mechanism, the stress response is now regarded more equivocally because its physiologic consequences, especially increasing the output of various organ systems, may lead to greater morbidity and mortality by overtaxing already compromised organ systems. For example, among patients with underlying coronary artery disease, the tachycardia and increased myocardial oxygen demand resulting from catecholamine stimulation can cause myocardial ischemia.

The stress response was initially described by Hans Selye as "the nonspecific response of the body to any demand upon it."[1] However, contemporary research demonstrates that the nature of response varies, depending on the type and intensity of the stressor and is only nonspecific when the stress is overwhelming. Furthermore, chronic activation of the stress response has been implicated as contributing to a variety of conditions, such as atherosclerosis and depression. Although chronic stress is not often the cause of the disorder, it contributes to its pathogenesis, exacerbations, and duration.[2]

SYSTEMS BIOLOGY AND METABOLOMICS

Organisms are *complex systems*—systems with many dynamic and nonlinear relationships among heterogeneous interconnecting parts, whose actions and properties cannot be completely explained by the structure and function of the individual components. This biocomplexity is further characterized by multiple levels of organization

(e.g., genes, cells, tissues), multiple feedback loops, robust responses to perturbations, the ability to adapt to endogenous and exogenous threats, and nonintuitive and often paradoxic behavior.[3] The need to better understand biocomplexity, such as during stress, has spawned interest in *systems biology/medicine,* which uses mathematical modeling and systems engineering methods to provide mechanistic explanations of physiologic and pathophysiologic interrelationships.[4] Complementing the systems approach have been *omic* techniques that analyze the *total* collection of genes (genomics), proteins (proteonomics), or metabolites (metabolomics) in a cell, tissue, or organism. For example, metabolomic techniques are used to compare differences in individual metabolites and metabolic pathways under normal and pathologic circumstances.[5] These newer approaches are a departure from the usual *reductionist* methods, which analyze a system's individual components by taking a wide-ranging view of the intricate biosome.

METABOLIC CONTROL SYSTEMS AND THE RESPONSE TO SURGICAL STRESS

Living organisms constantly undergo adjustments to adapt to ever-changing internal and external conditions. These natural alterations are termed *allostasis* and include diurnal variations in temperature and cortisol production, metabolic changes as a result of eating and drinking, and the cardiopulmonary responses to exercise.[6] Stress occurs when allostatic mechanisms are insufficient for maintaining homeostasis, thus causing the organism to alter many of its functions significantly to reduce and contain the stressful threat.[7]

Cuthbertson classically described the response to surgical and traumatic injury as having three phases:

1. The ebb phase (≤24 hours), also called the *resuscitative phase*, is characterized by tissue hypoperfusion that requires treatment.
2. The flow phase (its duration depends on injury severity) has a milieu characterized by catabolism, hypermetabolism, hyperglycemia, and an inflammatory response.
3. The anabolic phase (may last for months) is when anabolism facilitates the repair of injuries and a return to a normal metabolic environment.

However, the improved survival from major injury, occasioned by modern surgery and critical care, blurs this classic scheme. Today, patients who are critically injured often undergo multiple surgeries within a few days of their injury and suffer from iatrogenic infections during extended stays in an intensive care unit (ICU). These surgeries and infections add further stresses—second hit—to an already highly stressed system.[8] The consequences of these second hits are problematic because they perpetuate or intensify metabolic changes that increase the chance of developing multiple-organ failure.[9]

HYPOTHALAMUS-PITUITARY AXIS

Many allostatic, as well as homeostatic, changes are controlled by feedback control systems and centered on the hypothalamic-pituitary axis. Hypothalamic activation, secondary to afferent neuronal input from an area of injury, or emotional activity centered in the limbic system and humoral factors, such as the inflammatory cytokines tumor necrosis factor–alpha (TNF-α), interleukin (IL)-1, and IL-6, trigger the response to surgical and traumatic stress.[10] In addition, the loss of endocannabinoid signaling removes inhibition of the neuronal release of glutamate resulting in hypothalamic-pituitary activation.[11] Hypothalamic activation increases the activity of the sympathetic nervous system, which increases the output of the cardiovascular system and stimulates the adrenal medulla to secrete epinephrine and the pancreas to secrete glucagon (Fig. 106-1). Hypothalamic activation also stimulates corticotropin-releasing hormone (CRH) and reduces the secretion of the various hypothalamic releasing factors (e.g., growth hormone–releasing hormone [GHRH]). The hypothalamus, the body's thermostat, also controls body temperature. Stimulation by mediators such as IL-1β (endogenous pyrogen) causes fever via a biphasic mechanism; the first phase is mediated by increased intracellular ceramide and the second by cyclooxygenase-2 (COX-2)–mediated prostaglandin E_2.[12,13] CRH is also peripherally produced in the adrenal medulla, gastrointestinal tract, skin, nerve fibers, and immune cells. At inflammatory sites, CRH acts as a paracrine or autocrine inflammatory mediator (Fig. 106-2) via peripheral CRH receptors.[14,15]

During stress, the releasing factors, along with other stimuli, stimulate the posterior pituitary gland (neurohypophysis) to release arginine vasopressin (AVP), also known as antidiuretic hormone (ADH), and the anterior pituitary (adenohypophysis) to secrete prolactin (PRL) and growth hormone (GH) into the circulation.[16] CRH, acting synergistically with AVP, stimulates the secretion of pro-opiomelanocortin by the anterior pituitary. In the stressed state, IL-6, working through IL-6 receptors present on the pituitary corticotrophic cells, also acts synergistically with CRH. Pro-opiomelanocortin is cleaved to adrenocorticotropic hormone (ACTH), β-endorphin, and α–melanocyte-stimulating hormone (α-MSH), thus linking endogenous opioids with the hypothalamic-pituitary axis. ACTH, in turn, stimulates the zona fasciculata of the adrenal cortex to secrete glucocorticoids. A meta-analysis showed that the cortisol response increases with age and is greater in women than in men.[17] Glucocorticoids, including those administered exogenously, constitute a negative feedback system suppressing hypothalamic CRH and AVP secretion. In the unstressed state, the hypothalamic-pituitary control mechanism regulates cortisol secretion in a circadian rhythm, with peak concentrations occurring in the early morning and the nadir around 11 PM. In the postoperative stressed state, cortisol secretion increases twofold to threefold with disruption of the circadian rhythm, specifically, longer peak-to-nadir intervals.[18] Interestingly, α-MSH concentrations are decreased after major trauma.[19]

Arginine Vasopressin (Antidiuretic Hormone)

AVP, vital for maintaining intravascular homeostasis, is secreted when osmolality is increased, arterial pressure is decreased, and blood volume is reduced.[20] It causes vasoconstriction (V1 receptors) via the phosphatidyl-innositol-biphosphonate pathway and renal water retention (V2 receptors) by stimulating water channel aquaporin-2.[21] Plasma AVP concentrations are elevated after various

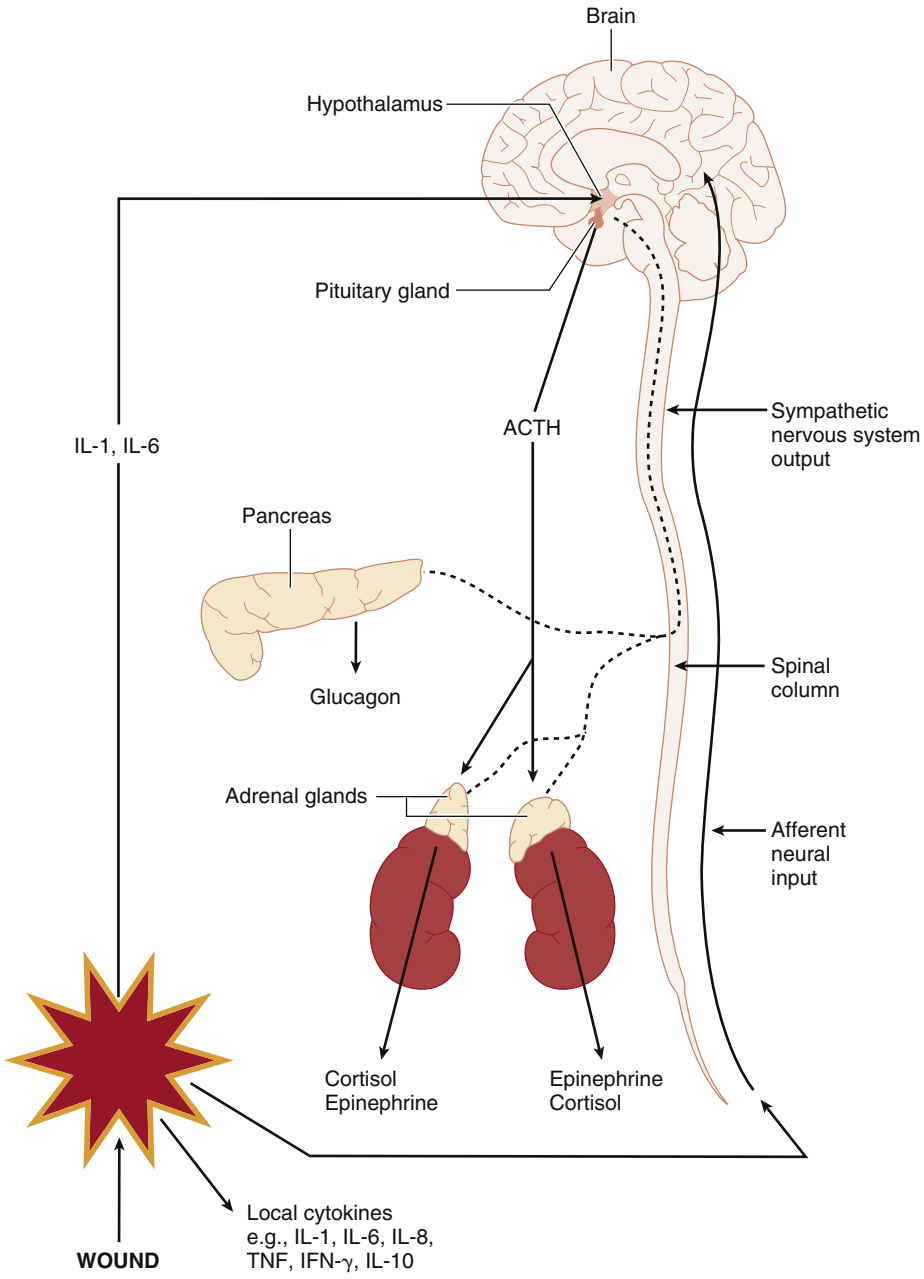

Figure 106-1. Mechanisms that initiate the stress response are shown. Afferent neural input plus cytokines, such as IL-6 and IL-1, stimulate the hypothalamic-pituitary axis, which leads to the secretion of adrenocorticotropic hormone (ACTH). This secretion stimulates the adrenal cortex to release cortisol and activates the sympathetic nervous system, which stimulates the pancreatic alpha cells to secrete glucagon and the adrenal medulla to secrete epinephrine. Cytokines and growth factors act locally in the area of the wound, and some also have endocrine effects. *IFN-γ*, Interferon gamma; *IL*, interleukin; *TNF*, tumor necrosis factor.

stresses, including surgery, pneumonia, and myocardial infarction with or without left ventricular failure. Plasma AVP concentrations increase after surgery begins and often remain increased for days after its completion. The magnitude and duration of the elevated plasma vasopressin concentrations are proportional to the degree of stress. In septic shock, an initial increase in AVP concentrations is followed by a decrease to extremely low concentrations.[22] Relatively low AVP concentrations are among the reasons for persistent vasodilation in septic shock and also in hemodynamic instability after cardiac surgery[23,24] (also see Chapter 67). Furthermore, some patients with septic shock for 3 or more days have impaired osmoregulation characterized by the lack of AVP response to a saline load.[25]

Growth Hormone

GH secretion by the anterior pituitary is stimulated by hypothalamic GH-releasing factor and inhibited by hypothalamic somatostatin. GH, vital in the regulation of growth during the prenatal and childhood periods, has a biphasic effect during stress. Initial exposure (2 to 3 hours) produces insulin-like effects, but longer exposure causes anti-insulin and anabolic effects. The latter increases the incorporation of amino acids into structural proteins, glucose intolerance as a result of insulin resistance, and increased lipolysis as a result of increased sensitivity to the lipolytic effects of catecholamines. GH stimulates the secretion of insulin growth factors 1 and 2 (IGF-1 and IGF-2) by the liver and other peripheral tissues. IGF-1 has insulin-like actions and also mediates the anabolic and skeletal growth–promoting activity effects of GH. IGF-1 facilitates anabolism by directly reducing protein oxidation and enhancing insulin sensitivity to enable insulin and GH to stimulate protein synthesis. A 5-day infusion of IGF-1 into normal subjects did not change the glucose oxidation rate but increased lipid oxidation, raised resting energy

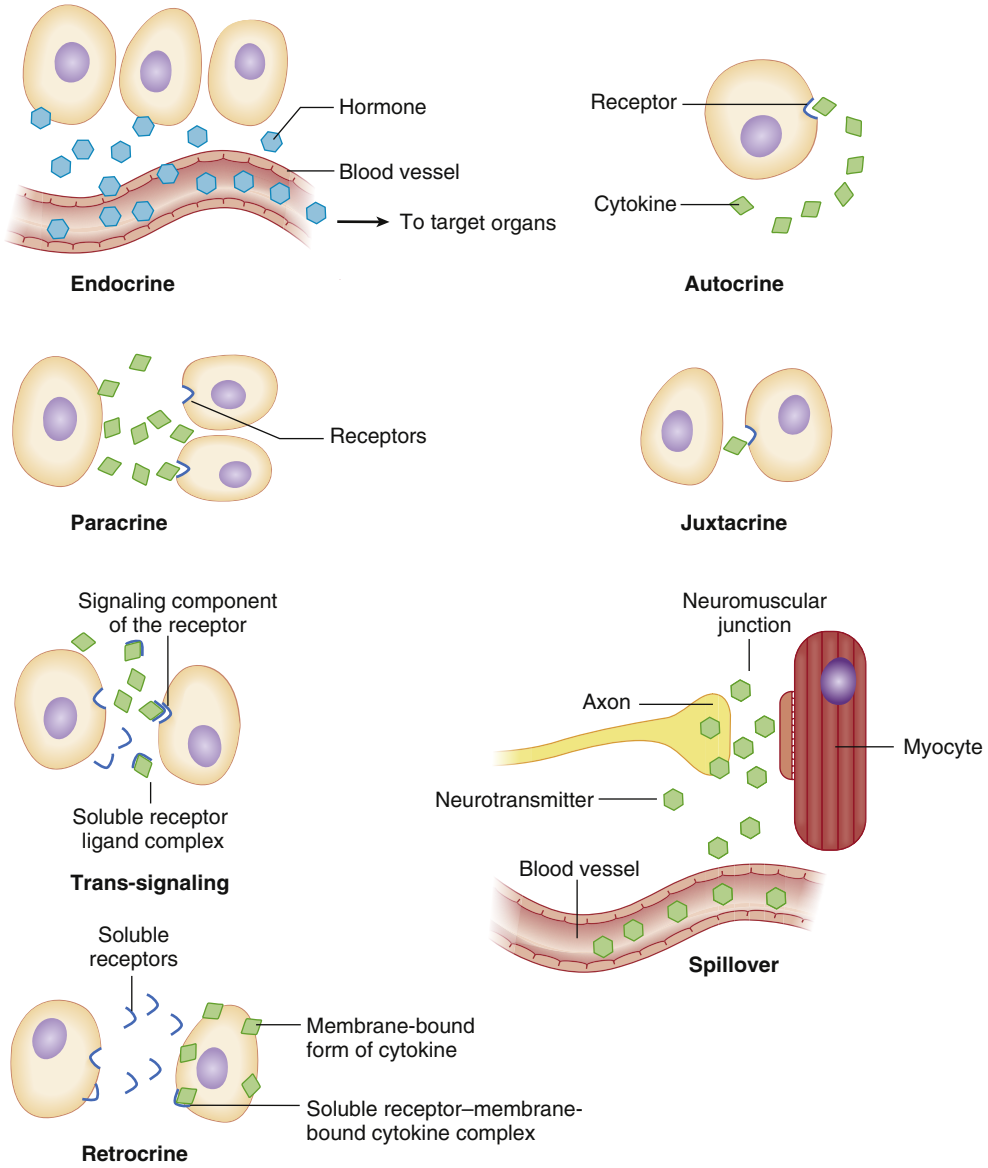

Figure 106-2. Hormones, cytokines, and other bioactive substances use various mechanisms to affect end-organ function. *Endocrine*—Hormones and other substances are transported to end organs via the bloodstream. *Autocrine*—Secreted substances affect the cell that produced them. *Paracrine*—Mediators act locally within the same tissue bed. *Juxtacrine*—Mediators act on adjacent cells. *Trans-signaling*—Soluble receptor binds in the presence of its ligand to the signaling component of a multimeric receptor complex. *Spillover*—Neurotransmitter not taken up by nerve endings enters blood vessels. *Retrocrine*—Soluble receptors interact with membrane-bound forms of cytokines and are used to control cytokine effects.

expenditure (REE), and reduced protein oxidation. The seven IGF-binding proteins modify the availability and actions of IGF-1. Most (~90%) circulating IGF-1 is bound to insulin-like growth factor–binding protein 3 (IGFBP-3), whereas IGFBP-1 plays a major role in regulating unbound (free) IGF-1.

Immediately after major traumatic injury, burns, and surgery, GH blood concentrations are increased roughly proportional to the degree of trauma. However, after day 1, the preoperative or preinjury GH concentrations start to decline. In patients who are severely traumatized, the pulsatile nature of GH secretion persists, but the bursts occur less frequently. IGF-1, IGF-2, and IGFBP-3 are reduced 40% to 60% after trauma and burns, as well as with acute respiratory distress syndrome (ARDS), whereas IGFBP-1 and IGFBP-4 are increased.[26] In septic patients, both serum IGFBP-1 and IGFBP-3 concentrations were decreased with IGFBP-3 being the major determinant of IGF- concentrations.[26a] The decreased IGF-1 and IGFBP-3, despite elevated GH, is possibly due to a resistance to the stimulatory effects of GH on the liver.[27] The decreases in GH and IGF-1 concentrations are ascribed to an inhibition by IL-1β. The consequence of these decreases is protein catabolism. Furthermore, reduced postoperative suppression of the GH and IGF-1 axis plus markedly elevated cortisol concentrations were associated with postoperative delirium.[26b,26c]

ENDOCRINE SYSTEM

The hypothalamic-pituitary axis is the main controller of the endocrine system, which, in turn, controls much

of the body's metabolic functions (see Fig. 106-1). Endocrine hormones are major mediators of the metabolic response to stress. The hormones glucagon, cortisol, and catecholamines oppose the effects of insulin on glucose and lipid metabolism and are thus called the *counter-regulatory hormones*.

Sympathoadrenergic System

The sympathoadrenergic system, made up of the sympathetic nervous system and adrenal gland, produces and secretes the catecholamines, norepinephrine, epinephrine, and dopamine (see also Chapter 16). Serum concentrations of these hormones increase after stresses such as anxiety, hypotension, hypothermia, surgery, burns, hypercarbia, and accidental injury. In patients who are severely burned, norepinephrine concentrations increase 2- to 10-fold in parallel with the burn size.[28] The pattern of catecholamine secretion is age dependent. Compared with younger (median age of 34 years) victims with trauma, older (median age of 66 years) sufferers had higher circulating norepinephrine but attenuated epinephrine levels with increasing injury severity (also see Chapter 81).[29] Concurrent with sympathetic system activation, parasympathetic activity is acutely suppressed. This suppression is important because the parasympathetic nervous system reduces proinflammatory responses.[30]

Epinephrine is secreted into the bloodstream by the adrenal medulla in response to sympathetic nervous system activation, whereas most norepinephrine is released from sympathetic nerve endings. Plasma epinephrine concentrations thus reflect adrenomedullary secretion, whereas plasma norepinephrine levels are an index of sympathetic nervous system activity. Plasma concentrations of epinephrine and norepinephrine do not necessarily increase simultaneously. Most norepinephrine released by sympathetic ganglia is removed from the synapse by reuptake into the nerve ending. Therefore, only norepinephrine that *spills* over into the plasma is assayed (see Fig. 106-2). Plasma norepinephrine concentrations are thus the difference between the spill over and plasma clearance rates. Besides increased secretion of endogenous catecholamines, many patients who are critically ill receive vasopressor and inotropic support with infusions of exogenous catecholamines, which have additive metabolic and other effects. For example, dopamine infusions depress thyroid-stimulating hormone (TSH), PRL, and GH secretions, whereas norepinephrine infusions reduce insulin sensitivity.[31]

In addition to cardiovascular effects, catecholamines have major metabolic effects. β_2-adrenergic stimulation increases glycogenolysis, hepatic gluconeogenesis, and glucagon release while blocking glycogen synthesis.[32,33] Lipolysis is increased by β_2- and β_3-adrenergic stimulation but inhibited by α_2-stimulation. Women are more sensitive to the lipolytic actions of catecholamines than men.[34] Epinephrine infusion in normal subjects does not affect protein metabolism.[35] The lesser role of the catecholamines, as opposed to glucagon, in instigating and maintaining abnormal glucose metabolism in patients with burns, was demonstrated by the failure of propranolol to reduce the rates of glucose production and glucose cycling.

The sympathoadrenal system also affects the immune system. Lymphoid parenchyma (spleen, thymus, lymph nodes, bone marrow) have sympathetic neuronal innervations that enable lymphocytes and macrophages (T-helper 1 [Th1] cells have surface β receptors) to be directly affected by sympathetic output. β_2-receptor stimulation of lymphoid cells downregulates the synthesis of proinflammatory cytokines, upregulates the synthesis of antiinflammatory cytokines, and inhibits Th1 cell function (cellular immunity), thus favoring humoral immunity (Th2 cells).[30,36] However, during sepsis, the immunosuppressive effects of catecholamines are attenuated, and epinephrine seems to either increase or not reduce TNF-α secretion.[36] The sympathoadrenergic system is thus a major mediator of the stress response and also part of its negative feedback arm.

Glucocorticoids

The plasma concentrations of cortisol, a major stress hormone, are significantly increased after surgical and traumatic stress primarily as a result of enhanced secretion by the adrenal cortex. However, in some situations the increased concentrations are also due to reduced renal function and reduced hepatic clearance, secondary to decreased hepatic blood flow.[37] In addition, enhanced cortisol production is minimally suppressed by exogenous glucocorticoid administration, as demonstrated by the inability of 24 mg/day of dexamethasone administered for 2 days after a craniotomy to suppress the elevated concentrations of either ACTH or cortisol. Increased plasma cortisol concentrations stimulate gluconeogenesis, sensitize adipose tissue to the action of lipolytic hormones (GH and catecholamines), and increase proteolysis by blocking the antiproteolytic actions of insulin.[38] Cortisol causes insulin resistance by decreasing the rate of insulin activation of the glucose uptake system (inhibiting the translocation of glucose transporter–4 to the cell membrane) and increasing 11β-hydroxysteroid dehydrogenase activity.[38a] Additionally, cortisol has antiinflammatory and immunosuppressive actions. The antiinflammatory actions include negative feedback to ACTH and proinflammatory cytokine production, as well as stimulation of the secretion of IL-10, an antiinflammatory cytokine. These antiinflammatory and immunosuppressive actions prevent stress-activated defense mechanisms from overshooting and damaging the organism. Unlike elevated concentrations, basal concentrations of cortisol are antilipolytic and probably facilitate normal immune responses.

Cortisol is a vital mediator of the stress response because it facilitates catecholamine action and secretion, thus helping maintain cardiovascular stability during surgical stress. The importance of glucocorticoids is demonstrated by the excessive mortality during stress observed in adrenalectomized animals and patients with Addison disease. Furthermore, increased mortality was observed when etomidate was used to sedate patients who were critically ill. Etomidate blocks adrenal steroidogenesis by inhibiting 11β-hydroxylation and 17α-hydroxylation. Similarly, patients receiving or having received exogenous steroids within the 6 months before a stressful event should receive steroid replacement therapy to avoid the problems of adrenal insufficiency.

The magnitude and duration of the increases in both intraoperative and postoperative ACTH and cortisol levels correlate well with the degree of surgical trauma. Cortisol concentrations may remain elevated for up to 2 weeks after femoral fractures and burns. The increased ACTH secretion during surgery is often far greater than that required to produce a maximal adrenocortical response, as demonstrated by the observation that administering exogenous ACTH during surgery did not increase plasma cortisol concentrations. In prolonged critical illness (7 to 10 days), serum ACTH concentrations are low, despite elevated cortisol levels, indicating other mechanisms stimulate the adrenal cortex.[39]

Cortisol is 80% bound to cortisol-binding globulin (CBG), which has a high affinity but low capacity for binding cortisol, and 10% to serum albumin, which has a low affinity but a high capacity for this process. The remaining unbound cortisol, referred to as *free cortisol*, is biologically active.[40] Direct measurement of the free cortisol concentration accounts for the binding effects of albumin, whose concentration is reduced after major surgeries and during sepsis.[41] After major surgery, during sepsis, and after burn injury, free cortisol concentrations are elevated because of both increased total cortisol concentrations and reduced CBG. After major elective surgery, serum total cortisol increased by 55% and CBG decreased by 30%.[42] In the stressed state, the free cortisol level provides a better measure of adrenal responses than total cortisol.[43] Measurements of tissue cortisol levels were significantly elevated in burned and nonburned skin and did not correlate with plasma free or total cortisol measurements but with the extent of the burns. Therefore, plasma levels do not necessarily reflect tissue activity.[44] The reduced CBG is likely caused by inhibition of CBG production by IL-6 and/or increased CBG degradation as a result of elevated neutrophil-released esterase.

The glucocorticoids work through multiple neurocircuits and signaling mechanisms to provide negative feedback to reduce the output of the activated hypothalamic-pituitary axis. Feedback occurs via multiple mechanisms, including a fast feedback mechanism in which glucocorticoids activate membrane glucocorticoid receptors to induce endocannabinoid synthesis in the hypothalamic paraventricular nucleus (PVN) with retrograde cannabinoid type I receptor-mediated suppression of the excitatory drive to PVN neuroendocrine cells.[39] Other mechanisms include corticosteroids shutting off hippocampal, amygdala, and pituitary outputs, causing negative feedback to the hypothalamic-pituitary axis.[39]

Glucagon and Insulin

Glucagon and insulin are both secreted by the pancreas, the former by alpha cells and the latter by beta cells. These hormones enter the portal vein, exposing the liver to high concentrations of both. The principal action of glucagon is to stimulate hepatic glycogenolysis and gluconeogenesis (also see Chapter 39). Glucagon increases hepatocyte cyclic adenosine monophosphate (cAMP) and, via cAMP-activated protein kinase and adenosine monophosphate (AMP)–activated protein kinase, promotes glycogenolysis.[45] When gluconeogenic substrate (lactate, alanine, glycerol) delivery to the liver is increased, glucagon promotes gluconeogenesis with phosphorylation of cAMP-response element modulator (CREM), which then binds to response elements in genes that are upregulated to produce the enzymes of gluconeogenesis.[45] Insulin has the opposite effect; it decreases intracellular cAMP concentrations, preventing gluconeogenesis. Glucagon increases intracellular cAMP via a different receptor—a secondary messenger mechanism than is used by adrenergic mediators.[46] Glucagon also increases hepatic glycogenolysis and ketogenesis during starvation and diabetic ketoacidosis. Whether or not the physiologic levels of glucagon stimulate lipolysis is still debated.[47] In the unstressed state, hypoglycemia, protein–amino acid intake, endorphins, exercise, GH, epinephrine, and glucocorticoids stimulate glucagon secretion. Somatostatin, insulin, and glucose infusion or ingestion suppresses glucagon secretion.

Insulin is an anabolic hormone with many effects. In addition to increasing glucose transport across the cell membranes of adipocytes and myocytes, it stimulates glycogen production, promotes glucose oxidation, inhibits lipolysis in adipose tissue and skeletal muscle, inhibits net fatty acid oxidation, inhibits hepatic and muscle ketogenesis, and increases the rate of amino acid transport and protein synthesis in muscle, adipose tissue, and liver. Insulin operates via phosphatidylinositol 3-kinase and activates Akt (protein kinase B), which, among other processes, results in increases in glucose transporter GLUT-4. The plasma glucagon:insulin ratio is the major determinant of the degree of gluconeogenesis. During fasting and starvation, the ratio is increased, secondary to increased glucagon and decreased insulin concentrations. This increased ratio facilitates glycogenolysis and promotes gluconeogenesis. In the fed state, the reverse is true, with insulin predominating.

Serum glucagon concentrations increase after most types of major surgery. The glucagon:insulin ratio increases because insulin concentrations decrease during surgery. The decreased insulin concentrations are attributed to a suppression of insulin secretion by elevated catecholamine concentrations or increased urinary losses. This suppression can be abrogated by α-adrenergic blockade. The hormonal milieu of low insulin with increased catecholamines, cortisol, and glucagon stimulates gluconeogenesis and, along with insulin resistance, causes hyperglycemia. In patients with sepsis, this mechanism may fail, resulting in hypoglycemia, a situation associated with extremely poor survival rates.[48] Postoperatively, insulin concentrations escalate because of increases in both plasma glucose and epinephrine-induced β-adrenergic stimulation. Unlike starvation, the plasma insulin concentrations are often significantly increased above basal values, although they are inappropriately low for the prevailing level of glycemia.

Counter-Regulatory Hormones

The hormones, glucagon, catecholamines, and cortisol, are called *counter-regulatory hormones* because they oppose the effects of insulin and synergistically act to increase hepatic glucose production. These hormones upregulate the genes responsible for producing the enzymes of the gluconeogenic pathway.[49] Shamoon and associates[50] explored the short-term effects in normal subjects of the

combined infusion of hydrocortisone, glucagon, and epinephrine designed to simulate the plasma levels found in a moderate injury. They observed increased glucose production (gluconeogenesis) and decreased glucose clearance; the effect was more pronounced when all three hormones were administered together than when they were infused individually or in groups of two, suggesting that they act synergistically.[50] Catecholamines and glucagon act synergistically; when either one is infused into normal subjects, only transient elevations in gluconeogenesis occur; when they are simultaneously infused, gluconeogenesis is more prolonged. A possible reason for this synergism is that glucagon increases intracellular cAMP, especially in the liver, by a non–β-receptor mechanism, which could amplify the actions of epinephrine. Cortisol acts synergistically with epinephrine and other β-adrenergic agonists (an action used in the treatment of asthma). Both glucagon and cortisol enhance the transcription of the genes responsible for producing gluconeogenic enzymes, such as glucose-6-phosphatase. Proposed mechanisms include cortisol-induced inhibition of catechol-*O*-methyltransferase and blockade of catecholamine reuptake. Glucocorticoids also prevent β_2-adrenergic receptor downreglation by increasing both β_2-receptor expression and increasing β_2-receptor gene transcription.[51] Additionally, glucocorticoids reduce cytokine concentrations, which is important because both IL-1 and TNF can downregulate β receptors. In addition, prolonged postoperative adrenergic stimulation downregulates and desensitizes β receptors, which is partially reversed by the glucocorticoids.[52] Simultaneous infusion of the three hormones also caused negative nitrogen and potassium balances, glucose intolerance, hyperinsulinemia, insulin resistance, sodium retention, and peripheral leukocytosis. The nitrogen losses appear to be mainly attributable to cortisol because nitrogen balance during cortisol infusion was similar to that during the infusion of all three hormones. The nitrogen losses were also not of the magnitude observed after accidental injury. With hormone infusions, significant alterations in leucine flux and oxidation occurred, but only small increases in 3-methylhistidine excretion, indicating little muscle breakdown. Therefore, other mediators must cause the proteolysis and massive nitrogen loss observed after major injury. In addition, the normal subjects were not febrile, failed to increase acute-phase proteins, and did not have decreased serum iron. When the pyrogenic (stimulates IL-1 secretion) steroid etiocholanolone was injected into normal subjects, fever, leukocytosis, and hypoferremia without elevations in the counter-regulatory hormones, hyperglycemia, or negative nitrogen balance resulted. Infusion of the counter-regulatory hormones plus etiocholanolone simulated more of the features of the response to injury than when they were individually administered. Therefore, both endocrine and inflammatory mediators are active during the response to injury and sepsis.

Reproductive Hormones

The response to surgical and traumatic injury results in hypogonadotropic hypogonadism. The pituitary gland is less responsive to hypothalamically secreted gonadotropin-releasing hormone (Gn-RH), decreasing the release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH). FSH and LH concentrations change little during surgery but decrease on the first postoperative day. Elevated concentrations of CRH and cortisol may also contribute to the suppressed reproductive function.[53] In men, testosterone concentrations are significantly decreased as a result of decreased production and increased clearance. The decrease was in direct relationship to illness severity; total testosterone decreased more than free testosterone, paralleling a decrease in sex hormone–binding protein.[54,55] In patients with burns, the decreased testosterone was due to lowered biologic activity of LH and a suppressed response to peaks in pulsatile LH secretion. In men, the adrenal androgens, dehydroepiandrosterone (DHEA) and its sulfate (DHEA-S), are suppressed after surgery. In premenopausal women, decreased estrogen concentrations during stress are associated with amenorrhea. However, in postmenopausal women, DHEA and DHEA-S were increased after cholecystectomy. This finding is interesting because adrenal androgen concentrations are in decline after menopause. Estradiol concentrations are elevated in critical illness. The magnitude of the increases directly correlates with mortality, regardless of gender.[56] Increased peripheral aromatization from androgens and not from increased production is the main cause of increased serum estradiol.[55]

Thyroid Hormones

During postoperative convalescence, after trauma, after extensive burns, and during sepsis (i.e., during nonthyroidal acute illnesses), alterations in thyroid homeostasis occur with low serum T_3, low or normal T_4, normal free T_4, elevated reverse T_3, and normal TSH. These alterations are called either *nonthyroidal illness syndrome* or *sick-euthyroid syndrome*. Inactivation of T_3 and T_4 is accelerated in skeletal muscle and liver attributable to greater type-3 deiodinase activity and less conversion of T_3 to T_4 because of reduced type-1 deiodinase activity. However, the role of decreased type-1 deiodinase activity has been questioned because T_3 often falls before the enzyme activity decreases.[57] Although TSH concentrations are within the normal range, nocturnal surges are lower, similar to the pattern found in central hypothyroidism. Additionally, sialylation (by oligosaccharide) of TSH is decreased, possibly explaining the altered TSH bioactivity. The mechanism of nonthyroidal acute illness development is still unclear, especially in prolonged critical illness during which T_4 concentrations also decrease. Some investigators have pointed to the lack of TSH elevation in the presence of a low serum T_3 concentration and questioned whether the problem is too little stimulation by thyroid-releasing hormone (TRH).[58] A postmortem study of the paraventricular nuclei of patients with antemortem sick-euthyroid syndrome reinforced this view. A positive correlation between low antemortem serum T_3 and TSH concentrations occurs with total postmortem TRH messenger ribonucleic acid (mRNA) in the nuclei. However, infusion of TRH in the patient with a stressful illness increased TSH and peripheral thyroid concentrations.[59]

Elevated serum levels of IL-6 and possibly IL-1 are associated with the low serum T_3 concentrations during illness.[60] Short-term (4-hour) and long-term (42-day) recombinant IL-6 infusions decrease T_3 but not T_4

concentrations. It is unclear whether elevation of IL-6 is one of the causes of nonthyroidal acute illnesses or is simply an associated phenomenon. Normal subjects infused with endotoxin indicated that TNF does not play a role in endotoxin-induced thyroid hormonal changes. Dopamine infusion decreases basal TSH concentrations, inhibits the TSH response to TRH, decreases both serum T_4 and T_3 levels, and may aggravate sick-euthyroid syndrome. Cessation of dopamine infusion results in increases in TSH, T_4, and T_3. In hospitalized patients older than 65 years of age, low T_3 is a sensitive predictor of poor short-term survival, whereas low free T_3 is a predictor of prolonged mechanical ventilation and mortality in patients in an ICU (also see Chapters 80, 101, and 102).[61,62,62a] There has been interest in treating nonthyroidal acute illnesses with thyroid hormone and TRH. A systematic review of thyroid therapy in patients after surgery showed that intravenous T_3 therapy increased cardiac output but did not affect mortality.[63]

In nonthyroidal acute illnesses, plasma free–T_4 concentrations remain normal, despite reduced total T_4 concentration because of reduced thyroxine-binding globulin (TBG) concentrations. During stress, hepatic synthesis of TBG is reduced and clearance may also be accelerated (protease cleavage). An intriguing aspect of thyroid metabolism in patients with stressful illnesses is that they are hypermetabolic, despite low T_3 and T_4 levels.

CYTOKINES

The response to injury and sepsis includes both neuroendocrine and inflammatory or immune responses. Cytokines, the main mediators of the inflammatory response, are produced by cells of the immune system (e.g., lymphocytes, macrophages), and many have multiple functions (Table 106-1). The pattern of cytokine release, that is, the type and intensity of the stress, is genetically and environmentally determined. These patterns control the severity of the inflammatory response and the degree of the immune response.[64] Some cytokines (e.g., TNF-α, IL-1α/β, interferon [IFN]–γ, IL-6, IL-8, IL-17, IL-18) are proinflammatory (type I), whereas others (e.g., IL-4, IL-10, TGF-β, IL-13, IL-37) are antiinflammatory (type II). Some (e.g., IL-12) induce cellular immunity by directing uncommitted T-helper cells toward the Th1 phenotype, whereas others (e.g., IL-10) induce the Th2 phenotype and enhance humoral immunity. The inflammatory response is controlled by the balance between the proinflammatory and antiinflammatory cytokines. During and after colorectal surgery, IL-6, IL-8, and IL-10 were elevated above the preoperative baseline levels.[65] Moreover, survival from sepsis was correlated with the recurrent secretion of proinflammatory rather than antiinflammatory cytokines, indicating that the inflammatory response's stimulation of the immune system is necessary to overcome sepsis. Furthermore, after trauma the suppression of proinflammatory cytokines IFN-γ and IL-12 along with the elevation of antiinflammatory cytokine IL-10 was associated with immunosuppression and sepsis.[64]

The release of proinflammatory cytokines requires two steps.[66] The initial step is the production of the cytokine pro-form as the result of signals from pathogen-associated molecular patterns (PAMPs). The activation and release of these cytokines, such as IL-1β and IL-18, involves inflammasomes, which are multimolecular complexes that recognize patterns associated with pathogenic bacteria and activate the inflammatory cascade.[67,68] Inflammasomes form in macrophages and contain nucleotide-binding oligomerization domain (NOD)–like receptor proteins (e.g., NLRP3, NLRC4) and DNA-sensing complexes, that congregate and activate proinflammatory caspase-1. NLRC4 activation also induces pyroptosis (a form of programmed cell death) of macrophages that robs macrophage-tropic bacteria of their hiding place, exposing them to the extracellular world and the immune system's full onslaught. The messy nature of pyroptosis is also an effective means of disseminating the inflammatory response and alerting the host to the presence of pathogens. Other inflammasomes, especially those found in neutrophils that contain NLRP3, are involved in the response to other pathogens. These release IL-1 beta and IL--18 but not IL-1 alpha and IL-33.[68a]

Cytokines closely interact with the endocrine system, as demonstrated by significant elevations in ACTH and cortisol after IL-6 administration to patients with cancer. Alternatively, endocrine hormones affect cytokine secretion; for example, cortisol suppresses the secretion of IL-1 and TNF-α.

Cytokines operate via local paracrine, autocrine, and juxtacrine mechanisms, as well as through endocrine effects (see Fig. 106-2). Therefore, plasma concentrations do not necessarily reflect cytokine activity. Cytokine actions are also modulated by a complex network of receptors, receptor-antagonists, and cytoplasmic signaling molecules. For example, the effects of IL-1 are moderated by the simultaneous secretion of IL-1 receptor antagonist (IL-1ra), which blocks its actions. Furthermore, soluble cytokine receptors are generated by the proteolytic cleavage of membrane-bound receptors or by *de novo* production. These circulating soluble receptors bind cytokines and may either neutralize cytokine actions or act as carrier proteins that protect the cytokine from proteolysis. Therefore, they may have either proinflammatory or antiinflammatory functions.

The local actions of cytokines are demonstrated by the acute wound healing process that occurs in overlapping phases: hemostasis, inflammation, proliferation, angiogenesis, and resolution. The inflammatory phase involves infiltration of neutrophils, macrophages, and lymphocytes that secrete growth factors and cytokines. These mediators, acting locally, are active at all stages of wound healing through chemotactic, mitogenic, and other effects. During the first 24 hours, cytokines in the wound drainage in elective incisional hernia repair include high concentrations of both proinflammatory (IL-1α, IL-6, and IFN-γ) and antiinflammatory (IL-10, IL-1ra) cytokines. The concentrations decline over the next few days. It appears that the two types of cytokines balance each other, with the proinflammatory cytokines stimulating immune cells to prevent infection while the antiinflammatory cytokines modulate their actions and promote healing.

Despite cytokine actions being primarily autocrine, paracrine, and juxtacrine, significant research has explored their blood concentrations in stressful situations. In general, the blood concentrations are proportional to the degree of stress. After the moderate stress of total hip replacement surgery, IL-6 was significantly elevated above preoperative levels during the first 6 postoperative hours but began returning

TABLE 106-1 **CYTOKINES**

Cytokine	Function
TNF-α (cachectin) Proinflammatory	• Stimulates T and B cells and macrophages. • Is a chemotactic agent for neutrophils. • Stimulates neutrophil respiratory burst and proliferation. • Stimulates the release of tissue factor from endothelium and monocytes. • Stimulates monocytes to release other proinflammatory cytokines. • Has antitumor activity. • Mediates cancer and AIDS cachexia. • Inhibits synthesis of lipoprotein lipase; suppresses lipogenesis in adipocytes. • Stimulates synthesis of acute-phase proteins. • Mediates part of the cell-mediated immunity against obligate and facultative bacteria and parasites. • Is involved in the development of insulin resistance. • Decreases erythropoietin production that leads to the anemia of inflammation. • Promotes the proliferation of fibroblasts.
IL-1 Proinflammatory	• Stimulates myelopoiesis via the stimulation of G-CSF and GM-CSF. • Is an endogenous pyrogen. • Stimulates T (NK cells) and B lymphocytes and macrophages. • Attenuates anticoagulatory mechanisms and promotes thrombotic processes; induces the production of tissue factor. • Induces monocytes to release various mediators. • Stimulates T-helper cells, which are induced to secrete IL-2 and to express IL-2 receptors. • Promotes the adhesion of neutrophils, monocytes, T cells, and B cells by enhancing the expression of adhesion molecules such as ICAM-1 and ELAM. • Mediates inflammatory reactions; enhances the metabolism of arachidonic acid (in particular, prostacyclin and PGE_2).
IL-4 Antiinflammatory	• Inhibits macrophage activity. • Proliferates and activates B cells. • Enhances Th2 cell differentiation. • Inhibits cell activation of NK cells induced by IL-2.
IL-6 Proinflammatory and antiinflammatory	• Stimulates the acute-phase protein response. • Stimulates the hypothalamus to secrete CRF. • Inhibits 5′-deiodinase in sick euthyroid syndrome, which converts T_4 to T_3. • Stimulates B lymphocytes and is involved in their differentiation into plasma cells. • Induces the differentiation of mature and immature T cells into cytotoxic T cells in the presence of IL-2. • Stimulates the secretion of antibodies.
IL-8 Proinflammatory	• Is a neutrophil chemotactic agent. • Synthesis is strongly stimulated by IL-1 and TNF-α. • Activates neutrophils; releases enzymes from granules. • Is chemotactic for all known types of migratory immune cells; enhances the expression of adhesion molecules.
IL-10 Antiinflammatory	• Is produced by and downregulates the function of Th1 and Th2 cells. • Inhibits antigen-presenting cell activity. • Suppresses macrophage activity. • Inhibits the production of proinflammatory cytokines such as IFN-γ, IL-2, and TNF-α in Th1 subpopulations. • Is stimulated by bacterial lipopolysaccharides in macrophages. • Inhibits the synthesis of IL-1, IL-6, and TNF-α by promoting the degradation of cytokine mRNA. • Prevents the activation of macrophages.
IL-13 Antiinflammatory	• Downregulates macrophage activity, reducing the production of proinflammatory cytokines (IL-1, IL-6, IL-8, IL-10, IL-12) and chemokines (MIP-1, MCP) in response to IFN-γ or bacterial lipopolysaccharides. • Enhances the production of IL-1ra. • Strongly inhibits tissue factor expression induced by bacterial lipopolysaccharides, and reduces the pyrogenic effects of IL-1 or TNF, thus protecting endothelial cells and monocytes against inflammatory mediator–induced procoagulant changes.
IFN-γ Antiinflammatory	• Has antiviral and antiparasitic activities. • Main biologic activity is as an immunomodulatory. • Activating macrophages is a major function. • Influences cell-mediated mechanisms of cytotoxicity. • Is a modulator of T-cell growth and functional differentiation. • Is the hallmark cytokine of Th1 cells.

AIDS, Acquired immunodeficiency syndrome; *CRF*, corticotropin-releasing factor; *ELAM*, endothelial leukocyte adhesion molecule; *G-CSF*, granulocyte colony-stimulating factor; *GM-CSF*, granulocyte-macrophage colony–stimulating factor, *ICAM-1*, intercellular adhesion molecule-1; *IFN*, interferon; *IFN-γ*, interferon gamma; *IL*, interleukin; *IL-1ra*, interleukin-1 receptor antagonist; *MCP*, monocyte chemoattractant protein; *MIP-1*, macrophage inflammatory protein-1; *mRNA*, messenger ribonucleic acid; *NK*, natural killer; *PGE_2*, prostaglandin E2; *Th1*, T-helper 1 cells; *Th2*, T-helper 2 cells; *TNF-α*, tumor necrosis factor alpha.

toward baseline by the first postoperative day. In contrast, IL-1β, IL-12, IL-10, and IL-8 levels were not elevated.[69] Laparoscopic radical prostatectomy resulted in lower IL-10, IL-6 and IL-1 beta immediately after surgery and postoperative day 1 than open radical prostatectomy.[69a]

Many cytokines have multiple functions (see Table 106-1). For example, IL-1 causes fever, induces hepatic acute-phase protein synthesis, upregulates prostanoid synthesis, induces the maturation of B lymphocytes, and activates natural killer (NK) lymphocytes. IL-6 (also called *B-cell–stimulating factor* and *hepatocyte-stimulating factor*) has endocrine and local functions. Many cells produce IL-6, including monocytes, fibroblasts, glial cells, and lymphocytes. Its production is stimulated by endocrine hormones such as catecholamines and suppressed by cortisol and estrogens. The soluble IL (sIL) receptors of the IL-6 family (e.g., sIL-6R, sIL-11R) are agonists capable of transmitting signals through interaction with the universal signal-transducing receptor for all IL-6 family cytokines, gp130 (see Fig. 106-2).

TNF-α, a multifunctional proinflammatory cytokine predominantly secreted by monocytes and macrophages, affects lipid metabolism, immunity, hematopoiesis, coagulation, and endothelial function (see Table 106-1). TNF-α has seeming contradictory properties. For example, it induces neutrophil proliferation during inflammation but it can also induce neutrophil apoptosis.[70] Moreover, TNF-α intensifies the inflammatory response by prolonging the survival of inflammatory cells through the suppression of Fas-mediated apoptosis (Fig. 106-3). The multiple roles of TNF are demonstrated by the TNF blockers, etanercept, adalimumab, and infliximab, which are used to treat rheumatoid arthritis. However, these drugs

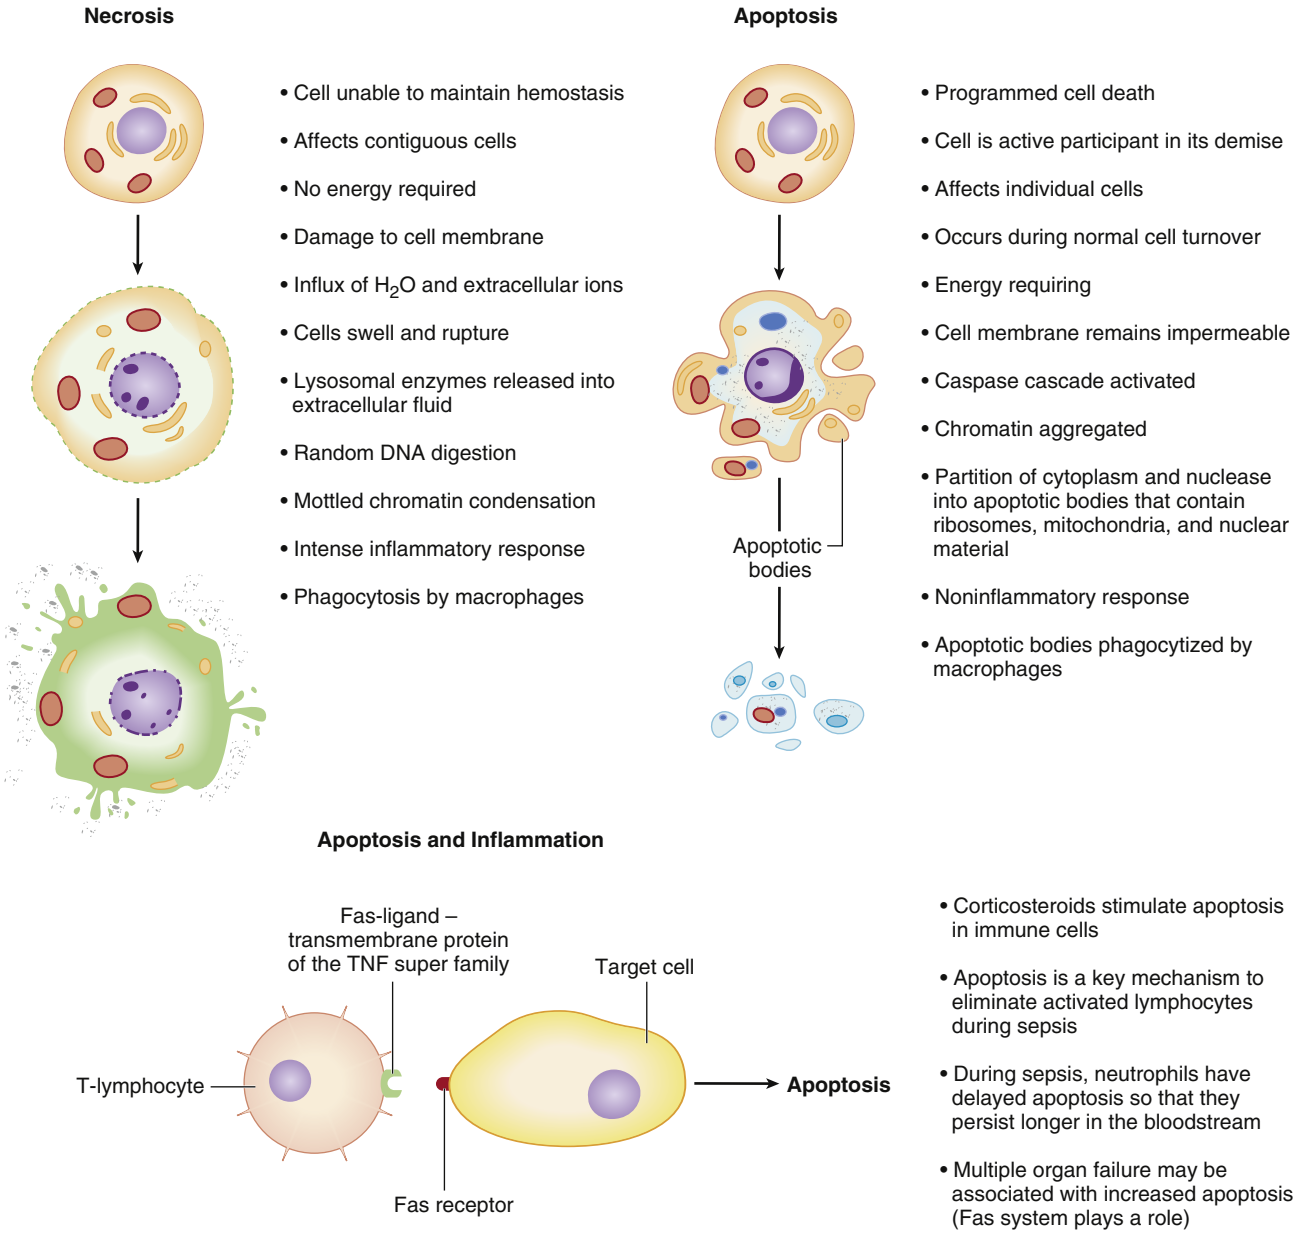

Figure 106-3. The differences between necrosis and apoptosis are shown. The importance of apoptosis during inflammation is also diagrammed. *DNA*, Deoxyribonucleic acid; *H_2O*, water; *TNF*, tumor necrosis factor.

increase the risk for developing tuberculosis because TNF plays a crucial role in the body's immune defense against the mycobacteria causing this disease.[71]

ADIPOKINES

Besides storing fat, adipose tissue is a metabolically active endocrine organ with metabolic effects differing, depending on the location of the adipose tissue.[72] Adiponectine, one of the many adipokines, is vasculoprotective and antiatherogenic because it can stimulate vascular endothelial nitric oxide (NO) production, which leads to decreased platelet aggregation and vasodilation.[72] The antiinflammatory actions of adiponectine are due to its suppression of TNF-α production and the sensitization of tissues to insulin. Leptin controls appetite, thus modulating food intake and body weight. Leptin concentrations are proportional to insulin levels and inversely proportional to glucocorticoid concentrations. Resistin stimulates the secretion of proinflammatory cytokines and decreases the endothelial production of adhesion molecules. In addition, adipose tissue secretes proinflammatory cytokines, such as TNFα, IL-1, IL-6, IL-8, and monocyte chemoattractant protein-1 (MCP-1).[73]

During critical illness, plasma adiponectine levels are decreased, leptin concentrations are either lower or unchanged, and resistin levels are increased.[74,75,75a] In such situations, serum resistin concentrations correlate with inflammatory mediators such as C-reactive protein (CRP), IL-6, and TNF-α.[76] In the lungs of patients with viral or bacterial pneumonia there is increased expression of leptin with evidence from animal studies that leptin has pulmonary pro-inflammatory properties.[76a] After major abdominal surgery, serum adiponectine concentrations and its intraadipocyte mRNA were decreased, intraadipocyte IL-6 mRNA was increased, and serum resistin levels increased.[77,78] Resistin, IL-6, and MCP-1 mRNA expression increased during cardiac surgery in both subcutaneous and epicardial adipose tissue, whereas TNF-α expression also increased in subcutaneous adipose tissue.[79] This upregulation of inflammatory mediators along with the downregulation of adiponectine indicate that adipose tissue contributes to the altered metabolic milieu found during surgical, traumatic, and septic stress. Furthermore, the infusion of endotoxin into healthy subjects indicated that adipose inflammatory and insulin-signaling pathways might be involved in the systemic insulin resistance found in such conditions.[80]

ENDOTHELIAL CELLS

Vascular endothelial cells are metabolically active, playing an active role in the stress response by synthesizing various important mediators such as NO and adhesion molecules.[80a] The adrenergic hyperactivity, hypoperfusion, hypoxemia, and inflammation associated with trauma and sepsis trigger this enhanced endothelial cell activity (Fig. 106-4).

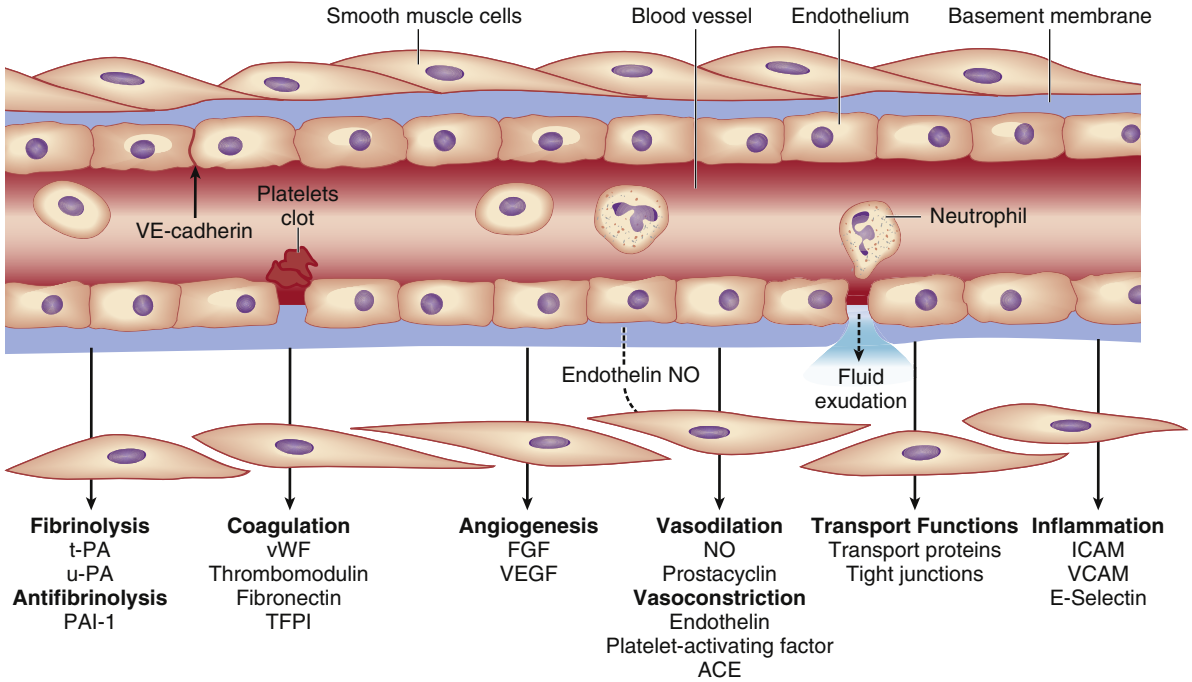

Figure 106-4. Endothelial cells have many functions. Nitric oxide (NO), produced by endothelial cells, vasodilates blood vessels by relaxing adjacent myocytes, whereas endothelin causes vasoconstriction. The NO-endothelin system is the local controller of vascular tone. During sepsis, inflammatory cytokines, such as tumor necrosis factor (TNF), upregulate inducible NO synthetase (iNOS), increasing endothelial production of NO and resulting in vasodilation. During sepsis, endothelial disruption occurs because of the shedding of the glycocalyx, the thin layer of glucosaminoglycans covering the endothelial surface, increased expression of adhesion molecules, resulting in white blood cell attachment and the disruption of both the vascular endothelial (VE)–cadherin and the basement membrane and in the exudation of fluid into the extracellular space. Moreover, the number of circulating endothelial cells is increased. Adhesion molecules and selectins recruit leukocytes to enter tissues. *ACE*, Angiotensin-converting enzyme; *FGF*, fibroblast growth factor; *ICAM*, intercellular adhesion molecule; *PAI-1*, plasminogen activator inhibitor-1; *TFPI*, tissue factor pathway inhibitor; *t-PA*, tissue-plasminogen activator; *u-PA*, urinary type plasminogen activator; *VCAM*, vascular cellular adhesion molecule; *VE-cadherin*, vascular endothelial cadherin (calcium-dependent adhesion); *VEGF*, vascular endothelial growth factor; vWF, von Willebrand factor.

IMMUNOLOGIC-COAGULATION CONNECTION

Surgery, burns, and trauma result in leukocytosis, thrombocytosis, and anemia. The granulocytosis that occurs with surgery and infection is mediated by the cytokine-induced release of the hematopoietic growth factor, granulocyte colony-stimulating factor (G-CSF). G-CSF increases neutrophil, monocyte, and T-lymphocyte production and is increased above preoperative levels for at least 1 week after major surgery.[81] Thrombopoietin, which increases in concert with IL-6 and acute-phase reactants, induces thrombocytosis.[82] Anemia of inflammation (also called anemia of chronic disease) occurs during acute and some chronic stressed states. Erythropoiesis is suppressed because of an inability to incorporate iron into erythrocyte precursors, despite the presence of adequate bone marrow iron stores. This suppression is ascribed to inflammatory cytokines, such as IL-6, stimulating the secretion of hepcidin, a hepatocyte-produced regulator of iron hemostasis. The increased hepcidin concentrations reduce the activity of ferroportin, thus reducing the transfer of iron out of macrophages, causing iron sequestration in macrophages.[83,84] In addition, erythropoietin secretion is decreased and sensitivity to its actions is reduced. [84a]

Significant bidirectional cross-talk occurs between the inflammatory and coagulation systems; for example, increased soluble CD40 ligand, a platelet-derived mediator of the TNF family, interacts with CD40 receptors on endothelial and immune cells, leading to increased proinflammatory, procoagulant, and immunomodulatory functions.[85,86] During the perioperative period, hypercoagulability occurs, secondary to upregulated procoagulant pathways, decreased physiologic anticoagulants and reduced fibrinolysis.[87] The former is caused by a combination of decreased antithrombin, tissue factor pathway inhibitor (TFPI), and protein C coupled with increased tissue factor (TF), causing increased thrombin generation and fibrin deposition and resulting in microvascular thrombosis. Decreased fibrinolysis is due to reduced tissue plasminogen activator (t-PA) and increased plasminogen activator inhibitor-1 (PAI-1). Cytokines are the responsible mediators: TNF-α upregulates PAI-1, monocytes express TF, and IL-6 stimulates TF. Furthermore, ex-vivo platelet reactivity increases, especially during sepsis. Acute-phase proteins contribute to the procoagulant state. Fibrinogen concentrations are elevated, as are those of α_1-antitrypsin and α_2-macroglobulin, which inhibit protein C. Increased C4-binding protein lowers free protein S, whereas CRP increases the expression of TF by monocytes and neutrophils. Circulating TF-expressing microparticles from activated or apoptotic cells also increase in sepsis and trauma.[88] The hypercoagulable state is also induced by other factors, including local tissue damage (PAI is secreted by endothelial cells) and materials such as methyl methacrylate monomers and bone marrow debris. Elevated thrombopoietin concentrations enhance platelet aggregation and contribute to the formation of monocyte-platelet aggregates.[89] In patients who are severely injured, the predominate hypercoagulable state is counterbalanced by the release of factors promoting hypocoagulability such as t-PA, soluble thrombomodulin, and glycocalyx shedding (release of heparin-like substances).[90]

During postoperative convalescence (days 3 to7), hypercoagulability gradually abates. Hypercoagulability is not triggered by the counter-regulatory hormones. Rather, when a cocktail of these hormones plus angiotensin II and vasopressin was infused into normal volunteers, fibrinolytic and anticoagulant activity increased; fibrinogen, t-PA, and protein C concentrations increased, as did platelet activity. These results are reinforced by the anticoagulant effects of an epinephrine infusion begun before an endotoxin infusion in normal subjects.

Regional anesthesia, especially after lower body surgery, causes less hypercoagulability than general anesthesia and is associated with less deep vein thrombosis (also see Chapter 56). Laparoscopic cholecystectomy appears to cause less hypercoagulability than open cholecystectomy.[91]

The procoagulant state, in turn, accelerates the inflammatory response. Thrombin, acting through protease-activated receptors, upregulates cytokines (e.g., IL-6, IL-8, MCP-1) and increases adhesion molecule expression. The TF/factor VII complex increases inflammatory responses of macrophages and neutrophils, as evidenced by increased plasma concentrations of IL-6 and IL-8 on infusion of recombinant factor VII into normal subjects.[92] Inflammation plus microvascular thrombosis is thought to be a cause of multiple organ system dysfunction.

FASTING AND MALNUTRITION

Fasting results in adaptive responses that permit the body to continue functioning, despite a lack of nutrient intake. During the 24 to 48 hours after cessation of nutrient intake, glycogen stores are broken down (glycogenolysis) to provide glucose to the tissues. This glucose is vital for the brain, red blood cells, skin, and renal medulla, which have obligatory glucose requirements. Glycogenolysis is mediated by an increased glucagon:insulin ratio (increased glucagon and decreased insulin), which also promotes endogenous glucose production (gluconeogenesis). In addition to the increases in glucagon and decreases in insulin, hypoglycemia is avoided by small increases in catecholamine and cortisol secretion. The increase in catecholamine-induced β-adrenergic stimulation accelerates lipolysis so that triglycerides (TGs) stored in adipose tissue are broken down to free fatty acids (FFAs) and glycerol. As glycogenolysis declines, some of the FFAs undergo hepatic conversion to ketones (β-hydroxybutyrate and acetoacetate), which are then used as energy sources.[93,94] As glycogen is depleted, glucose is increasingly provided by gluconeogenesis, delivering more than 90% of the glucose after 42 hours of fasting.[94] Glycerol released during lipolysis and lactate produced by glycolysis are among the substrates for gluconeogenesis.

As starvation continues, skeletal and smooth muscles undergo proteolysis to amino acids. The amino acids, alanine and glutamine, are transported primarily to the liver, but some are also transported to the kidneys to be used as substrates for gluconeogenesis. This muscle breakdown results in a negative nitrogen balance (catabolism). As starvation progresses, the body adapts by reducing the rate of gluconeogenesis and muscle breakdown, which,

along with decreases in free T_3 and catecholamines, reduces REE. Decreases in serum leptin are associated with the decrease in T_3. The reduced muscle protein breakdown results in lower nitrogen losses so that nitrogen balance becomes less negative. The decrease in gluconeogenesis is possible because the brain adapts to using ketones for some of its energy needs.[95] Simultaneously, adenosine triphosphate (ATP) is produced from the oxidation of fatty acids released by lipolysis.

Prolonged starvation leads to weight loss, secondary to major losses of fat and lean (muscle) body mass. Significant weakness and fatigue develop as the result of proteolysis and reduced muscle protein synthesis. Sodium and water retention also occurs. Prolonged starvation reduces immune function and results in increased adherence of gram-negative bacteria to nasopharyngeal and pulmonary endothelial cells. This bacterial adherence, along with weakness of the respiratory muscles and immune system, makes these patients susceptible to pneumonia, the leading cause of death in patients who are starved or severely malnourished (also see Chapters 101 and 102).

EATING

Eating sets into motion a series of steps that digest, absorb, and metabolize the ingested food. Gut hormones initiate a sequence of systematic events by signaling the body to secrete hormones such as insulin. Ingested carbohydrates are converted to glucose and stimulate insulin secretion, and the glucose not immediately needed for energy is stored as glycogen or converted to fat (lipogenesis). Ingested proteins are digested and broken down into amino acids, used to synthesize proteins, and serve as precursors for neurotransmitters and other substances. Fats are stored and used for energy or as precursors for prostaglandins and other substances. Food ingestion increases metabolic rate—diet-induced thermogenesis or thermogenic effects of food—and contributes 10% to 15% of total daily energy expenditure. Protein ingestion increases metabolic rate more than isoenergetic amounts of carbohydrates or fat.[96] The postprandial rise in energy expenditure lasts for 3 to 4 hours.

METABOLIC RESPONSES TO SURGICAL AND TRAUMATIC INJURY

The metabolic responses to surgical and traumatic stress differ greatly from the response to starvation. Unlike the adaptive responses aimed at preserving body mass that occur during starvation, the response to stress has been called *auto-cannibalism*.[97] This categorization is occasioned by the loss of fat and lean body mass caused by an obligate catabolic state with proteolysis, gluconeogenesis, lipolysis, hypermetabolism, and insulin resistance. Autocannibalism is not reduced to any great extent by exogenous nutrients (also see Chapter 81).

The intensity and duration of the metabolic response to surgery and trauma depend on the magnitude of injury, total surgical time, amount of intraoperative blood loss, and degree of postoperative pain. The smaller injury of laparoscopic surgery, compared with open surgery, results in lower concentrations of IL-1, IL-6, and the acute-phase CRP. The greatest metabolic responses are observed after a severe burn injury (>40% body surface area) with metabolic rates twice normal and catabolism that lasts for many months, leading to immunodepression, recurrent infections, and poor wound healing.[21]

CARBOHYDRATE METABOLISM

Surgical and accidental injury increase the secretion of the counter-regulatory (to insulin) hormones cortisol, catecholamines, and glucagon, resulting in elevated endogenous glucose production, secondary to accelerated hepatic gluconeogenesis (Fig. 106-5). This increased glucose production, coupled with peripheral tissue resistance

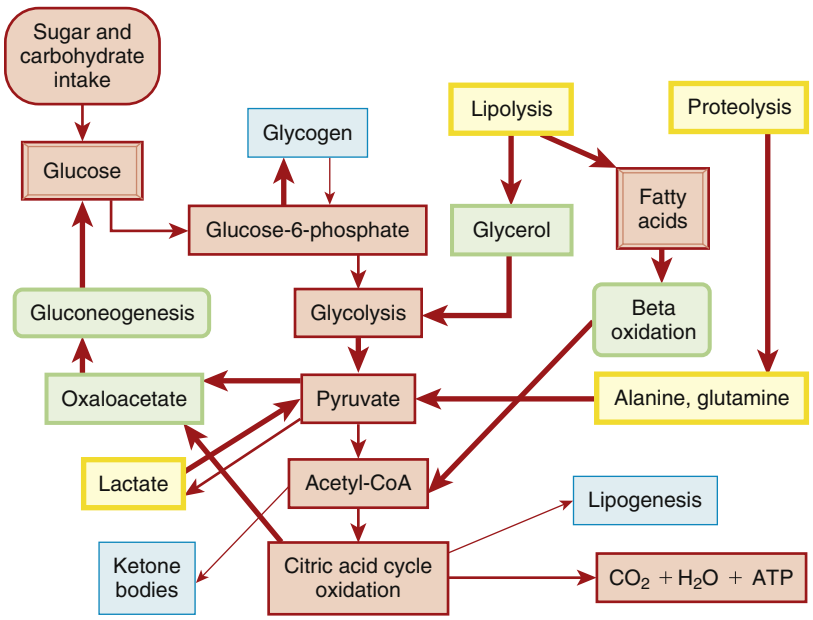

Figure 106-5. The metabolic milieu during stress. The rate of endogenous glucose production (gluconeogenesis) is greatly increased. Glycerol (from lipolysis), alanine (from proteolysis), and lactate (from the wound) are the substrates. Because of insulin resistance, less glucose is used to produce energy adenosine triphosphate (ATP); thus β-oxidation of fatty acids becomes the major energy-producing pathway. Exogenous glucose intake does not decrease the rate of gluconeogenesis. The production of ketones is not greatly increased because of normal-to-elevated concentrations of insulin. *Acetyl-CoA*, Acetyl–coenzyme A; *CO_2*, carbon dioxide; *H_2O*, water.

to insulin, results in reduced glucose utilization and hyperglycemia. Serum insulin concentrations are normal or elevated but are insufficient to prevent hyperglycemia but do prevent ketosis. Hyperglycemia is thought to ensure a ready supply of glucose to predominantly glucose-consuming cells, such as the wound inflammatory cells and immune cells.

Insulin resistance is defined as impaired glucose disposal in the presence of either normal or elevated serum insulin concentrations.[98] Insulin resistance occurs in peripheral tissues, reduces insulin sensitivity by 50% to 70%, compared with healthy controls, is likely due to a postreceptor defect that hinders cellular glucose uptake, and is related to the magnitude of surgery, the extent of burn, or the severity of sepsis.[98] Impaired activity of the intracellular glucose transport system or nonoxidative glucose disposal (i.e., reduced muscle glycogen synthetase activity) is the possible cause of this postreceptor defect.[99] Increased protein degradation, mitochondrial dysfunction, and accumulation in the endoplasmic-sarcoplasmic reticulum of unfolded protein, leading to a proapoptotic state, are associated with insulin resistance.[100,101] Insulin resistance can persist for up to 3 weeks after elective open cholecystectomy and up to 3 years after major burns.[100,102,103] In patients in the medical ICU, the severity of insulin resistance is associated with the severity of illness, body mass index (BMI), and degree of hypermetabolism.[98]

In patients with stressful illnesses, the overall amount of glucose oxidized (especially considering the overall hypermetabolism) may be decreased, despite a glucose oxidization pathway that is intact, because insulin resistance limits the rate of glucose uptake into the cell. The incremental response to increases in insulin concentration is maintained, but the ability to reduce blood glucose concentration per insulin concentration is significantly diminished. Despite the insulin resistance, the overall peripheral uptake of glucose is often normal or mildly elevated owing to increased non–insulin-mediated glucose uptake and the large amounts of glucose (as a result of hyperglycemia) being presented to the resistant insulin pathway. However, relative to the blood glucose concentration and hypermetabolism, the uptake is small.

Glucose can be oxidized to produce ATP, water, and carbon dioxide (CO_2); converted to glycogen for storage in the liver and muscles; or converted to fat. The latter process is called *lipogenesis* and occurs in both liver and adipose tissue, although the latter appears to be the main site for lipogenesis. Under normal circumstances, carbohydrate intake inhibits fat oxidation, increases glucose oxidation, and promotes fat storage. Lipogenesis is quantitatively unimportant in humans because the rate of lipogenesis does not exceed the rate of lipid oxidation. Yet, when carbohydrate intake exceeds total energy expenditure (TEE), lipogenesis becomes a more important pathway, and respiratory quotients (RQs) may exceed 1.0, indicating net lipogenesis (Box 106-1). Patients who are critically ill and administered intravenous glucose at 4 mg/kg/min as part of glucose-based total parenteral nutrition (TPN) exhibited some increased hepatic *de novo* lipogenesis, despite achieving an RQ of only 0.90.[104] This lipogenesis occurred even though lipogenetic capability is thought to be reduced in surgical or septic stress. The reduced lipogenesis is possibly secondary to TNF, which, among other things, can induce apoptosis of preadipocytes and adipocytes. IL1-β may also inhibit lipogenesis in human adipocytes.

BOX 106-1 ***Criteria for the Systemic Inflammatory Response Syndrome and Sepsis***

SYSTEMIC INFLAMMATORY RESPONSE SYNDROME (SIRS)

Two or more of the following criteria are required:

1. Body temperature: >38° C or <36° C
2. Heart rate: >90 beats/minute
3. Respiratory rate: >20 breaths/minute or partial arterial pressure of carbon dioxide ($Paco_2$): <32 mm Hg
4. White blood cell (WBC) count: >12,000 mm^3 or <4000 mm^3 or >10% immature forms

SEPSIS

SIRS plus a documented infection site (documented by positive culture for organisms from that site). Blood cultures do **NOT** need to be positive. Although SIRS, sepsis, and septic shock are commonly associated with bacterial infection, bacteremia may not be present.

SEVERE SEPSIS

Sepsis plus associated organ dysfunction, hypoperfusion abnormalities, **OR** hypotension.

Hypoperfusion abnormalities include but are not limited to:

1. Lactic acidosis
2. Oliguria
3. Acute alteration in mental status

SEPTIC SHOCK

Sepsis-induced hypotension, despite fluid resuscitation **PLUS** hypoperfusion abnormalities.

LIPID METABOLISM

Stressful situations (e.g., injury, sepsis) alter lipid metabolism. The major change is accelerated lipolysis attributed to increased β_2-adrenergic stimulation.[105] Stimulation of the β_2-receptors increases cAMP concentrations, which stimulates the activity of hormone-sensitive lipase through protein kinase A, and also likely adipose TG lipase (Fig. 106-6).[106] Endotoxin appears to stimulate lipolysis also via inflammatory IKKB/NF-kappaB (IκB kinase–nuclear factor kappa–light-chain-enhancer of activated B cells) pathway.[107] The lipolytic response to β_2 stimulation is greater in lean, rather than obese, individuals. β_3-adrenergic receptors also play a role in human lipolysis. Elevated concentrations of glucagon, TNF-α, IL-1, INF-α, and INF-γ likely have roles in stimulating lipolysis.[108] IL-6 stimulates lipolysis in skeletal muscle but not adipocytes.[109] Insulin resistance contributes to lipolysis because the antilipolytic effect of insulin is attenuated.[98] Regional variations in lipolytic rates exist. Visceral fat cells have the highest rate as a result of increased β_2- and β_3-receptor activity and reduced α_2-receptor activity. Subcutaneous fat has less lipolytic activity as a result of greater insulin receptors and α_2-receptor activity. These regional differences originate from differences in adipose stem cells.[110] The RQ in injured patients is consistently lower than in normal subjects for a given level of intake,

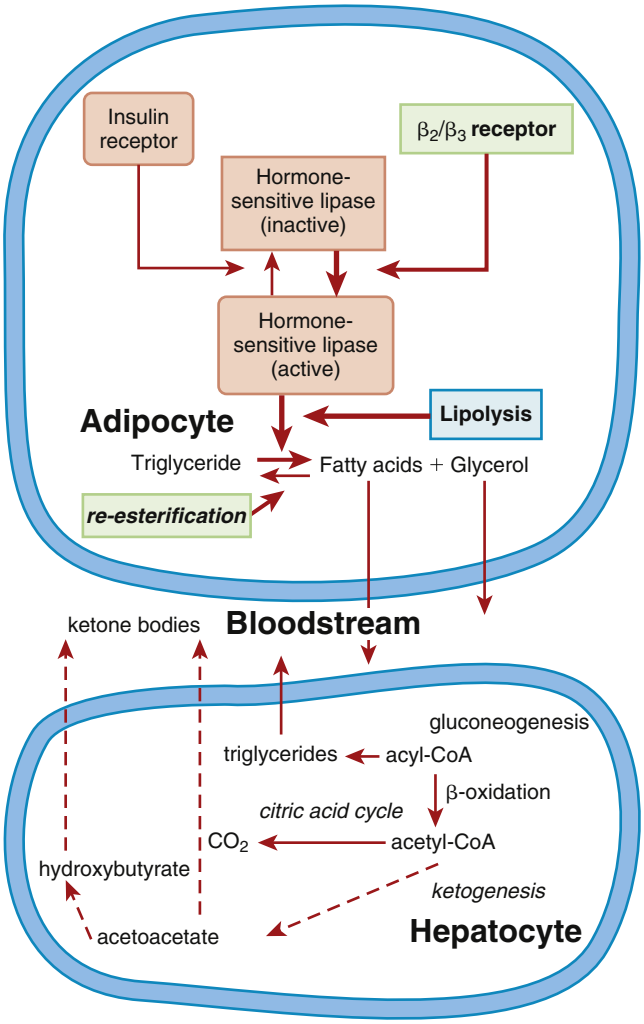

Figure 106-6. Lipid metabolism during the stressed state. Catecholamines stimulate β_2 and β_3 receptors, activating hormone-sensitive lipase, leading to lipolysis. Free fatty acids are transported to the liver where they undergo β-oxidation and are the main source of energy during stress (palmitoyl-CoA yields a net of 130 adenosine triphosphate [ATP]). Glycerol released by lipolysis is a substrate for gluconeogenesis and is converted to glucose. Because insulin concentrations are elevated, ketone production is not increased. Both lipolysis and re-esterification are increased, leading to a futile cycle. *CoA*, Coenzyme A; *CO_2*, carbon dioxide.

indicating greater fat oxidation (Table 106-2). Infusion of glucose in amounts that lead to net fat synthesis in normal subjects fails to suppress fat oxidation in patients who are injured and with sepsis, leading to negative fat balance. Plasma FFA concentrations are high because the lipolytic rate exceeds the rate of fat oxidation.

Rapid glycerol and FFA turnover rates reflect the accelerated lipolysis observed during stress. The increased lipolysis increases the systemic supply of circulating FFAs. However, the turnover rates are greater than those expected from the increases in the plasma concentrations of these substrates, which indicates that both increased re-esterification of FFAs to TGs and increased lipolysis of TGs to FFAs have occurred. This increased activity of the TG-FFA/glycerol substrate cycle is thought to be one of the causes of the hypermetabolism observed during stress (Fig. 106-7). β-Adrenergic receptor blockade with propranolol decreases lipid oxidation and the resting metabolic rates of patients with burns. Glucose infusions further increase lipolysis during abdominal surgery because they increase sympathetic nervous system activity.

In the stressed state, the relative contribution of fat oxidation to REE is increased, whereas the contribution of glucose oxidation is decreased. FFAs released by lipolysis undergo β-oxidation, which is the predominant ATP-producing pathway in patients who are stressed (see Figs. 106-5 and 106-6). This situation is reflected in observations made after esophagectomy when a gradual decrease in the contribution of fat oxidation to energy production and an increase in the contribution of glucose oxidation occur as patients convalesce.

PROTEIN METABOLISM

Among the hallmarks of the metabolic response to injury and sepsis is catabolism (negative nitrogen balance). Accelerated proteolysis of skeletal muscle, which provides some of the substrate for increased hepatic gluconeogenesis (see Fig. 106-5), causes catabolism. Reducing the rate of hepatic gluconeogenesis with somatostatin does not decrease the rate of peripheral protein breakdown, demonstrating that the accelerated rate of hepatic glucose production is not linked to the increased level of peripheral protein breakdown. The degree of nitrogen loss is proportional to the degree of stress and abates as the patient convalesces. After severe burns, protein breakdown and subsequent amino acid efflux from muscle is increased almost twofold. The endocrine stress hormones, specifically cortisol, only partially modulate the enhanced protein breakdown. Instead, other mediators such as TNF-α, IL-1, IL-6, and IFN-γ mediate catabolic activity.[111] The balance between these catabolic mediators and anabolic hormones (e.g., insulin and IGFs) determine the magnitude of catabolism. Among the pathways responsible for skeletal muscle proteolysis are lysosomal cathepsin and the ubiquitin–proteasome proteolytic pathways.[111,112] The liver also contributes to catabolism through increased clearance of α-amino nitrogen (urea). After surgery, the rate of this conversion is doubled. Blockade of glucagon and cortisol secretions with a combination of etomidate, somatostatin, and thoracic epidural anesthesia decrease this clearance, thus indicating roles for glucagon and possibly cortisol and afferent neural reflexes in this process.

Conflicting data regarding the mechanism of the net loss of skeletal muscle protein has been reported. Constantin and associates[112] report increased protein breakdown plus reduced muscle protein synthesis (e.g., 31% decrease 24 hours after open cholecystectomy) whether saline or TPN is infused.[112] The deranged protein metabolism is profound because administering TPN after open cholecystectomy did not prevent the decline in muscle protein synthesis observed 24 hours after surgery. Liver biopsies taken during surgery demonstrated depressed hepatic protein synthesis after 20 minutes of surgery that further decreased as the surgery progressed. Tissues with rapidly replicating cells, such as enterocytes, immune cells, and keratinocytes, also exhibit reduced protein synthesis. Other investigators report that the net negative

TABLE 106-2 ENERGY EXPENDITURE AND CALORIC REQUIREMENTS

Energy Expenditure (Definitions)

Basal energy expenditure (BEE); also called *basal metabolic rate* (BMR): Is the energy expended on awakening from a 12-hour fast; it is measured in a thermoneutral environment (25° C).
Thermogenic effect of food; also called *specific dynamic action*: Is the energy expended after the ingestion of food. Energy expenditure may increase 5% to 10% after a meal.
Resting energy expenditure (REE): Is the energy expended while resting in the supine position with eyes open. It includes the thermogenic effect of food if performed within a few hours of a meal or during continuous infusions of nutrients such as during continuous total parenteral nutrition (TPN) administration. REE is approximately 10% greater than BEE.
Sleeping energy expenditure (SEE): Is the energy expended during sleep and is usually 10% to 15% lower than REE.
Activity energy expenditure (AEE): Is the energy expended during physical activity. During maximum exercise, AEE can be 6- to 10-fold greater than the BEE.
Environmental temperature: Energy expenditure increases to warm patients who are in a cold environment. Warming occurs through shivering and increased metabolism of brown fat (neonates).
Fever: Fever increases the metabolic rate 10% per degree Celsius (C) (or 7% per degree Fahrenheit (F).
Total energy expenditure (TEE): Is the total energy expended over 24 hours; that is, TEE is the sum of the energy expended during periods of sleep, resting, and activity.

Estimating Resting Energy Expenditure

1. Harris-Benedict equation
   Males: eBEE (kcal/d) = 66 + (13.7 × W) + (5 × H) – (6.8 × A)
   Females: eBEE (kcal/d) = 655 + (9.6 × W) + (1.7 × H) – (4.7 × A)
   eREE = eBEE × stress factor
   eTEE = eREE × activity factor
   eBEE, Estimated basal energy expenditure; *eREE*, estimated resting energy expenditure; *eTEE*, estimated total energy expenditure; *W*, weight (kg); *H*, height (cm); *A*, age (years).
2. Stress factors
   Nonsedated patients who are spontaneously breathing:
   Major surgery: 15%-25%
   Infection: 20%
   Long-bone fracture: 20%-35%
   Malnutrition: Subtract 10%-15%
   Burns: Up to 120%, depending on the extent
   Sepsis: 30%-55%
   Major trauma: 20%-35%
   Chronic obstructive pulmonary disease (COPD): 10%-15%
   Sedated patients who are mechanically ventilated (full ventilatory support): Subtract 10%-15%
3. Activity factors
   Sedated patients who are mechanically ventilated: 0%-5%
   Patients who are mechanically ventilated (assisted ventilation): 5%-10%
   Bedridden, nonsedated patients who are spontaneously breathing: 10%-15%
   Patients who are sitting in a chair: 15%-20%
   Ambulating patients: 20%-25%

Measuring Energy Expenditure

Indirect calorimetry involves measuring oxygen consumption (VO_2) and carbon dioxide production (Vco_2). The gas exchange method is used to measure VO_2 and Vco_2, whereas the Fick method can be used to measure only VO_2.
Weir equation: Energy expenditure (EE) (kcal/d) = 1.44 (3.9 × VO_2) + (1.1 × Vco_2)
To provide the REE: Measurements made at rest
To determine the TEE: REE × activity factor
To provide the TEE: Continuous measurement over 24 hours

Measuring Nitrogen Balance

N balance = [N intake] – [N output]; Negative balance = catabolism; Positive balance = anabolism
Where [N intake] = all protein/amino acid intake over 24 hours, whether enteral or parenteral
[N output] = [UUN + 4 + EL]
UUN, Urine urea nitrogen over 24 hours; 4 g average fecal and cutaneous losses; *EL*, excessive losses, such as protein-rich drainages (e.g., pus).
6.25 g protein/amino acids = 1 g nitrogen

Daily Caloric Requirements

Patients	Using Measured or eREE	Using Body Weight
Sedated and mechanically ventilated	1.0 – 1.2 × REE	20-24 kcal/kg
Unsedated and mechanically ventilated	1.2 × REE	22-24 kcal/kg
Spontaneously breathing	1.2 – 1.3 × REE	24-26 kcal/kg
Spontaneously breathing (maintenance)	1.3 × REE	24-26 kcal/kg
Spontaneously breathing (repletion)	1.5 – 1.7 × REE	25-30 kcal/kg

To gain one pound of body weight, an excess above the TEE of approximately 3500 kcal is needed.

TABLE 106-2 **ENERGY EXPENDITURE AND CALORIC REQUIREMENTS—cont'd**

Respiratory Quotients	Energy (kcal/g)	Respiratory Quotient (RQ)*
Carbohydrate	4.0	1.00
Dextrose (glucose monohydrate)	3.4	1.00
Fat	9.0	0.70
Protein	4.0	0.80
Ethanol	7.0	0.67
Lipogenesis		8.00

RQ, Ratio of resting CO_2 production to resting O_2 consumption.
* Whole body RQ is influenced by the relative amounts of carbohydrate, fat and protein oxidation, and lipogenesis. For example, a patient who has received a 5% dextrose infusion of 100 mL/hr (440 kcal/day) for 4 days has a whole body RQ of 0.77-0.80, reflecting the predominance of fat and protein oxidation as the energy source. Whole body RQ above 1.0 indicates net lipogenesis. Human RQs above 1.2-1.3 are not generally seen, even with extremely high carbohydrate intakes.

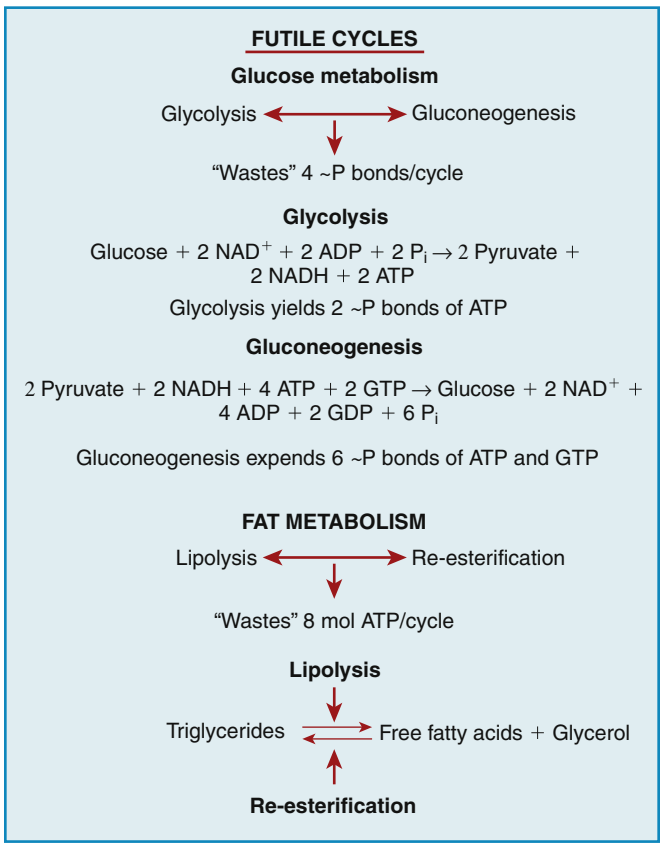

Figure 106-7. Two futile cycles contribute to the hypermetabolism of the stress response. A futile cycle is a set of opposing reactions catalyzed by different enzymes acting simultaneously, with at least one of the reactions driven by adenosine triphosphate (ATP) hydrolysis, enabling heat to be produced. In the lipid metabolism cycle, net lipolysis occurs, whereas in the glucose metabolism cycle, net gluconeogenesis is present. *~P*, High-energy phosphate bond, generally from ATP. *ADP*, adenosine diphosphate; *GDP*, guanosine diphosphate; *GTP*, guanosine-5′-triphosphate; *NAD+*, nicotinamide adenine dinucleotide; *NADH*, nicotinamide adenine dinucleotide hydrogen; *P_i*, *phosphoglucose isomerase*.

nitrogen balance is due to accelerated protein breakdown in excess of increased protein synthesis.[113,114]

The detrimental effects of prolonged bed rest further contribute to the derangements in protein metabolism caused by the stress hormones and cytokines after injury and surgery. In normal volunteers, 28 days of bed rest resulted in a 0.4-kg loss of leg muscle mass and a reduction of 23% in leg extension strength.[115] When hydrocortisone was administered to such bed-rested volunteers in doses intended to reproduce cortisol concentrations encountered during illness or trauma, a threefold greater loss of lean leg mass (1.4 kg) was reported, which represents a 6% loss of muscle mass from the legs and a 4-kg loss of whole-body lean mass. In addition, a 28% reduction in leg extension strength occurred. The muscle protein synthesis rate was decreased, whereas muscle protein breakdown was unchanged from rates before bed rest.[116] In contrast, patients with blunt trauma had a greater mean loss of whole-body lean mass because they suffered from proteolysis in addition to reduced protein synthesis. Extended periods of immobilization in bed contribute to the loss of muscle mass and the weakness suffered by patients with stressful illnesses. Early mobilization and exercise are thus important aspects of care.

During stress, hepatic synthesis of the acute-phase proteins such as fibrinogen, haptoglobin, complement, immunoglobulins, serum amyloid A, and CRP is increased.[117] The secretion of the acute-phase proteins is stimulated by elevated concentrations of endogenous corticosteroids (which by themselves do not initiate the response) in concert with IL-1β, TNF-α, and IFN-γ. These cytokines induce the secretion of IL-6 by the hepatic Kupffer cells, which acts synergistically with corticosteroids to initiate and stimulate acute-phase protein production via the transcription factor signal transducer and activator of transcription 3 (STAT3).[117] Simultaneously, IL-6 and the corticosteroids initiate a negative feedback loop, suppressing IL-1β and TNF-α production by mononuclear phagocytes. Bacterial infections tend to trigger a stronger acute-phase response than viral infections. The acute-phase response improves the ability to fight infection, stimulates wound healing, and improves hemostasis. The increase in fibrinogen increases hemostatic ability and plasma viscosity.[118] The latter is the reason the erythrocyte sedimentation rate is used as a nonspecific diagnostic test for disease activity. CRP is a measure of the acute-phase response and degree of stress because of enormous concentration increases (e.g., on the second day after hip replacement concentrations increased from <6 to >200 mg/L).[69]

Reduced synthesis of binding proteins, such as albumin, transthyretin (prealbumin), retinol-binding protein, and transferrin, simultaneously occur with the increased synthesis of acute-phase proteins. This reduction in the synthesis and plasma concentrations of binding proteins elevates the plasma concentrations and bioavailability of free hormones and electrolytes. As previously discussed, decreased plasma concentrations of cortisol-binding globulin and albumin increase the concentrations of free cortisol. Albumin concentrations (half-life, 21 days) decrease because of reduced synthesis, redistribution in the expanded extracellular fluid, and a greater fractional catabolic rate. Therefore, short-term changes in albumin concentrations do not reflect changes in synthesis. For nutritional evaluation, proteins (e.g., prealbumin) with short half-lives (2 days) are measured. However, they also have limitations because concentrations are decreased in hepatic failure and increased with renal failure.[119]

ENERGY EXPENDITURE

Metabolism consumes fuels, such as glucose and fatty acids, to produce energy-containing compounds (e.g., ATP) for use in many energy-consuming body functions. Among the major functions of eating is replenishing this fuel. The amount of fuel burned is directly reflected by the amount of energy released as heat (direct calorimetry) and indirectly reflected by the amount of oxygen consumed, CO_2 produced, and urine urea nitrogen excreted (indirect calorimetry). The components of the daily TEE are outlined in Table 106-2. Daily caloric intake should be sufficient to meet the daily energy expenditure. Intakes in excess of TEE result in the deposition of fat and weight gain, whereas sustained intakes less than TEE result in weight loss.

In patients with stressful illnesses, the altered metabolic milieu increases REE. The Harris-Benedict equation (see Table 106-2) estimated that patients with trauma, sepsis, chronic obstructive pulmonary disease (COPD), or burns and are spontaneously breathing after surgery have REEs that are above the estimated REE (eREE).[120-122] The resultant elevation of REE is in contradistinction to starved or semi-starved individuals whose energy expenditure decreases as part of an adaptive response.

Patients who are spontaneously breathing after surgery have shown a measured (via indirect calorimetry) REE greater than the eREE. The higher REEs ranged from 10% to 20% after elective surgery to 20% to 40% during sepsis (although values as high as 80% have been reported after sepsis). Patients with fractures of the long bones tend to have higher REEs and eREEs than those with similar degrees of injury without fractures. A peak REE occurs during approximately the third postoperative day, and hypermetabolism may last as long as 3 to 4 weeks in patients with trauma or with burns who are critically ill. Patients with burns can be extremely hypermetabolic (with a REE as much as 120% greater than the eREE) with the degree of hypermetabolism proportional to the extent and severity of the burns.[123] Older patients (>60 years of age) have less of a hypermetabolic response (also see Chapter 80).

Patients who are mechanically ventilated after surgery and patients with trauma have lower increases in REE than patients who are spontaneously breathing because they are receiving sedatives and/or muscle relaxants, both of which decrease the REE by as much as 20%.[124] In such patients, measured REEs are often within ±10% to 16% of the eREEs.[125,126] Another cause of this lack of hypermetabolism is that they have no or minimal work of breathing when ventilation is controlled by the mechanical ventilator. As they begin to breathe spontaneously, the REE rises because of the increased work of breathing and reduced sedation. During weaning from mechanical ventilation, energy expenditure rises further as the patient sustains more of his or her breathing, sedation is stopped, and anxiety sets in.[127] However, these patients in the ICU who are extremely ill retain resuscitation fluid (*third space*) that increases their body weight by as much as 10% to 12%. Because edema fluid has no metabolic activity, using their current instead of their preinjury weight in the Harris-Benedict equation may overestimate the eREE and thus underestimate the degree of hypermetabolism.[128]

The causes of hypermetabolism during stress are multifactorial. Fever results in an increase of 11% in energy expenditure for each increased degree of Celsius in body temperature. In addition, the effects of the increase in energy-consuming processes such as gluconeogenesis and ureagenesis increase the rate of metabolism. Catecholamines infused into normal subjects increase the metabolic rate.[129] This increase is even greater when cortisol, glucagon, and catecholamines are infused together. The significant hypermetabolism in patients with head injuries has been ascribed to major sympathetic nervous system activation, which also occurs with other types of intracranial pathologic conditions. For example, for at least 5 days after subarachnoid hemorrhage, the REE was 18% above the eREE. Shivering during induced hyperthermia can result in significant increases (>200%) in energy expenditure; therefore, treatment with sedatives and/or neuromuscular blockade is indicated. The increased energy expenditure has also been ascribed to increased protein oxidation and synthesis. Yet, after elective surgery, only a modest change in energy expenditure has been reported, despite increased protein turnover. Another process that contributes to hypermetabolism is *futile substrate cycling* (see Fig. 106-7). Reducing the rate of the lipolysis in the re-esterification futile cycle with β-adrenergic blockade reduced REE in burned children. The teleologic reason for the increase in futile cycling is that it affords patients the flexibility to adapt quickly to changes in energy substrate demands.

Environmental factors may also affect energy expenditure. Elevated ambient temperature and humidity have been shown to reduce the REE of patients with burns by reducing evaporative losses and, in turn, reducing the need to generate energy to maintain body temperature.

METABOLIC RESPONSES TO SEPSIS

Unlike the short-term stress of elective surgery with its ensuing recovery period, sepsis is characterized by an ongoing stressful stimulus with systemic effects that can lead to multiple organ system dysfunction. The basic

metabolic response observed during sepsis is similar to that after major surgery, burns trauma, and major nonseptic illnesses such as pancreatitis and serious transfusion reactions (e.g., blunting of the inhibitory effects of insulin on lipolysis and gluconeogenesis).[130] However, the presence of bacteria and bacterial components that initiate and sustain additional metabolic, inflammatory, immunologic, and coagulation responses further characterize sepsis.[131] These responses are demonstrated by the greater number of complement and coagulation proteins found in the plasma proteome profile of infected, as opposed to uninfected, patients with trauma who are critically ill.[79] Such biochemical differences, whether proteonomic or metabolomic, are important because they may serve as biomarkers for early detection of active infection and for differentiating between sepsis or septic shock and the noninfective systemic inflammatory response syndrome (see Box 106-1).[132]

As part of the innate immune host defenses, Toll-like receptors (a group of pattern recognition receptors) recognize extracellular or phagosomal alarmins, either PAMPs, which are products of bacteria, viruses, fungi, and protozoa, or intracellular proteins (damage-associated molecular patterns [DAMPs], such as high-mobility group box 1) released by damaged cells.[133] In addition to the Toll-like receptors, there are cytosolic NOD-like receptors, which recognize intracellular PAMPs and RIG-I–like receptors, which recognize viral RNA.[134] Stimulation of Toll-like receptors activates transcription factor NF-κB and c-*Jun* N-terminal kinase (JNK) in immune cells, which initiate transcription of genes encoding proinflammatory cytokines. Mice deficient in Toll-like receptors still succumb to sepsis, indicating that multiple pathways are active during sepsis. The type of infection influences the nature of the inflammatory response. Endotoxins (lipopolysaccharide) from gram-negative bacteria induce the production of TNF-α, IL-1, and IL-6, whereas exotoxin from gram-positive organisms significantly increases IL-8 more than TNF-α, IL-1, and IL-6.[135] Furthermore, sterile inflammation produces a different expression of Toll-like receptor genes than sepsis,[136] whereas septic shock produces a different cytokine profile than severe sepsis.[137] Viral infections produce different profiles from those produced by bacterial infections.

Critical illness–related corticosteroid insufficiency, which is defined as inadequate serum corticosteroid activity for the severity of illness, reportedly occurs with some frequency in patients with sepsis[138] (also see Chapter 101). Cortisol concentration may be in the supranormal range and may increase in response to additional ACTH stimulation. The clinical presentation of critical illness–related corticosteroid insufficiency is usually reduced responsiveness to fluid and vasopressor therapy; it is also associated with increased mortality. This relative adrenal insufficiency is acute and self-limited as it reverses upon resolution of the acute illness. The cause is unknown but might be attributable to decreased ACTH level or cortisol secretion and/or reduced tissue sensitivity to glucocorticoids.[139] Therefore, finding ways to easily and rapidly identify patients with this problem and to determine whether glucocorticoid replacement improves outcome are the challenges.[138] Multicenter, randomized, double-blind, placebo-controlled trials and meta-analyses of patients with septic shock who are receiving placebo or a low-dose steroid (e.g., 50 mg intravenous hydrocortisone every 6 hours for 5 days, followed by a 5 to 6 day taper) found no differences in either group in mortality between those who did and those who did not respond to an ACTH challenge. Although hydrocortisone did reverse shock more quickly than the placebo, more episodes of superinfection, bleeding, and hyperglycemia occurred.[139-141]

MODULATING THE STRESS RESPONSE

Although the stress response evolved as a mechanism for assisting organisms in reacting to immediate danger, its effects may be detrimental to patients undergoing surgery or suffering from sepsis. For example, the hypercoagulable state intended to stem acute bleeding may lead to deep vein thrombosis and pulmonary emboli in immobilized patients. Furthermore, in extended stress situations, the prolonged catabolism resulting from cytokine and stress hormone production leads to the loss of fat and muscle with ensuing weakness and fatigue. This weakness and fatigue, coupled with stress-related disordered immunologic function, increases vulnerability to infections.

The detrimental consequences of the stress response have increased the interest in aborting its appearance and/or actions. However, considering whether the goal of stress response modulation is full elimination or simply attenuation is necessary. By eliminating the stress response, its beneficial effects, such as support of blood pressure by catecholamines in the face of hypovolemia or the stimulation of cytokine production to enhance immunity, may be lost. Therefore, partial or selective suppression of the response may be more reasonable. In this manner, some responses may be partly preserved, such as the cardiovascular response to hypovolemia. Decreasing certain consequences of the stress response, such as diminishing the degree of catabolism and lipolysis to reduce the loss of muscle and fat mass, offer other advantages. One approach tried in patients with sepsis was selective mediator blockade. A prime example was anticytokine therapy (e.g., anti-TNF antibodies, IL-1 receptor antagonists) during sepsis and septic shock. The results of such therapy were disappointing because they not only failed to demonstrate any improvement in survival but, in some instances, even reduced survival. Postulated reasons for these failures include the possibility that targeting a single mediator may not be sufficient to block the wide-ranging ongoing biologic cascade. Another possible reason is that cytokines have beneficial immunoenhancing effects that assist the organism in combating infection. Impeding these effects thus leads to decreased immune function, causing increased mortality. Therefore, any attempt at modulating the stress response must be monitored for detrimental effects.

PREOPERATIVE STRESS RESPONSE

Patients undergoing elective surgery often suffer from preoperative anxiety, a state of psychologic stress involving low-level activation of the hypothalamic-pituitary axis and possibly cytokines. Evidence for such early activation comes from the observation that salivary cortisol

increases by 50% after receipt of information about surgery. Other studies show that both β-endorphin and epinephrine concentrations increase preoperatively. Whether this preexisting activation of the stress response has an additive effect on the subsequent stress response induced by surgery remains unclear (also see Chapter 38).

Preoperative medication tempers anxiety, thus attenuating the stress response. Midazolam as a premedication reduces anxiety and limits increases in intraoperative epinephrine and, possibly, norepinephrine and cortisol. Although it is unknown how benzodiazepines exert their activity, patients do increase cortisol production in response to exogenous ACTH, supporting the contention that the benzodiazepines exert their effect at a higher level, that is, on the hypothalamus or pituitary. Heavy premedication with a combination of opioid and antihistamine or opioid, anticholinergic agent, and benzodiazepine more successfully blunted serum catecholamine, AVP, ACTH, and cortisol increases than benzodiazepines alone. When administered as a premedication, melatonin, a hormone secreted by the pineal gland, reduces anxiety.[142] Nonpharmacologic approaches to anxiety reduction have also been investigated. Music, video glasses, and smartphone applications reduce preoperative anxiety and thus may have practical applications.[143-143c]

Fasting before anesthesia is an accepted practice to lessen the risk for pulmonary aspiration (also see Chapter 38). Many patients fast for 8 to 12 hours before the start of surgery. This practice has been challenged because patients arrive to the surgical unit in a state of starvation with its attendant glycogenolysis caused by low insulin and high glycogen levels. These patients are then subjected to surgical stress with its resulting insulin resistance, catabolism, and gluconeogenesis. Contemporary guidelines permit clear fluid intake until 2 hours before surgery. This guideline has led to interest in administering a carbohydrate (e.g., 50 g) or carbohydrate-protein (e.g., 50 g carbohydrate plus 15 g glutamine) load 2 to 3 hours before surgery in an attempt to increase insulin concentrations and to reduce glucagon levels, leading to lesser degrees of postoperative insulin resistance and catabolism.[144-148] Small studies showed reduced postoperative insulin resistance, lower protein loss, and the preservation of mitochondrial function with these feedings.[146-148] A meta-analysis concluded that preoperative carbohydrate loading may be safe and attenuate postoperative insulin resistance better than placebo, but the quality of the trials was low.[149] Carbohydrate administration is part of the Enhanced Recovery after Surgery (ERAS) program, which also includes thoracic epidural anesthesia or analgesia, no nasogastric decompression, and early resumption of oral intake. Meta-analysis showed reduced overall (but not major) complications and lengths of hospital stay after open colorectal surgery.[150,151] A systematic review of 17 studies (1445 patients) showed reduced postoperative insulin resistance and decreased anxiety and nausea, but not evidence of preserved muscle mass, after preoperative carbohydrate-rich drinks.[151a]

INTRAOPERATIVE STRESS RESPONSE

Modulating the intraoperative stress response with anesthetics depends on various factors, including the type of anesthesia and surgery. Because separating the effects of the anesthetics themselves from the stress response generated by the surgical injury is nearly impossible, studies generally compare the effects of two or more anesthetic regimens on the overall stress response during a specific surgical procedure.

INHALED ANESTHETICS

Volatile anesthetics minimally suppress the hormonal stress response and are basically ineffective in counteracting biochemical responses (e.g., lipolysis) induced by surgical stimulation. The evidence is conflicting as to whether volatile agents prevent surgically induced catecholamine secretion, although enflurane is most capable of blocking intraoperative catecholamine surges. Halothane and isoflurane failed to affect serum cortisol concentrations in both the absence and presence of surgery. No differences were cited between intraoperative cortisol or glucose levels of desflurane anesthesia during abdominal hysterectomy between light bispectral index (BIS) monitoring of 50 and deep BIS monitoring of 25.[152] Sevoflurane, however, attenuated the cortisol and ACTH responses to laparoscopic ovarian cyst removal.[153] No differences in plasma cortisol, ACTH, insulin, or glucagon concentrations were reported between extended (>10 hours) isoflurane/NO_2 or sevoflurane/NO_2 anesthesia during head and neck surgery. Although with sevoflurane/NO_2, epinephrine and norepinephrine concentrations were attenuated during surgery and rose only after surgery[154] (also see Chapter 26).

INTRAVENOUS ANESTHETICS

Some intravenous anesthetics partially modify the endocrine and metabolic components of the stress response. Sodium thiopental (5.0 to 5.1 mg/kg) does not prevent increases in catecholamine concentrations after intubation. However, many studies show lower epinephrine and norepinephrine concentrations when propofol (2.0 to 2.2 mg/kg), rather than pentothal, is used for intubation. This finding is attributed to propofol's intrinsic ability to inhibit catecholamine secretion, possibly by decreasing catecholamine release from chromaffin cells. Propofol (1.5 to 2.5 mg/kg) also decreases cortisol concentrations during intubation. Etomidate does not affect metabolic responses except to decrease hyperglycemia, which is attributed to etomidate suppressing the adrenocortical response by blocking cortisol and aldosterone synthesis.

Compared with benzodiazepines, the α_2-adrenergic agonists, clonidine and dexmedetomidine, are more successful at blunting the hemodynamic and catecholamine responses to intubation and intraoperative stress. The α_2-agonists blunt the stress response by reducing norepinephrine release from central and peripheral nerve endings. When 4.5 μg/kg of oral clonidine was given preoperatively, intraoperative plasma catecholamine concentrations were reduced. Similar doses reduced not only plasma but also cerebrospinal fluid (CSF) concentrations of TNF-α and norepinephrine.[155] Such doses also attenuated the intraoperative and postoperative hyperglycemic responses to minor surgery. Whether clonidine also

attenuates the cortisol response is unclear.[156] Moreover, α_2-agonists, such as dexmedetomidine, do not suppress steroidogenesis[157] (also see Chapter 30).

OPIOIDS

Opioids can blunt the stress response. Fentanyl (50 μg/kg) plus halothane and NO abolished the elevations in cortisol, GH, and glucose normally seen during hysterectomy. Morphine (1.0 mg/kg) reduced GH and cortisol elevations during abdominal surgery. However, other studies show that the same dose of morphine was unable to suppress increased GH secretion during similar surgeries. In some but not all studies, opiates decreased cytokine production.[65,158,159] Propofol-alfentanil anesthesia, compared with isoflurane anesthesia, caused lower IL-6 concentrations. These lower IL-6 concentrations are thought to occur because opioids bind to monocyte receptors and reduce intracellular cAMP concentrations. cAMP is necessary for monocyte secretion of IL-6. However, propofol-remifentanil anesthesia, compared with sevoflurane and sevoflurane-fentanyl anesthesia, did not always attenuate the IL-6 elevations.[158,159] High-dose remifentanil (1.0 μg/kg/min) infusion plus sevoflurane attenuated the ACTH, cortisol, epinephrine, norepinephrine, and ADH responses to limb tourniquet application compared with anesthesia with lower dose (0.25 μg/kg/min) remifentanil plus sevoflurane anesthesia.[159a]

The limitation of the stress-reducing effects of opioids is most evident during cardiac surgery. Although high-dose fentanyl (50 to 200 μg/kg) and morphine (2 to 4 mg/kg) prevent increases in catecholamine and cortisol concentrations before cardiopulmonary bypass surgery, both catecholamine and cortisol concentrations increase during bypass surgery. Similarly, high-dose sufentanil (12 μg/kg induction, 3 μg/kg before skin incision, and 5 μg/kg before bypass) limited increases in catecholamines, cortisol, and AVP before surgery, but it failed to attenuate their elevation both during and after bypass surgery. The reversal of the opioid-related stress-reducing effects by bypass is attributed to nonpulsatile blood flow, artificial surfaces of the bypass circuit, renin and angiotensin release, hypothermia, and dilution of the plasma opioid concentration.

How opiates curb the stress response is unknown. One theory is that this action is mediated through hypothalamic and pituitary opiate receptors. This theory has been questioned because of the similar effects of fentanyl and sufentanil on the stress response, despite the significantly greater affinity of sufentanil for brain opiate receptors. Both intravenous (50 μg then 20 μg every 30 minutes) and intrathecal high-dose (150 μg) sufentanil attenuated the intraoperative epinephrine and norepinephrine responses in patients undergoing general anesthesia for major abdominal surgery. However, only in the intrathecal group were the intraoperative ACTH and cortisol responses attenuated. Therefore, the unique actions of sufentanil may only be apparent on intrathecal administration.[160]

Although general anesthesia undoubtedly prevents an even greater stress response by rendering patients insensate to the discomfort and pain of surgery, it is unable to eliminate many manifestations of the stress response completely, which is ascribed to the inability of anesthesia to diminish or abolish the afferent nervous input from the area of the injury. Additionally, general anesthesia does not alter the effects of cytokines such as IL-6 and TNF, which are produced within the area of the wound (also see Chapter 30).

NEURAXIAL ANESTHESIA

Neuraxial anesthesia more effectively attenuates the stress response than general anesthesia (also see Chapter 56). The ability of such anesthesia to modify the intraoperative stress response depends on the level of the blockade, the location of the surgery, and the drugs used. Lower extremity surgery with epidural anesthesia results in lower intraoperative catecholamine concentrations when compared with general anesthesia.[100] These reductions in catecholamines may be caused by blockade of afferent nerve stimuli, reducing hypothalamic activation of the sympathetic nervous system and adrenal medulla. Further evidence for reduced hypothalamic activation is that epidural anesthesia to a T4 level successfully blunts increases in TSH. Similarly, epidural anesthesia attenuates the usual increases in AVP during vaginal surgery.

Lower abdominal and lower extremity surgery with neuraxial anesthesia reduces or abolishes the hyperglycemic response to surgery, likely because of the lack of stimulation of hepatic glycogenolysis attributable to a reduced epinephrine response or blockade of hepatic sympathetic pathways or both. Reduced sympathetic and adrenal activity with epidural blockade also prevents normal intraoperative increases in FFAs and glycerol (lipolysis) during lower abdominal surgery. Further evidence that sympathetic blockade reduces intraoperative lipolysis is that lipolysis was reduced during inguinal hernia repair only when spinal anesthesia reached the T1-T3 sensory level. The influence of neuraxial blockade on cortisol secretion is less clear. Although neural blockade during lower abdominal surgery reduces the stress-induced cortisol response, whether the degree of suppression is similar to that of other hormones remains unclear. This incomplete reduction in the stress response may be caused by the inability of epidural anesthesia to alter the IL-6 response to abdominal surgery, suggesting that IL-6 secretion is neither mediated by nociceptive stimuli nor affected by sympathetic blockade. IL-6 increases pituitary ACTH secretion and thus stimulates cortisol secretion. Similar attenuation of catecholamine and cortisol secretion occurred when patients with spinal cord injury had surgery below their lesions.[161]

Neuraxial anesthesia more successfully reduces the stress response during lower abdominal than upper abdominal or thoracic surgery. Whether T3-T4 epidural blockade can suppress surges in cortisol and catecholamine concentrations during upper abdominal surgery remains controversial. Epidural blockade as high as C6 does not influence the cortisol response during upper abdominal or thoracic surgery. This hypothesis was disputed when blockade extending from T3-T4 to L1-L2 significantly reduced the cortisol response during gastrectomies. Similarly, it remains uncertain whether epidural blockade for upper abdominal surgery alters lipid or protein metabolism, although it seems to partially suppress the hyperglycemic response.[162] The fact that regional anesthesia is unable to suppress the stress responses induced by upper abdominal stimulation can

be attributed to inadequate afferent sympathetic blockade, unblocked vagal afferent pathways, unblocked phrenic afferents, or locally released humoral substances. Others suggested that regional anesthesia that does not completely block afferent stimuli will not affect the hypothalamic-pituitary axis because epidurally induced sympathetic block does not completely block neural traffic but only reduces it. Supporting this hypothesis, the combination of epidural and splanchnic blockade (injection of bupivacaine directly into the splanchnic plexus) during upper abdominal surgery reduced both the catecholamine response and plasma cortisol concentrations more effectively than epidural anesthesia alone. Similarly, continuous spinal local anesthetic infusion more successfully attenuated the cortisol and glucose responses to upper abdominal surgery than epidural anesthesia, presumably by better blockade of afferent nerves.

Another possible explanation for the inability of epidural anesthesia to attenuate the response to upper abdominal surgery is stimulus transmission through unblocked vagal afferent nerves. However, no attenuation of the stress response is observed after either vagal blockade or surgical vagotomy. Evidence for phrenic nerve involvement was shown when epidural blockade to the C3-C4 dermatome level during upper abdominal surgery more successfully blunted increases in ACTH and AVP than did C8-T2 blockade.

The drugs used for regional anesthesia also influence the ability to affect the stress response. Epidural opiates are unable to prevent catecholamine surges. Increases in catecholamine concentrations were limited by 2-chloroprocaine and bupivacaine but not by lidocaine. This difference may be attributable to the central stimulatory effects of lidocaine.

COMBINED GENERAL AND NEURAXIAL ANESTHESIA

Combined general and neuraxial anesthesia should reduce the stress response if the general anesthetic is sufficiently deep to attenuate the stimulation of the endotracheal tube and if the neuraxial anesthesia is adequate to block afferent signals from the surgical site. Compared with general (sevoflurane-remifentanil) anesthesia alone, the general anesthetic plus ropivacaine-sufentanil thoracic epidural anesthesia attenuated increases in cortisol, epinephrine, and norepinephrine concentrations during and after radical retropubic prostatectomy.[163] Both desflurane-epidural (sensory block T4-S1) and desflurane-remifentanil anesthesia for colorectal surgery resulted in less glucose production and less hyperglycemia, compared with desflurane alone.[164] During upper abdominal surgery, plasma levels of cortisol, epinephrine, and IL-10 were lower with thoracic epidural plus general (isoflurane) anesthesia, compared with general anesthesia alone.[165]

Combined general and epidural anesthesia in coronary artery bypass grafting has been extensively studied. Patients receiving fentanyl anesthesia plus thoracic epidural bupivacaine (10 mg [5 mg/mL] every 4 hours) during coronary artery bypass grafting had lower epinephrine and norepinephrine levels both intraoperatively (including during bypass) and postoperatively, compared with controls receiving only large doses of fentanyl. Results are conflicting as to whether the cortisol response is also reduced. Although cytokine responses were not affected, CRP and fibrinogen, but not troponin-I, levels were lower 16 to 24 hours after surgery.[166] Combined general and epidural anesthesia with continued postoperative epidural analgesia for off-pump cardiac surgery resulted in lower IL-6 and IL-8, but not cortisol or troponin-I, concentrations after surgery (12 to 48 hours) when compared with general anesthesia plus postoperative patient-controlled analgesia (PCA) of morphine.[167] Despite some attenuation of the stress response, a meta-analysis did not show fewer myocardial infarctions or lower mortality with thoracic epidural plus general anesthesia for on-pump coronary artery bypass surgery[168] (also see Chapter 56).

THERMOREGULATION

Another way of minimizing the stress response is maintaining perioperative normothermia (see Chapter 54). Intraoperative hypothermia, followed by postoperative rewarming, stimulates the response. Patients with hypothermia (35.3° C core temperature) had higher postoperative plasma norepinephrine and epinephrine concentrations than their warmer counterparts.[169] These elevated catecholamine concentrations are partially the result of postoperative rewarming with shivering and vasodilation that leads to hypotension. Elevated catecholamines have been postulated to be among the reasons for the greater incidence of myocardial ischemia after vascular surgery in patients with hypothermia. There are thus several reasons to maintain intraoperative normothermia.

POSTOPERATIVE PERIOD

The intraoperative attenuation of the stress response by anesthesia is often lost on emergence from anesthesia because of pain and awareness, coupled with a series of stress-producing events (e.g., tracheal extubation, shivering) (also see Chapter 96). This postoperative response has been demonstrated by extreme elevations in plasma ACTH and cortisol immediately after surgery with isoflurane anesthesia. Likewise, after sevoflurane-NO anesthesia, peak cortisol, ACTH, and catecholamine concentrations occurred after tracheal extubation, implicating anesthesia emergence as more stressful than surgery. This phenomenon may be especially striking with sevoflurane anesthesia because of its typical rapid emergence. Associated with these significantly elevated catecholamine concentrations is an increased incidence of myocardial infarction that peaks 24 to 48 hours after surgery.

Similar to an inhaled anesthetic, general anesthesia with intravenous drugs does not prevent the postoperative stress response. Intravenous opioid anesthesia did not blunt the stress response in the late postoperative period (>3 hours). Abrogation of the suppressive effects of anesthesia on the stress response on emergence was further demonstrated when patients were deeply sedated with propofol for 12 hours after cardiopulmonary bypass surgery. This sedation attenuated the rise in cortisol and catecholamine concentrations and was associated with less tachycardia and hypertension than in a control group.

However, once propofol was discontinued, hormone concentrations rose, indicating that deep sedation only delayed the appearance of the stress response.[170] Therefore, unless therapy that suppresses the stress response is continued during and after emergence and extubation, the postoperative period is marked by the full appearance of the stress response.

After lower abdominal surgery, continuous postoperative analgesia via an epidural catheter using local anesthetics reduced the stress response. For example, continuous epidural analgesia (sensory block of T4-S5) for 24 hours after colorectal surgery successfully blunted increases in catecholamine but not cortisol concentrations. A similar regimen administered for 24 hours after hysterectomy resulted in lower glucose and FFA concentrations than did general anesthesia. Furthermore, better nitrogen economy was observed in patients after hip replacement who were provided with 24 hours of epidural local anesthetics (sensory level: T10) than in patients who were administered only general anesthesia. This observation occurred with postoperative local anesthetic doses that provided only analgesia and not anesthesia. Similarly, combined spinal-epidural anesthesia during hip replacement with postoperative epidural analgesia (ropivacaine-sufentanil) resulted in reduced leucine oxidation rate on the first postoperative day, whereas hyperglycemia was prevented only intraoperatively.[171] Attenuating the stress response with continuous postoperative epidural analgesia was more successful in lower than in upper abdominal surgeries, a finding similar to the observations during intraoperative epidural anesthesia. Yet, stress response reduction after upper abdominal surgery has been reported. For example, after abdominal aortic surgery, epidural morphine reduced the postoperative sympathetic but not adrenal epinephrine response, thus reducing the incidence of postoperative hypertension. However, neither epidural ropivacaine nor epidural morphine analgesia suppressed the catabolic response when administered to patients after colonic surgery, but ropivacaine did increase the carbohydrate oxidation rate, likely reflecting reduced insulin resistance.[172] The reduced insulin resistance, coupled with decreased gluconeogenesis, led to less hyperglycemia.[172] Therefore, pain control with epidural opioids or local anesthetics is unable to lessen many of the metabolic changes associated with such surgeries.[173] However, combined epidural opioid–local anesthetic analgesia appears more effective in attenuating catabolism.[174]

Whether modifying the stress response improves outcome is unclear. Ideally, one of the desired effects of anesthesia is a stress-free state, and achieving such an effect has become increasingly important as the stress response is more frequently implicated in the development of postoperative complications, especially among patients who are chronically ill and aging.[175] However, contemporary anesthesia practice can only partially modify this response and then only under specific conditions. General anesthesia has a limited ability to attenuate the stress response, whereas regional anesthesia is more effective. Therefore, it stands to reason that outcome would improve with regional anesthesia. A meta-analysis showed decreased mortality with regional anesthesia as opposed to general anesthesia in a variety of surgical procedures. However, this analysis has been criticized because only patients who underwent orthopedic procedures had improved outcomes. Furthermore, morbidity studies demonstrated that under some circumstances, epidural anesthesia reduced postoperative complications, such as deep vein thrombosis.

Attempts to modulate the perioperative stress response include nonanesthetic approaches (e.g., using β-adrenergic antagonists) to block cardiovascular end-organ receptors and α_2-adrenergic agonists to stimulate central receptors. These approaches have met with some success. Using β-adrenergic antagonists in patients with ischemic heart disease does not reduce the perioperative neuroendocrine or endocrine stress response but blocks the end-organ response. Such end-organ blockade also has metabolic effects. Administering propranolol to children who are severely burned decreased their REE, attenuated muscle catabolism, reduced lipolysis, preserved lean body mass, and reduced TNF and IL-1 concentrations without increasing infections.[176] Hepatomegaly attributable to fatty liver was prevented because reductions in both lipolysis and hepatic blood flow decreased fatty acid delivery to the liver.[177] Mortality was unaffected by propranolol.[176] In patients with severe sepsis, selective β_1-adrenergic blockade had no effect on REE or muscle protein kinetics,[178] indicating that attenuation is primarily due to β_2-receptor blockade. However, discontinuing the β blockade into the anabolic period is important because β-adrenergic activity might be significant in muscle tissue restoration.[179]

Another nonanesthetic modulation of the stress response is administering a single preoperative dose of exogenous glucocorticoids. Administering intravenous methylprednisolone (30 mg/kg) 60 to 90 minutes before the start of major abdominal, hepatic, and esophageal surgery reduced the stress response with lesser increases in IL-6, CRP, norepinephrine, and AVP and increased the secretion of IL-10. A meta-analysis of 51 studies in which a single dose of methylprednisolone (15 or 30 mg/kg) was given showed no increase in complication rates.[180] Further study is needed to determine whether this approach significantly affects outcome. Similarly, methylprednisolone treatment before cardiac surgery attenuated cytokine secretion.

The inability of any one modality to reduce the stress response and significantly alter outcome has spawned the multimodal approach. The goals are to shorten the convalescence period and reduce the postoperative decline in functional status by an improvement of pain control, early return of gut function, and early mobilization. This approach involves combining some or all of the following: premedication (benzodiazepines, β-blockers, α_2-agonists), preoperative carbohydrate intake, glycemic control, maintenance of normothermia, combining epidural anesthesia or analgesia and nonsteroidal antiinflammatory drugs, avoiding opioids, early oral feedings or parenteral nutrition, and early mobilization after major abdominal surgery.[181,182] Such a regimen permitted 32 of 60 patients after colorectal resection to go home within 48 hours of surgery and, in a study of anterior colon resection, reduced hospital lengths of stay from 10 to 7 days.[183] Patients undergoing radical cystectomy, anesthetized with general and thoracic epidural anesthesia and postoperative thoracic epidural analgesia, and treated with early oral nutrition and forced mobilization had

lower urinary catecholamines, less negative nitrogen balance, earlier return of bowel function, and a lower acute-phase response than patients who were conventionally treated.[119] The multimodal approach to modulating the perioperative stress response has considerable logic and practicality and, coupled with noninvasive surgery, has the potential to change postoperative care.

GLUCOSE CONTROL

Hyperglycemia appears almost immediately after the start of a major stress as a result of accelerated endogenous glucose production plus insulin resistance (also see Chapter 39). During major noncardiac surgery, peak glucose concentrations were seen at 2 hours after anesthesia induction.[183a] Administering exogenous catecholamines and glucocorticoids exacerbates hyperglycemia. The teleologic explanation for the hyperglycemia is that it provides the wound and other glucose-dependent tissues with a ready supply of glucose. The experience gained from diabetic care showing the advantages of tightly controlling blood glucose concentrations was the impetus for exploring whether tight glucose control is also advantageous in managing acute hyperglycemia associated with stress (i.e., surgical, burn, trauma, sepsis).

Acute hyperglycemia is associated with immunosuppression, stimulated sympathoadrenergic activity, increased mortality, increased infections, reduced skin graft success, increased catabolism in patients with burns, and osmotic diuresis leading to volume depletion.[184-187] These effects are ascribed to the proinflammatory actions of glucose attributed to increased secretion of TNF-α and IL-1, greater adherence and sequestration of neutrophils in peripheral tissue, impaired microvascular relaxation in the presence of NO, and decreased monocyte human leukocyte antigen-DR (HLA-DR) expression, reflecting reduced innate immunity.[188] The proinflammatory cytokine response to endotoxin infusion in normal subjects was enhanced by concomitant hyperglycemia.[189] These observations question whether elevated blood glucose concentrations are, themselves, detrimental or whether hyperglycemia is simply a marker of severe stress. Hyperglycemia on hospital admission in trauma victims portends greater mortality, and hyperglycemia in both diabetic and nondiabetic patients after cardiac surgery is associated with a higher incidence of infections.

Van den Berghe and associates[184] showed reduced mortality in surgical (primarily cardiac) patients treated with intensive insulin therapy to maintain euglycemia (≤110 mg/dL). Compared with conventional therapy, the aggressive insulin therapy reduced ICU mortality especially from multiple organ failure by 43%, sepsis by 46%, and acute renal failure requiring dialysis or hemofiltration by 41%. In addition, patients in the ICU for longer than 7 days who were aggressively treated had less critical illness polyneuropathy or myopathy.[190] These results led to the question of whether it was lowering blood glucose concentration or administering insulin, an anabolic and antiinflammatory hormone, that reduced morbidity and mortality. Furthermore, studies suggest that avoiding hyperglycemia, rather than administering insulin for its correction, is beneficial because the total amount of insulin administered correlated with increased mortality, regardless of the blood glucose concentration.[191] The latter observation indicates that a major determinant of mortality and morbidity is the severity of the critical illness, as demonstrated by the degree of tissue insulin resistance and hence the amount of insulin needed to control blood glucose.

The enthusiasm for tight control of blood glucose in patients with stressful illnesses must be tempered. The increased incidence of unrecognized hypoglycemia, especially in patients who are anesthetized and sedated, led to recommendations that glucose be controlled to concentrations greater than 140 mg/dL).[184,185] The multicenter Normoglycemia in Intensive Care Evaluation and Surviving Using Glucose Algorithm Regulation (NICE-SUGAR) trial found greater mortality (increased absolute risk at 90 days of 2.6%) and more hypoglycemia of 6.8% versus 0.5%) in patients in the ICU who were treated with insulin to a glucose target of 81 to 108 ml/dL than those who were treated to a target of less than 180 mg/dL.[192] Whether the increased mortality was due to the hypoglycemia or other factors was unclear because insulin appears to have proinflammatory actions and upregulates NF-κB under certain circumstances.[193] The high insulin doses could also further increase the REE. Another issue is whether all or only specific populations benefit from tight glucose control. One meta-analysis in cardiac surgery showed less ICU mortality and lower hospital lengths of stay, less postoperative atrial fibrillation, and reduced duration of mechanical ventilation with intensive insulin therapy; whereas another such analysis showed no reduction in mortality but fewer postoperative infections.[194,195] The latter results are similar to those obtained in pediatric surgery patients.[195a] Glucose-insulin treatment might be beneficial in myocardial infarction and ischemia.[196] A meta-analysis incorporating 13,567 patients in 26 studies concluded that in patients who were critically ill, tight glucose control did not decrease mortality but did control the increased risk of hypoglycemia.[197,198] In pediatric ICU patients a multicenter trial involving 1369 patients showed no significant effect on outcome with tight (72-126 mg/dL) versus conventional (<216 mg/dL) glucose control.[198a]

The benefits of lowering blood glucose concentrations (<180 mg/dL) with insulin therapy after major surgery and in critical illness are ascribed to abrogation of the proinflammatory actions of hyperglycemia (i.e., reduced IL-6, IL-8, high-mobility group box-1, and TNF-α, as well as interference with IL-6 signal transduction), along with the antiinflammatory effects of insulin; protection of the mitochondrial compartment and endothelium; lower serum cortisol concentrations; lower urinary nitrogen losses; and increased secretion of antiinflammatory hormones, such as IL-4 and IL-10.[199-204] Moreover, insulin therapy attenuated lipolysis, reduced endogenous glucose production, and increased glucose clearance, but not protein losses, in patients in medical ICUs.[205]

NUTRITIONAL SUPPORT

PERIOPERATIVE PERIOD

Immediately after surgery, patients traditionally receive infusions of 5% dextrose (glucose monohydrate), which

provide 50 g/L dextrose or 170 kcal/L (dextrose provides 3.4 kcal/g). Therefore, patients receiving 2 to 3 L/day of 5% dextrose are essentially being semistarved. The rationale for infusing small amounts of dextrose is its protein-sparing effects (i.e., reduced gluconeogenesis, which decreases the need for proteolysis, leading to lower urinary nitrogen losses). In normal subjects, nitrogen losses decrease linearly as the amount of dextrose administered increases, up to an intake of 150 g/day. More than 150 g/day of dextrose results in no further protein sparing unless protein and fat are also provided. Furthermore, small amounts of carbohydrate (100 g/day) prevent ketosis[95] and can contribute to postoperative hyperglycemia. Even with larger amounts of glucose, the ability of exogenous glucose to suppress gluconeogenesis is diminished during stress. An infusion of 2 g/kg/min glucose during the first 3 hours of surgery reduced endogenous glucose production by 60%, as opposed to 90% reduction in patients before surgery.[182] Dextrose regimens should only be continued for a few days (4 to 6 days) after surgery until the patient can resume oral intake. Patients unable to begin oral intake after such time should be evaluated for enteral or parenteral nutritional support.

Efforts have been directed at finding ways to improve the effectiveness of hypocaloric amounts of glucose administered during the postoperative period. When compared with an intravenous pain regimen, the greater pain relief provided after abdominal surgery by continuous intraoperative and postoperative epidural blockade with local anesthetics and opioids (0.1% bupivacaine plus 2 μg/mL fentanyl to a T7-L3 sensory block) further decreased endogenous amino acid oxidation and increased whole-body glucose uptake by decreasing insulin resistance.[206,207] These results are not unexpected because pain, itself, induces insulin resistance and contributes to the catabolic state after surgery.[208] Furthermore, epidural analgesia reduces the duration of postoperative ileus (e.g., thoracic lumbar, local anesthetics opioids), allowing earlier resumption of oral intake.[209]

Postoperative protein sparing has been attempted with hypocaloric amino acid infusions.[210] The idea is to provide small amounts of exogenous amino acids as gluconeogenic substrate (1 g produces 0.5 g of glucose) while avoiding the hyperglycemia observed during 5% dextrose infusions. However, there is a limit to how much protein can be used as an energy source, and postoperative amino acid infusions decreased gluconeogenesis only slightly but did suppress protein breakdown, reduced IGF-1 decreases, and stimulated protein synthesis.[211,212] Administering amino acids instead of 5% dextrose appears to have few advantages, although the amino acids do reduce the loss of some lean body mass.[210]

Another use of intraoperative amino acid infusions are as thermogenic agents that are started either a few hours before surgery or after anesthesia induction to prevent or attenuate intraoperative hypothermia.[213] During anesthesia, the central thermoregulation is silenced, leading to exaggerated amino acid thermogenesis. Amino acid–induced heat generation during anesthesia occurs mainly in extrasplanchnic tissues, such as skeletal muscle, and is attributed to greater amino acid turnover because both protein breakdown and synthesis are energy-consuming (heat-generating) processes.[214] Such infusions reduced the body temperature decline during spinal anesthesia by 0.5° C to 0.8° C[215,216] and during off-pump coronary artery bypass surgery.[217] Amino acid infusion (11.4% solution at 2mL/kg/hr for 1 hour) successfully treated postoperative hypothermia-induced shivering.[217a]

INDICATIONS FOR NUTRITIONAL SUPPORT

The primary indication for initiating nutritional support is preventing or treating malnutrition among patients unable or unwilling to sustain sufficient oral intake. Between 20% and 35% of hospitalized patients suffer from malnutrition on admission or during their stay. Therefore, nutritional assessment and decisions concerning nutritional support should be part of the routine care of all hospitalized patients. A major consideration when contemplating nutritional support of an individual patient is whether the nutrition will improve his or her prognosis or quality of life, since nutritional wasting is the inevitable consequence of many terminal diseases.[218] Another important aspect of providing nutritional support to patients with stressful illnesses is that their already altered metabolic milieu greatly affects nutrient use and metabolism. Moreover, patients who are critically ill with recurrent bouts of sepsis have an ongoing proinflammatory response that contributes to continued catabolism. Therefore, during the acute phase of stressful illness, nutritional support is an adjunctive therapy whose goal is to provide energy substrates to aid cellular functions and attempt to stem losses of lean and fat mass. Repletion of lost fat and muscle tissue must wait until the anabolic phase of the illness.

Preoperative malnutrition is associated with poor surgical outcomes attributable to a more severe systemic inflammatory response and more postoperative infections.[219] Preoperative criteria for increased postoperative risk include serum albumin less than 3.0 mg/L, BMI less than18 kg/m,[2] and weight loss greater than 10% to 15% within 6 months.[220-222] Compared with patients not at risk, 14% of patients undergoing elective gastrointestinal surgery who, on preoperative nutritional assessment, were at nutritional risk for postoperative complications had 3.5 times as many severe complications and 2.5 times their median length of hospital stay.[223] Yet demonstrating any benefit of preoperative parenteral and enteral nutrition in malnourished patients has been difficult, except for those who were severely malnourished and who had fewer noninfectious postoperative complications after 7 to 10 days of preoperative nutritional repletion.[224-226a] Continuing TPN during and after surgery is beneficial in such patients.

The resumption of significant oral intake within 1 to 2 days after elective resectional gastrointestinal surgery, rather than an extended period of no intake with or without gastric decompression via a nasogastric tube, has been shown upon meta-analysis to reduce total postoperative complications and not negatively affect mortality, anastomotic integrity, or hospital lengths of stay. In other types of elective and emergency major surgery, postoperative nutritional support is not indicated unless it is anticipated that the patient will be unable to resume adequate oral intake within 7 to 8 days after surgery.[220] Patients not expected to resume adequate oral feedings by this time should begin nutritional support early (1 to 4 days) after surgery. In patients with preoperative nutritional depletion not expected to resume oral intake

soon after surgery, such as those with head-neck and esophageal cancers, nasoenteric or jejunal feeding tubes should be placed at surgery and enteral nutrition begun immediately after surgery.[220] A systematic review concluded that enteral nutrition started early (in 1 to 3 days) after hepatectomy reduced infectious complications when compared with TPN.[227] Similarly, a systematic review of the literature concluded that although many patients undergoing pancreaticoduodenectomy are nutritionally depleted before surgery, routine postoperative TPN is not recommended because of the complication rate. However, postoperative enteral nutrition is recommended.[228] Nasojejunal enteral nutrition compared with parenteral nutrition begun 8 hours after major rectal resection resulted in fewer anastomic leaks, earlier defecation, and shorter length of hospital stay.[228a]

Patients in the ICU who are mechanically ventilated have a malnutrition rate of 38% to 100%[211] (also see Chapter 102). Therefore, nutritional support guidelines recommend starting enteral nutrition early, that is, within 24 to 48 hours of ICU admission, to reduce infectious complications and shorten the duration of hospitalization.[229,230] Patients unable to receive or tolerate enteral intake should be considered as candidates for TPN. However, disagreement remains as to when to start the TPN in patients not tolerating enteral nutrition. The European Society for Clinical Nutrition and Metabolism (ESPEN) guidelines state that if patients have not achieved adequate enteral intake in 2 days after ICU admission, then TPN should be started. The American Society of Parenteral and Enteral Nutrition, the Society of Critical Care Medicine (ASPEN/SCCM), and Canadian guidelines advocate waiting 7 days to start TPN.[230,231] Compared with the early initiation of TPN (within 48 hours) to supplement inadequate enteral nutrition, late initiation (≥8 days) was found on a randomized, multicenter trial to provide faster recovery (fewer days of mechanical ventilation), fewer infections, shorter duration of renal replacement therapy, and less cholestasis.[232] This study thus supports a period of hypocaloric feeding for the first week of ICU stay. Furthermore, trophic feeding (10 to 20 kcal/hr) for up to 6 days upon ICU admission did not reduce ventilator-free days, 60-day mortality, or infectious complications, but it was associated with less gastrointestinal intolerance, compared with full enteral feeding in patients with acute lung injury.[233,234] Another randomized multicenter study of ICU patients with relative short-term contraindications to enteral nutrition found that providing them with parenteral nutrition did not change 60-day mortality or the length of ICU and hospital stay compared with patients treated less aggressively, although the duration of mechanical ventilation was reduced.[234a] However, others showed that providing energy intake according to measurements of REE by supplementing enteral nutrition with TPN, if needed, within 48 hours of ICU admission appeared to improve survival.[235,236] Starting nutrition on ICU admission is important, however, when and the rate that full caloric intake should be reached are still unclear.

PARENTERAL VERSUS ENTERAL NUTRITION

A major decision when designing a nutritional support regimen is the route of administration. If patients are eating on their own, then monitoring their intake is necessary to ascertain its adequacy. Many patients have little appetite and thus may need nutritional supplementation between meals (snacking) to increase their caloric intake. Patients may be unable to feed themselves because of confusion or weakness and may need to be fed. During eating, the intake of patients with severe COPD may be limited by arterial oxygen desaturation, causing fatigue. Such patients may require supplemental oxygen via nasal cannula while eating. Patients who fail to sustain adequate caloric intake by eating require either supplemental enteral or parenteral nutrition.

The enteral route is favored over the parenteral method because it is the natural portal of entry for exogenous nutrients. However, current evidence does not fully support this view except that enteral nutrition costs less.[236,237] The enteral route obviates the need for intravascular access with its attendant risk of infections and sepsis. In addition, the array of nutrients that can be administered via the gastrointestinal tract is greater than what is available for parenteral use, allowing for better tailoring of nutrient intake. Other advantages of enteral nutrition are the ease of preparation and the maintenance of gut function. The importance of maintaining gut integrity (the gut derives up to 70% of its nutrients from luminal food) is to reduce the translocation of bacteria from the gut. Animal studies have shown that translocation of bacteria from intestines with reduced integrity and increased permeability leads to local activation of the gut's immune inflammatory system (Peyer patches and hepatic Kupffer cells). These cells then release cytokines that intensify the already existing systemic inflammatory response, increasing the risk for multiple organ failure. However, no overwhelming evidence of significant translocation in humans has been documented.[238] The lack of enteral intake, such as the absence that occurs among patients after surgery who are critically ill and receiving no nutrition or only TPN, is associated with small intestinal villous atrophy, decreased villous cell count, and reduced mucosal thickness. Intestinal permeability, measured using the urinary lactulose-mannitol ratio, is increased. These changes reverse with enteral feeding. Interestingly, no evidence confirms mucosal atrophy among patients who received 10 days of preoperative parenteral nutrition. It is thought that atrophy, itself, does not lead to bacterial translocation; instead, a further insult is needed. One such insult is small intestinal ischemia-reperfusion injury after resuscitation from an episode of shock, which by itself can change gut integrity.[239] This belief is supported by the observation that the incidence of bacterial growth from surgically removed mesenteric lymph nodes was higher in patients undergoing emergency surgery. Patients with such lymph nodes more commonly had postoperative sepsis.[240] Moreover, in a patient with a stressful illness, constantly proliferating gut epithelial and lymphoid tissues may possibly have an insufficient nutrient supply, further compromising gut integrity. The fear of reduced gut integrity along with studies showing preserved xylose absorption in patients who have been enterally, but not parenterally, fed has been among the reasons for recommending that enteral nutrition begin early, even if only very small amounts can be administered. In the latter case, concomitant TPN is indicated to provide adequate caloric intake.[241]

A major decision with enteral nutrition is the delivery method. Most patients are initially fed via nasoenteric

tubes, including large-bore tubes. The advantages of the latter include the ability to quantify residual feedings and quickly reinitiate nasogastric suction. The disadvantages are the potential for pulmonary aspiration occasioned by gastroparesis and incompetence of the gastroesophageal junction as a result of the diameter of the tube. Additionally, long-term use of large-bore tubes can lead to sinusitis and otitis media. Therefore, the type of feeding tube and the location of its distal end are major issues. For medium- and long-term feedings, using a small-bore (8 to 12 Fr), soft (e.g., Silastic), and long (to reach the jejunum) feeding tube with a weighted distal end is best. Such tubes reduce nasal and pharyngeal trauma and minimize gastroesophageal junction incompetence. Gastroparesis is common in patients who are critically ill; therefore, placing the tube distal to the ligament of Treitz (small intestinal function generally remains intact) prevents pooling of feeds in the stomach with its risk of pulmonary aspiration.[215] Yet, whether jejunal feeding actually reduces the risk of aspiration remains controversial. Compared with gastric feedings, jejunal feedings facilitate higher caloric intakes. Passing the tube through the pylorus is often problematic because of gastroparesis and a supine and immobile state. Therefore, if possible, the tube should be passed through the pylorus during abdominal surgery. In nonsurgical situations, an attempt may be made to pass a weighted tube through the pylorus by placing the tube in the stomach, turning the patient on the right side, and administering a prokinetic drug (e.g., metoclopramide). If this attempt fails, then the tube should be endoscopically or fluoroscopically placed.

Placing a jejunostomy tube during surgery is recommended in patients not expected to eat soon after surgery (i.e., those with severe trauma, major head injury, or esophageal surgery). Patients fed through nasoenteric tubes who will require prolonged enteral feeding (>4 weeks) should have either gastrostomies or jejunostomies surgically or percutaneously placed with endoscopic assistance. Percutaneous endoscopic gastrostomies (PEGs) are commonly performed, and a modification is to place a jejunal tube through the PEG.

Parenteral nutrition is used when the enteral route is unable to provide or sustain sufficient caloric intake. Although using the gut is preferable, situations arise in which parenteral nutrition is essential. Patients with short bowel syndrome require TPN after surgery and even for life if their residual bowel does not undergo sufficient adaptation to sustain adequate oral intake. Other absolute indications for TPN are small bowel obstruction, active gastrointestinal bleeding, pseudoobstruction with complete intolerance to food, and high-output enteric-cutaneous fistulas (unless a feeding tube can be passed distal to the fistula). In partial large bowel obstruction, feeding a low-residue diet may not be possible. Relative indications for parenteral nutrition include nonhealing, moderate-output, enteric-cutaneous fistulas; the need for bowel "rest," such as during inflammatory bowel flare-ups and acute radiation enteritis; significant abdominal distention and ileus attributable to intraabdominal sepsis; continued distention after relief of intestinal obstruction; and chylothorax unresponsive to a medium-chain TG diet. TPN is also indicated when the enteral route cannot provide enough nutrition.[242] In patients in the ICU, the inability to provide adequate enteral nutrition occurs because of diarrhea, vomiting, poor stomach emptying, feeding tube displacement, and the interruption of feeding for diagnostic tests, procedures, and surgery.[243]

Parenteral nutrition is administered through either central or peripheral venous catheters. Peripheral veins cannot tolerate an osmolarity of more than 750 mOsm/L (the equivalent of 12.5% dextrose); consequently, the fluid volume that can be tolerated limits the caloric intake. Therefore, the peripheral route is primarily used for supplementation or short-term feeding. Central venous catheters are the main route of TPN administration. The preferred entry location is the subclavian vein, which provides a stable site, good patient acceptability, and lower infection rates than either the internal jugular or femoral routes. To minimize insertion and infectious complications, a skilled clinician should insert subclavian catheters under sterile conditions as directed by the commonly used central venous lines (CVL) checklist.[244] This checklist promotes hand washing; full-barrier precautions that include gown, hat, mask, and gloves; and 5% alcoholic chlorhexidine skin preparation. Catheters should be inserted using ultrasound guidance.[245] The catheter should be a single-lumen catheter used only for TPN. Multiple-lumen catheters and multiple-purpose single-lumen catheters have high infection rates.[246] For long-term use, tunnelled Silastic Hickman-Broviac catheters, which have Dacron cuffs located at the proximal end of the tunnel to reduce infections, should be inserted.

FORMULATIONS

Glucose and Carbohydrates

In patients who are injured and septic, exogenous glucose and carbohydrates minimally reduce the rates of gluconeogenesis and lipolysis,[247] which differs from refeeding starved patients when carbohydrate administration reduces gluconeogenesis and lipolysis. Despite the reduced glucose use, administering carbohydrates to patients with stressful illnesses is still important because some body tissues do not readily use other substrates. Furthermore, glucose and carbohydrate intakes stimulate the secretion of insulin, which has anabolic properties that promote protein synthesis and decrease lipolysis. However, hyperglycemia, even with aggressive insulin treatment, often limits how much glucose and carbohydrates can be administered. The severity of TPN-induced hyperglycemia is directly proportional to the rate of glucose infusion and the degree of injury. Older adults are more predisposed to hyperglycemia.

It is important to recognize that patients often receive carbohydrates that are frequently administered from sources other than the glucose in TPN or carbohydrates in enteral nutrition. Patients usually receive 5% dextrose infusions (170 kcal/L), whereas intravenous lipid emulsions contain at least 22 g/L glycerol, which enters the gluconeogenic pathway. Overfeeding glucose (>4 mg/kg/min) to patients with acutely stressful illnesses and receiving a total caloric intake greater than the REE results in a thermogenic response, further elevation of blood glucose concentrations, and production of additional CO_2. This added CO_2 must be excreted by the lungs and, if

insufficiently excreted, can lead to elevated partial arterial pressure of CO_2 ($Paco_2$).

In patients who are critically ill, the rate and extent of enteral glucose absorption are reduced. Among the reasons for this reduction are delayed gastric emptying and reduced small intestinal absorption.[248,249] Delaying enteral feeding for 4 days after ICU admission impairs intestinal glucose absorption, as compared with starting enteral nutrition within 24 hours of admission,[250] which is another reason to begin enteral nutrition as soon as possible after ICU admission.

Lipids

Intravenous lipid is usually administered as a long-chain TG (LCT) emulsion.[251] These emulsions contain soybean oil and an emulsifier (egg phospholipid) and are calorically dense (e.g., 10% and 20% solutions contain 1.0 and 2.0 kcal/mL, respectively). Once infused, the lipid emulsion is converted to both TG-rich particles with sizes similar to that of chylomicrons and phospholipid-rich particles produced from emulsifiers called *liposomes*. The chylomicron-like particles are hydrolyzed by lipoprotein lipase to fatty acids and glycerol. The liposomes stimulate cholesterogenesis, incorporate cholesterol, and accumulate in the blood as the long-lived abnormal lipoprotein-X.[252] To minimize liposome formation, lipid emulsions should be slowly administered. Lipid emulsions are also the vehicle for many lipid-soluble drugs such as propofol, amphotericin B, and etomidate. Therefore, propofol infusions for sedation can provide significant amounts of lipid calories, which should be included when calculating caloric intake.

Exogenous fat is required to prevent essential FFA deficiency; therefore, patients receiving TPN should receive lipid emulsion (500 mL of a 10% LCT emulsion) at a minimum two to three times a week. Lipid emulsion is also used for energy because lipid oxidation is the predominant energy-producing pathway during stress. Fat emulsions are well oxidized when administered to patients with sepsis and trauma, even when glucose is provided. Patients with chronic hepatic failure suffering from sepsis and multiple organ dysfunction efficiently metabolize intravenous lipid emulsions. The current practice is to consider lipid emulsions as energy substrates and administer them as 30% to 40% of total TPN calories.

LCT lipid emulsions might have immunosuppressive effects. Ex vivo studies showed decreased neutrophil bacterial killing, depressed monokine expression, and other immune-depressant effects. A study of patients with trauma attributed increased infections to the administration of lipid emulsions, whereas a meta-analysis did not find LCT lipid emulsions to be detrimental to immune function.[253] Furthermore, healthy volunteers exposed to endotoxin showed an enhanced inflammatory response (increased IL-6 and TNF-α) when infused with a soybean-derived lipid emulsion.[254]

Soybean-derived LCT emulsions traditionally used for TPN have high proportions of omega-6, polyunsaturated fatty acids, specifically linoleic acid (53%). Linoleic acid is the precursor of thromboxane A_2 and prostaglandin E_1, which cause platelet aggregation and inflammation. Alternatively, fish oils containing omega-3 fatty acids (e.g., eicosapentaenoic and linolenic acids) are precursors of different prostaglandins (e.g., thromboxane A_3), which have less platelet aggregating activity and cause less inflammation. Platelets from patients infused for 7 days after surgery with fish oil–enriched lipid emulsions aggregated less than those of patients administered non-enriched emulsions.[255] A meta-analysis showed that fish oil–supplemented TPN reduced hospital and ICU lengths of stay and reduced postoperative infections but did not affect mortality.[162] Postoperative oral eicosapentaenoic acid improved lymphocyte proliferation and NK cell activity. Enteral nutrition regimens enriched with eicosapentaenoic acid and γ-linolenic acid promote the production of antiinflammatory prostaglandin E_1 and were used in the acute respiratory distress syndrome to reduce pulmonary microvascular permeability and to decrease prostaglandin, IL-8, and leukotriene synthesis by alveolar macrophages. In studies in which these formulations were given by continuous infusion, they were associated with shorter mechanical ventilation, decreased ICU lengths of stay, and lower mortality.[256,257] However, bolus supplementation of enteral nutrition with omega-3 fatty acids, γ-linolenic acid, and antioxidants failed to increase ventilator-free days in patients with ARDS.[258]

To reduce the purported limitations of intravenous LCT emulsions, such as the production of toxic lipid peroxides, immunosuppression, and heightened inflammation, there is increasing interest in substituting medium-chain TGs (MCTs) or monosaturated fatty acids derived from olive-oil for some of the LCTs. MCTs do not need carnitine to enter the mitochondria and may be advantageous when carnitine is decreased, such as during sepsis. MCTs are essentially an energy substrate, and it appears that they cannot be stored. MCTs appear to have fewer immunosuppressive effects than LCTs and do not participate in eicosanoid synthesis.[259] Many commercial enteral formulas contain both MCTs and LCTs, supposedly because MCTs are better absorbed. Intravenous MCT-LCT or LCT–olive oil emulsions are not available in the United States.[260]

Protein and Amino Acid

Amino acids and protein are essential ingredients of nutritional support regimens. TPN contains commercially prepared amino acid mixtures, whereas enteral formulas contain free amino acids, peptides, or whole proteins. The purpose of administering protein or amino acids to patients with stressful illnesses is to decrease the breakdown of endogenous proteins by providing an alternative source of amino acids for gluconeogenesis and protein synthesis. Unfortunately, in the stressed state, exogenously administered amino acids and protein are not well utilized because proteolysis is relatively unresponsive to the usual negative feedback mechanisms, such as the administration of exogenous glucose, protein, or amino acids. Nitrogen balance remains negative well into the convalescent stage. In children with burns, leg skeletal muscle protein deposition is unresponsive to amino acid infusion 6 months and up to a year after injury.[261,261a] In the catabolic state, protein–amino acid intake of 1.2 to 1.5 g/kg/day is recommended. Higher amounts do not promote further nitrogen retention and are metabolized to urea; consequently, the blood urea nitrogen may rise. Situations with large external losses of protein, such as extensive burns and large draining abscesses, make it necessary to increase protein–amino acid intake. Adequate

nonprotein calories (e.g., glucose, fat) must be concomitantly administered to ensure that the protein–amino acids are not used as an energy source.

The inability of protein–amino acids to attenuate nitrogen losses significantly led investigators to explore ways of decreasing proteolysis and increasing protein synthesis. One attempt was to use branched-chain–enriched amino acid solutions as a component of TPN, which resulted in some improvement in nitrogen balance[262] but no improvements in outcome. Some enteral nutrition formulas for highly stressed patients are so enriched.[263] The use of anabolic substances, such as IGF-1 plus IGFBP-3 and anabolic steroids to reduce protein oxidation and improve protein synthesis is still in the investigative stages.[264] Another anabolic substance is insulin, which at lower doses decreases protein breakdown by inhibiting the major catabolic pathway—the ATP-ubiquitin proteasome proteolytic pathway[265]; it also stimulates protein synthesis at higher doses.[264] Administering small doses of insulin to patients with burns increased skeletal muscle protein synthesis and improved wound matrix formation. However, the anabolic effects of insulin on protein metabolism were not observed in patients with trauma who were enterally fed. Therefore, the route of nutrient intake may play a role in insulin's anabolic effects.

Amino acids are the precursors of many endogenous substances. Therefore, by manipulating the proportion of the various amino acids in TPN and enteral nutrition formulations, it might be possible to influence the metabolic milieu.[267] Glutamine is the most abundant free amino acid in blood and skeletal muscle and is a primary fuel for rapidly dividing cells such as enterocytes and immunocytes and a precursor of purines, pyrimidines, and nucleotides. It is primarily synthesized in skeletal muscle and is involved in the interorgan transport of nitrogen. Plasma glutamine concentrations decrease during severe stress, probably secondary to decreased glutamine synthesis, providing a possible explanation why alanine is the major interorgan nitrogen transporter. Animal studies show that glutamine likely becomes an essential amino acid during catabolic illness when *de novo* synthesis is insufficient. These studies also show that parenteral and enteral glutamine-supplemented nutrition may prevent gut bacterial translocation, induce neutrophilic phagocytic activity, reduce neutrophil apoptosis, maintain gut integrity, and increase concentrations of the antioxidant glutathione. A meta-analysis of parenteral glutamine supplemented TPN in surgical patients concluded that it shortened hospital lengths of stay and reduced the morbidity of postoperative infections.[268] A placebo-controlled randomized study among critically ill patients who received glutamine supplements starting within 24 hours after ICU admission showed increased in-hospital and 60-day mortality in patients with multiorgan failure.[268a] Therefore, glutamine supplementation is not recommended in such patients. Others for whom supplementation may be indicated include patients with burns, patients who are critically ill, recipients of hematopoietic transplants, and those with acute pancreatitis.[172a] Glutamine is rather insoluble and has limited stability in aqueous solution. Therefore, it is administered as an alanine-glutamine dipeptide when infused intravenously. The amino acid arginine has also been added to nutritional support. In patients with trauma, it stimulates immune cells to reduce NO production, whereas during sepsis it increases NO production. Therefore, arginine supplementation must be used in situations where it does not exacerbate the underlying illness.

Nutritional regimens require many ingredients (Table 106-3; also see Table 106-2). Choosing the route of administration is the key decision, because the type and composition of the formula are wholly dependent on the route. With the parenteral route, protein intake is limited to commercial mixtures of amino acids, carbohydrate to glucose, and lipids to the available emulsions. With enteral nutrition, more options are available because a variety of commercial formulas exist. Supplementing enteral formulas with modular protein, lipid, and carbohydrate products is possible. Either measuring REE using indirect calorimetry or estimating requirements may determine caloric intake (see Table 106-2).

COMPLICATIONS

Complications of nutritional support can result from problems with the delivery system or the nutrition itself. Morbidity related to the delivery system or the nutrients occurs more often with enteral nutrition than with parenteral nutrition. However, infectious complications are more frequent with parenteral nutrition (also see Chapters 101 and 102). Guidelines are available to guide safe compounding and administration of parenteral nutrition.[268b,268c]

Complications of central venous catheterization occur with parenteral nutrition. These complications include pneumothorax, secondary to subclavian or internal jugular vein catheterization. The pneumothorax rate for subclavian catheterization is 1% to 5% but is lower if performed by an experienced clinician. Other complications include hemorrhage-causing hemothorax, brachial plexus injury, and catheter misplacement in the azygos vein, right ventricle, or retrograde into the jugular vein. Central venous catheters (PICCs) that are peripherally inserted, such as via an arm vein, have the advantage of avoiding pneumothoraces but are more difficult to place and have a higher incidence of poor position, upper extremity thrombosis, and skin site irritation. Catheter tips should be above the left atrium and confirmed by chest radiography before starting nutrition. Peripheral venous access, whether via a short peripheral venous catheter or a PICC line, can result in thrombophlebitis. With short catheters, the osmolarity of the solution must be limited to less than 750 mOsm/L to prevent phlebitis. To further prevent phlebitis, some clinicians add heparin and hydrocortisone to the solution, whereas others place a nitroglycerin patch over the catheter site. It is imperative that peripheral parenteral nutrition catheter sites be regularly inspected and catheters changed when evidence of phlebitis develops.

Catheter-related infections are the major venous access complication encountered with TPN. Microbial colonization and bacteremia result from the interaction of four factors: (1) hydrophobicity and exopolysaccharide production of the microbe, (2) amount of fibrin and fibronectin attached to the catheter surface, (3) catheter material (e.g., hydrophobicity, surface charge, thrombogenicity), and (4) iatrogenic factors such as sterile technique and immunocompetence. Infections are uncommon during

TABLE 106-3 CONSIDERATIONS WHEN DESIGNING NUTRITIONAL SUPPORT REGIMENS

Considerations	Requirements	Issues
Route of administration	Evaluate enteral vs. parenteral, or use both.	
Caloric requirements	Measure REE with indirect calorimetry. Estimate REE with established equations. Use a weight-based formula.	See Table 106-2.
Protein–amino acids	Evaluate degree of stress; measure nitrogen balance. Parenteral nutrition: Use amino acid solutions. Enteral nutrition: Use standard or high-protein formulas; evaluate amino acids (elemental diet) vs. peptides vs. protein hydrolysates. If protein losses are excessive, then increased protein intake is needed.	Unstressed patients: 0.8-1.2 g/kg/day protein Stressed patients: 1.0-1.5 g/kg/day protein
Calorie/protein ratio	Is expressed as calorie/nitrogen ratio.	Standard formulas: 130-170:1 Stress formulas: 125-100:1
Carbohydrates	Parenteral nutrition: Glucose is the only available nutrient. Enteral nutrition: Oligosaccharides and starches are used.	Glucose intake not to exceed 4 mg/kg/min during stress.
Lipids	Parenteral nutrition: LCT emulsions; emulsions containing MCTs, olive oil, fish oils (omega-3–fatty acids) are available in some countries. Enteral formulas: Contain LCT or LCT/MCT emulsions; some are enriched with omega-3–fatty acids.	
Lipids/carbohydrate ratio	Parenteral nutrition: C:H:O ratio in lipids: 30:70-60:40. Enteral nutrition: Depends on the formula; calorie-dense formulas (1.5-2.0 kcal/ml) have higher fat ratios.	
Electrolytes	Parenteral nutrition: Contains sodium (NaCl, Na acetate); potassium (KCl, K acetate); phosphate (KPO_4, $NaPO_4$); magnesium ($MgSO_4$), calcium (Ca-gluconate). Enteral nutrition: Per formulation; may add electrolytes, if needed.	Potassium (K): 1-1.2 mEq/kg Magnesium (Mg): 8-20 mEq/day Calcium (Ca): 10-15 mEq/day Phosphate (PO_4): 20-30 mmol/day
Trace elements	Parenteral nutrition: Contains copper, molybdenum, selenium, zinc, manganese, chromium. Enteral nutrition: Also contains iron and iodine.	
Vitamins	Parenteral nutrition: Commercial multivitamin preparations contain all vitamins; some do not include vitamin K. Enteral nutrition: Contains all vitamins including vitamin K; the volume of the formula that provides the recommended daily requirements depends on the formula. Fat-soluble vitamins: Contain A, D, E, and K. Water-soluble vitamins: Contain B_1 (thiamine), B_2 (riboflavin), B_3 (niacin), B_5 (pantothenic acid), B_6 (pyridoxine), folate, B_{12}, and C.	Need to monitor PT (INR) weekly and administer vitamin K, if indicated. Vitamin C requirement is increased for wound repair.
Water	Parenteral nutrition: Dilute vs. concentrated formulas are evaluated. Enteral nutrition: Standard (1.06 kcal/ml) vs. caloric-dense (2.0 kcal/ml) formulas are evaluated.	Dilute formulas are used for peripheral vein administration. Concentrated formulas are used for fluid restriction or high caloric intake formulas.
Disease-specific considerations	Renal failure Hepatic failure Pulmonary disease Burns Diabetes Congestive heart failure	See "Special Considerations" section in the text. See "Special Considerations" section in the text. Reduce absolute carbohydrate intake, substitute lipid for carbohydrates with high total caloric intake. See "Special Considerations" section in the text. Control blood glucose, monitor serum triglyceride levels. Use concentrated formulas, low sodium intake.

C:H:O, Carbon-to-hydrogen-to-oxygen; *INR*, international normalized ratio; *KCl*, potassium chloride; *KPO_4*, potassium phosphate; *LCT*, long-chain triglyceride; *MCT*, medium-chain triglyceride; *$MgSO_4$*, magnesium sulfate; *NaCl*, sodium chloride; *$NaPO_4$*, sodium phosphate; *PT*, prothrombin time; *REE*, resting energy expenditure.

the first 72 hours after insertion but then increase in incidence. The incidence of central venous catheter–related bloodstream infections ranges from 0.3 to 30 per 1000 catheter days and are most often caused by *Staphylococcus epidermidis*, *Staphylococcus aureus*, or *Candida* species, although gram-negative bacteria are being increasingly observed.[270,271] Mortality attributed to catheter-related infections is as high as 25%. A major part of TPN care is aimed at reducing infections. Therefore, solutions are prepared under laminar flow hoods. Once they are prepared, nothing may be added to the solution, and they must be refrigerated until use. Any manipulation of the catheter or line must be performed using sterile procedures, manipulation of the line should be kept to a minimum, and the site must be regularly examined for signs of erythema and infection.

Inserting nasoenteric tubes for enteral nutrition can result in complications because such tubes can enter the pulmonary airways, coil and knot in the stomach, and fail to enter the stomach and thus remain in the esophagus. Therefore, confirming the feeding tube location with chest and/or abdominal radiographs before starting the feeding is vital. Nasoenteric tubes can be withdrawn into the stomach (in case of jejunal feeding) or the esophagus, increasing the risk for aspiration. Nasojejunal tubes dislodged in one third of patients after panceaticoduodenenctomy.[272] Such tube misplacement occurs because of patients pulling on the tube and during suctioning of the mouth. Therefore, the tube should be securely fastened to the nose; if any dislodgment is suspected, a radiograph should be obtained. The major problem with enteral nutrition is frequent decreases or discontinuations of the intake, which prevent administering all the daily caloric requirements. These decreases and discontinuations have been ascribed to high gastric residuals, mechanical problems with the feeding tubes (e.g., dislodgment into the esophagus and obstruction), medical or surgical procedures, sepsis, and vomiting. As many as one third of patients receiving enteral nutrition are unable to achieve a target intake of 25 kcal/kg/day. Therefore, close monitoring of the actual enteral nutrition intake is important to ensure that measures can be taken to ensure adequate caloric intake. These measures include establishing more secure access to obviate or prevent tube dislodgment (e.g., placing a PEG) and placing the tube tip distal to the ligament of Treitz to avoid gastric residuals. In patients in whom the enteral intake remains inadequate, supplementing with parenteral nutrients should be considered.[273] A cumulative caloric debt may occur in patients not fed early and adequately. Therefore, monitoring caloric intake and attempting to avoid caloric deficits are important.

In general, surgically placed needle jejunostomies provide safe and effective access for postoperative enteral feeding. However, complications may occur, including tube dislodgment, local cellulitis, and obstruction. Obstruction can be avoided by frequent flushing and limiting the viscosity of the feeds. Major complications were observed in 4% of 220 patients with trauma who had jejunostomies placed during laparotomies. These complications included small bowel perforations, small bowel volvuli with infarction, intraperitoneal leaks, and small bowel necrosis.[274,275] Small bowel necrosis has a mortality rate approaching 100%.[276] These complications occurred more often with larger diameter tubes than needle jejunostomies.[274] Others have reported intraabdominal and subcutaneous abscesses and small bowel obstruction. Other complications include catheters breaking, especially at the hub, and jejunocutaneous fistulas on removal.

Metabolic Complications

Nutritional support should be slowly initiated and increased only if the patient tolerates the feeding. Because metabolic complications of nutritional support frequently occur, monitoring electrolytes and glucose daily in patients who are acutely ill, particularly when starting the nutrition, is important. If necessary, adjustments should be made in the formulation. Hyperglycemia is a common problem, especially with severe stress, steroid use, and diabetes mellitus requiring treatment with insulin. Administering insulin is preferable over reducing the glucose intake unless hyperglycemia is excessive (>250 mg/dL), despite high insulin doses. Insulin treatment can reduce serum potassium and phosphate concentrations, which require repletion. Importantly, as the stress response abates, the degree of glucose intolerance lessens and insulin requirements drop. Therefore, closely monitoring blood glucose to prevent hypoglycemia is imperative.

Hypoglycemia can occur on the abrupt discontinuation of continuous feedings containing significant amounts of carbohydrate. Continuous feedings result in high blood insulin concentrations so that hypoglycemia intervenes when the carbohydrate intake stops. Therefore, when stopping continuous parenteral and enteral nutrition, any concomitant insulin infusion must be stopped, intravenous glucose should be infused, and blood glucose frequently monitored. The practice of using TPN solutions containing lower glucose:lipid ratios (70:30 to 50:50) has reduced the incidence of hypoglycemia after abrupt discontinuation. TPN should be continued during surgery, whereas enteral nutrition should be discontinued 8 hours before surgery and a glucose infusion begun to prevent hypoglycemia.

Refeeding

Refeeding patients who are nutritionally depleted (≥10% loss of body weight over ≤6 months) must be carefully done to avoid overloading a metabolic system that has adapted to minimal or no food intake.[277] Feeding such patients must begin with balanced diets of carbohydrates, fats, and proteins at intakes below REE. The intake should be increased stepwise over 7 to 10 days. Intake must be monitored to prevent overindulgence because these patients may be hyperphagic. Patients must be monitored for signs of fluid overload, pulmonary edema, and electrolyte disturbances. Electrocardiographic (ECG) changes should be followed for prolongation of the QT interval, which can be a harbinger of torsades de pointes. Hypophosphatemia occurs when tissues begin to rebuild and is especially problematic if the phosphate intake is inadequate, known as the *refeeding syndrome*. Hypophosphatemia may lead to major muscle (including respiratory muscle) weakness and glucose intolerance because

phosphate is a vital component of tissue membranes, enzymes, and nucleosides, especially ATP. Concurrent hypomagnesemia, hypocalcemia, and hypokalemia may exacerbate muscle weakness. Of 62 patients who had not received nutritional intake for at least 48 hours after ICU admission, 34% developed hypophosphatemia (serum levels <0.65 mmol/L or a drop of 0.16 mmol/L) on refeeding. Chronic alcoholics are especially prone to hypophosphatemia. Hypophosphatemia occurs more commonly after enteral than parenteral nutrition.[278]

Nitrogen balance may take time to turn positive because protein intake needs to be gradually increased and gluconeogenesis needs to continue for some time after refeeding begins. Generally, individuals who are nutritionally depleted efficiently replete fat and glycogen stores and rebuild muscle tissue. To rebuild muscles requires exercise; therefore, rebuilding the muscles of patients who are bedridden or immobile is virtually impossible.

Overfeeding

Overfeeding patients with stressful illnesses has many consequences (Box 106-2).[230,279-281]

Gastrointestinal System Complications

Hepatobiliary complications often occur during parenteral nutrition. Factors associated with their development include underlying diseases and their severity, intercurrent sepsis, and drugs. The role of TPN may be additive, if not primary. Large glucose loads (>4 mg/kg/min) can result in hepatic steatosis and steatohepatitis with *portal triaditis* on biopsy. The latter is accompanied by elevated γ-glutamyl transpeptidase, alanine aminotransferase, aspartate aminotransferase, and alkaline phosphatase. Intrahepatic cholestasis with elevated alkaline phosphatase and bilirubin can occur 3 to 6 weeks after beginning TPN. Large omega-6 polyunsaturated lipid loads (≥2 g/day) administered for prolonged periods may also cause cholestasis.[282] Fish oil–based omega-3 polyunsaturated lipids appear to reverse this problem.[283]

Gastrointestinal tract dysfunction frequently occurs with enteral nutrition. Approximately 50% of patients who are mechanically ventilated have delayed gastric emptying. The magnitude of gastric residual volumes are correlated with disease severity in patients in medical ICUs.[284] Consequently, feeds are usually continuously administered, and gastric residual volume is measured at frequent intervals.[285] Compared with feeding into the small intestines, intragastric feeding results in more frequent gastric residuals, vomiting, and regurgitation. In a multicenter prospective study of 400 patients in the ICU who were fed primarily via nasogastric tubes, gastrointestinal complications occurred in 62.8% and were due to diarrhea (14.7%), constipation (15.7%), large gastric residuals (39%), abdominal distention (13.2%), vomiting (12.2%), and regurgitation (5.5%). Enteral nutrition was withdrawn in 15% of patients because of gastrointestinal complications.[276] In the presence of gastroparesis and large volume (150 to 220 mL) residuals, prokinetic agents should be considered. Individual studies showed that intravenous erythromycin is more effective than metoclopramide (improvement in 87% versus 62% of patients), but their effectiveness declined over time.[286]

BOX 106-2 *Consequences of Overfeeding in Parenteral and Enteral Nutrition*

Caloric intake: Substrate in excess of energy needs and synthetic function
>1.5-1.7 REE in patients with stressful illnesses

- Increased fat storage
- CO_2 production, urea production, and thermogenic effects

Carbohydrates: >4.5 mg/kg/min

Lungs
- Increased CO_2 production leads to increased $\dot{V}_E$, which may cause breathlessness.
- If increases in $\dot{V}_E$ are insufficient, then $Paco_2$ increases.

Liver
- *Fatty liver:* Hepatomegally increases AST, ALT, and alkaline phosphatase.
- *Hyperglycemia:* May lead to osmotic diuresis and prerenal azotemia.
- *Exacerbation of peripheral insulin resistance:* Reduces insulin sensitivity and increases oxidative stress.
- *Increased intracellular potassium:* Decreases serum potassium.
- *Increased intracellular phosphate:* Decreases serum phosphate.
- *Increased REE:* Is due to increased thermogenesis caused by increased catecholamine secretions.

Lipids: >2g/kg/day

Liver: Cholestasis, fatty liver
Congestion of RES with fat increases.
Serum triglyceride levels increase.

Protein: >2g/kg/day

Kidneys
- Ureagenesis is increased.
- BUN increases with decreased renal function.
- With normal renal function, diuresis may occur as a result of increased BUN secretion, which may lead to prerenal azotemia.

Lungs
- Protein–amino acids increase respiratory drive and might cause breathlessness.

Fluid intake: Excessive fluid intake may lead to fluid overload and is especially problematic with reduced cardiac or renal function.
Infection: Bloodstream infections are increased.

AST, Aspartate aminotransferase; *ALT*, alanine aminotransferase; *BUN*, blood urea nitrogen; *CO_2*, carbon dioxide; *$Paco_2$*, partial arterial pressure of carbon dioxide; *REE*, resting energy expenditure; *RES*, reticuloendothelial system; *$\dot{V}_E$*, minute ventilation.

Rescue therapy using both drugs was effective.[285,287] To decrease pulmonary aspiration, patients should be fed in the semirecumbent position, and promotility agents should be used if residual gastric volumes are high. Whether postpyloric feeding reduces aspiration is yet unclear.[229] With enteral nutrition, being aware that drug-nutrient interactions can occur is important.

Diarrhea is a particularly unpleasant complication of enteral nutrition for both the patient and staff with its incidence, depending on its definition, ranging from 2% to 53% of patients and 38% of feeding days. The definition of diarrhea used is important because many enteral products are *low residual*: that is, they do not contain fiber and may not cause formed stools. Formula-related causes of diarrhea

include hyperosmolar feedings, too rapid administration, and contamination of feedings with toxigenic or pathogenic organisms. Therefore, feeds should be sterile and not allowed to hang in the bag for longer than 8 to 12 hours.[288] Non–formula-related causes include concomitant administration of drugs constituted in sorbitol elixirs, mannitol, or polyethylene glycol; *Clostridium difficile* enterocolitis; intraabdominal infection; receipt of broad-spectrum antibiotics; and hypoalbuminemia. Hypoalbuminemia-associated diarrhea has been attributed to small bowel wall edema, leading to malabsorption. Yet, using elemental and peptide diets has achieved diarrhea-free feedings in patients with hypoalbuminemia. Fiber-containing formulations might reduce diarrhea but not consistently.[289] Most enteral formulas are lactose and gluten free, eliminating lactose and gluten intolerances as problems. In patients without infectious diarrhea, pectin and antimotility drugs may reduce the diarrhea. However, such patients must be monitored for the development of constipation. Hepatobiliary complications of enteral nutrition are rare (<5%).

SPECIAL CONSIDERATIONS

BURNS

Patients with burns present special problems because of their extremely high energy expenditures, transcutaneous losses of protein, and great fluid requirements (also see Chapter 59). If patients are unable to eat, then enteral nutrition is the preferred modality. A number of trials indicate that enteral nutrition started within a few hours of admission reduces the magnitude of the stress response to burns. Therefore, beginning nutrition early, that is, within fewer than 16 hours of admission, is common practice with significant burns (>20%). However, insufficient evidence on systemic review shows an advantage of early versus late enteral nutrition or that enteral nutrition reduces the stress response.[290] To ensure successful administration of many calories of a high protein diet, nasoenteric feeding tubes should be placed into the jejunum. Caloric intake must be closely monitored in patients with burns. If inadequate calories are being ingested, then supplementation is needed. In patients who are eating, supplementation may be in the form of nutritional supplements ingested between meals. In patients who are enterally fed, supplementation can be provided with parenteral nutrition. Furthermore, burn patients have elevated protein requirements and increased vitamin and trace element needs.[290a]

HEPATIC DYSFUNCTION

Hepatic dysfunction, especially cirrhosis with intercurrent acute illness, presents a complex metabolic scenario (see Chapters 73 and 74). As many as 90% of patients with decompensated cirrhosis suffer weight loss, muscle wasting secondary to anorexia, large protein loses into ascites, poor oral intake because of unpalatable low-salt and low-protein diets, and hypermetabolism.[291] They have hyperinsulinemia, insulin resistance, accelerated gluconeogenesis, increased lipid oxidation, fat malabsorption attributable to decreased bile salts, and possibly, reduced glycogenesis.[292] Essential fatty acid, magnesium, zinc, and selenium deficiencies also occur. After liver transplantation, glucose clearance improves, owing to the correction of the hyperinsulinemia and insulin resistance. However, patients receiving corticosteroids as immunosuppressive therapy continue having abnormal glucose metabolism.

As a result of their depleted state, patients with cirrhosis appear to be candidates for nutritional repletion. Yet, because of their poor prognosis, especially when complicated by serious illness, enteral nutritional support of hospitalized patients who are seriously ill with cirrhosis was associated with reduced survival. A Cochrane Review did not reveal compelling evidence to routinely use parenteral or enteral nutrition or oral supplements in patients with liver disease.[293] However, the success of liver transplantation renewed interest in nutritionally supporting transplant candidates. These patients require fluid and sodium restriction and diuretic agents to control their fluid overload. They need increased protein–amino acid intakes (1.2 to 1.5 g/kg/day) because of increased protein synthetic rates and to replace the losses caused by ascites formation. Furthermore, they require a caloric intake to account for hypermetabolism (25 to 40 kcal/day).[294] Some patients with cirrhosis develop hepatic encephalopathy. When encephalopathic, current recommendations are not to reduce protein intake but to provide an intake of 1.0 to 1.2 g/kg/day plus lactulose and/or neomycin.[295] In persistent encephalopathy, branched-chain amino acid–enriched solutions and feedings should be considered. In cirrhosis, the plasma concentrations of these amino acids are low. When intravenously administered, they are thought to counter the effects of intracerebral aromatic amino acids, which are involved in hepatic encephalopathy.[296] Furthermore, they are not metabolized in the liver and are available for protein synthesis. A Cochrane Review showed a decreased rate of hepatic encephalopathy without a reduction in mortality rate or adverse events.[297]

RENAL DYSFUNCTION

Preexisting chronic renal disease and newly developed acute renal failure present special nutritional challenges (see Chapters 72, 73, and 74). Acute renal failure is especially problematic in the surgical arena because of its association with shock and sepsis. Such patients are insulin resistant, catabolic, and hypermetabolic, similar to other patients with stressful illnesses. However, uremia exacerbates catabolism because it exacerbates insulin resistance, metabolic acidosis, and circulating proteases. The kidney interconverts various amino acids and also degrades specific peptides; consequently, major abnormalities in protein–amino acid handling are also present. Cytokines liberated during hemodialysis may further aggravate the catabolic state. Patients with renal failure are intolerant of large fluid loads, especially when they are oliguric, cannot self-regulate electrolyte concentrations, and do not tolerate large protein–amino acid loads because of an inability to excrete urea. Because these patients require approximately 30 kcal/kg/day and 1.0 to 1.5 g/kg/day of protein, frequent dialysis is needed to remove wastes and excess fluid. The protein–amino acid intake may need to be increased because of dialysis-related loss of amino acids.

Essential amino acid–enriched solutions have been used to reduce urea production, and a Cochran Review concluded that essential amino acids may shorten the overall duration and improve survival from acute kidney dysfunction.[298] Current recommendations are to provide a combination of essential and nonessential amino acids plus dialysis, based on the theory that normally nonessential amino acids may become essential in diseased states.[299]

Hemodialysis, continuous renal replacement therapy (CRRT), that is, venovenous and arteriovenous hemodiafiltration, and peritoneal dialysis facilitate enteral nutrition and parenteral nutrition by removing excess fluid and urea, as well as balancing electrolyte concentrations, thus permitting patients to receive a full complement of calories and protein–amino acids. However, these therapies result in the loss of amino acids (10 to 15 g/day) unrelated to amino acid intake but related to plasma amino acid concentrations, volume of dialysate effluent, and filter efficiency. The concentrations of most amino acids are equal in plasma and dialysate. Therefore, the protein–amino acid content of the nutritional support should be increased. With aggressive CRRT, patients required as much as 2.5 g/kg/day of protein to achieve positive nitrogen balance.[300,301] Current protein recommendations are 1.5 to 1.8 g/kg/day.[302] Dialysis also results in losses of peptides, proteins (with peritoneal dialysis), and water-soluble vitamins. Therefore, some renal enteral nutrition formulations have added B vitamins.

Peritoneal dialysis and CRRT solutions usually contain 1.5% glucose, although concentrations as high as 4.25% are used. Up to 35% to 45% of this glucose can be absorbed and is a source of carbohydrate calories. With peritoneal dialysis, as much as 500 g/day of dextrose may be absorbed. Similarly, glucose-containing solutions used as replacement solutions during hemofiltration can be a source of glucose calories, in one study providing 300 g/day of glucose. This glucose load must be considered when designing nutritional regimens and glucose-carbohydrate contents reduced accordingly. Additionally, glucose concentrations need to be monitored because of both the profound stress state and dialysis-associated glucose absorption. Insulin therapy may be needed to reduce the hyperglycemia. However, patients with renal failure may be especially sensitive to insulin. If glucose-poor solutions, which result in the loss of glucose, are used for CRRT, then glucose replacement should be incorporated into the nutritional support.[302]

Generally, nutritional regimens for patients in renal failure should not contain phosphate, potassium, or magnesium because concentrations of these electrolytes are already elevated. Calcium intake may need to be increased, whereas sodium content should be nearly isotonic because of an inability to regulate serum sodium concentrations. However, during dialysis, all the serum electrolytes must be closely monitored and deficiencies corrected as indicated.[301]

PANCREATITIS

Traditional treatment of acute pancreatitis and of acute exacerbations of chronic pancreatitis is to exclude all oral intakes, institute nasogastric suction, and deliver all nutritional support parenterally. However, contemporary practice is to begin enteral nutrition early (within 48 to 72 hours) in the course of the disease. Several meta-analyses showed that compared with TPN, enteral nutrition is associated with fewer infectious complications, less multiple organ failure, and lower mortality.[303] Furthermore, enteral nutrition causes less hyperglycemia and lower insulin requirements.[304] Therefore, enteral nutrition via a nasojejunal tube is the preferred route of nutritional support in acute pancreatitis, although feeding via nasogastric tubes is noninferior. TPN should be used only when enteral nutrition is not tolerated.[305,305a]

CONCLUSIONS

On a daily basis, anesthesiologists care for patients who are surgically and critically ill and suffering from the consequences of the metabolic and inflammatory responses to injury and sepsis. They must often modulate the detrimental aspects of the response itself (e.g., with epidural anesthesia), modify end-organ responses (e.g., β-adrenergic blockade), and treat its consequences (e.g., blood glucose control, nutritional support) while retaining its beneficial (e.g., immune-enhancing) aspects. However, patients' metabolic conditions are dynamic; consequently, interventions must be appropriate, effective, and most of all, timely. This dynamic situation requires tools that can rapidly assess the metabolic and immunologic milieu.[306] This assessment involves using systems biology approaches incorporating genomic, transcriptomic (mRNA), proteomic, and metabolomic information to better understand the stages of this response. These omic techniques, with their ability to profile many biomarkers rapidly, differ from the current approach of tracking only one or two biomarkers.[307,307a] Genomics research has revealed that the secretion of cytokines and end-organ responses in response to activation of Toll-like receptors during sepsis differ, depending on an individual's genetics.[308] Similarly, gender plays a role in the response. For example, young girls with burns have less hypermetabolism and higher anabolic hormone concentrations than boys, whereas healthy adult women appear to have lower susceptibility to sepsis than men, possibly because of more pronounced proinflammatory innate immunity and a lesser decrease in norepinephrine sensitivity when exposed to endotoxin.[309] Therefore, the use of these newer techniques promises more tailored treatment.

Chapter 107

Extracorporeal Support Therapies

ZACCARIA RICCI • STEFANO ROMAGNOLI • CLAUDIO RONCO

Key Points

- Extracorporeal membrane oxygenation (ECMO) and renal replacement therapy (RRT) are two very important techniques of extracorporeal support commonly used for the care of patients who are critically ill: kidneys, lungs, and heart can be effectively substituted artificially.
- ECMO consists of a specific heart-lung machine that provides gas exchange for prolonged support of patients with severe but potentially reversible respiratory or cardiac failure or both. Although the term *extracorporeal life support* (ECLS) might describe the system more accurately, ECMO is actually most often used and universally accepted for describing all its applications.
- Different configurations (venovenous, venoarterial, arteriovenous) can be applied to patients, depending on their specific organ failure and severity (e.g., respiratory failure, cardiogenic shock, cardiogenic shock associated with respiratory failure).
- Great technologic improvements have been made during the past years in the manufacture of ECMO circuits, pumps, gas exchangers, and cannulas, rendering the systems simpler, safer, and more efficient for long-term assistance. Such developments have occurred as a consequence of the close integration and exchange of knowledge among industry, clinicians, and scientific investigators.
- Extracorporeal blood purification is a method for removing waste products, such as creatinine and urea, as well as free water from the blood when severe acute kidney injury (AKI) has occurred. The system to achieve blood purification is typically called RRT. In patients who are critically ill, RRT is commonly applied continuously using continuous RRT (CRRT) but also intermittent RRT.
- Solute removal can be achieved by dialysis through diffusion, by hemofiltration (convection), or by the application of both solute transport methods. Water removal is exclusively achieved through ultrafiltration (UF).
- RRT requires intimate knowledge of critical care nephrology and the clinical picture and symptom progression of multiorgan failure. The application of RRT should be decided in a timely manner by an adequately trained team. Solute removal for blood purification is achieved by an accurate RRT prescription, monitoring, and delivery. Fluid overload has to be addressed by net UF prescription and aggressively targeted.

INTRODUCTION TO EXTRACORPOREAL SUPPORT THERAPIES: MULTIORGAN SUPPORT FOR THE PATIENT WHO IS CRITICALLY ILL

Today, patients who are critically ill keep dying from multiorgan dysfunction, a complex and multifactorial syndrome. Mortality ranges from 50% to 90% of patients. Furthermore, as a result of improvements in surgical and pharmacologic options in the past 10 years, patients with the most severe diseases are being admitted to intensive care units (ICUs). When multiorgan failure occurs, therapeutic options are still not specific and mostly aim at vital function support. The kidneys, with their fragile and delicate systems of autoregulation, are almost always involved in the multiorgan failure, and dialytic techniques are routinely used. Renal replacement therapy (RRT) development and utilization has increased to the point that today a multifaceted intervention directed at supporting the function of several organs appears feasible and rational. The concept of multi-organ support therapy (MOST)[1] is to treat a patient's blood artificially, outside of the body, substituting heart, lungs, liver, and kidneys with dedicated pumps, circuits, and membranes (also see Chapter 101).

This chapter gives a general overview of the specific aspects of renal, pulmonary, and circulatory extracorporeal mechanical assistance for renal, respiratory, and cardiocirculatory failure in newborn, pediatric, and adult patients who are critically ill. The technical features and clinical applications are discussed in the following pages.

HISTORICAL NOTES

EXTRACORPOREAL MEMBRANE OXYGENATION

Extracorporeal membrane oxygenation (ECMO) consists of a specific heart-lung machine to provide gas exchange for prolonged support of patients with severe but potentially reversible respiratory or cardiac failure or both. The term *extracorporeal life support* (ECLS) might describe the system more accurately because it includes venovenous (VV), venoarterial (VA), and arteriovenous (AV) configurations, but the term *ECMO* is typically most often used and universally accepted for describing all of these operating modalities. Studies on the extracorporeal circulation and oxygenation of blood began many years ago. The first concrete attempt at extracorporeal support took place around 1930 when John H. Gibbon and his wife developed a roller pump device and an oxygenator with the help of the IBM Corporation at Jefferson Medical College in Philadelphia after a young female patient died of a pulmonary embolus.[2] However, the first clinical application of this new heart-lung machine was attempted in 1953 when an 18-year-old patient, Cecila Bavolek, underwent an atrial septal defect repair. Although Gibbon's original heart-lung machine was cumbersome, complicated, and difficult to manage, it started the era of open-heart surgery. In 1954, C. Walton Lillehei, the "father of open heart surgery," and Richard A. De Wall performed cardiac surgery with a bubble oxygenator.[3] However, the design of the original oxygenators was not suitable for prolonged support. In 1957, Karl Kammermeyer discovered that gas exchange could effectively occur if a thin membrane of dimethylsiloxane, commonly known as *silicone rubber*, was used to separate blood and gas.[4] The use of a silicone membrane oxygenator led to the adoption of the term *ECMO*. Baffes and colleagues in 1970 reported the use of extracorporeal support in 15 patients who underwent palliative cardiac surgeries.[5] The first application of extracorporeal support outside the surgical unit was reported by Hill and colleagues in 1972. A 24-year-old man with acute respiratory failure as a result of a motorcycle accident was supported for 75 hours in VA assistance with peripheral cannulation by means of a Bramson-membrane heart-lung machine. The assistance made it possible to increase the oxygen tension from 38 to 75 mm Hg, reduce the peak airway pressure from 60 to 35 cm H_2O, and reduce the fraction of inspired oxygen concentration (FiO_2) from 1 to 0.6, with a bypass flow of 3 to 3.6 L/min. The respiratory failure reversed, and the patient recovered.[6] During the same year, Dr. Robert Bartlett, who is considered the father of modern extracorporeal support and who first used ECMO support for neonates and children, successfully applied ECMO for 36 hours to a 2-year-old child after a Mustard procedure (total correction of transposition of the great vessels).[7] In 1975, one of the most significant events in the history of modern ECMO occurred. A pregnant woman crossed the border separating Mexico from the United States, desperately hoping for a better life for her child. When she arrived in Orange County, California, her membranes ruptured and, during a complex delivery, the child aspirated a large quantity of meconium, developing severe pneumonia. When the oxygenation fell to hopeless levels, Robert Bartlett placed her in ECMO. After 3 days of bypass, the baby whom nurses named Esperanza, Spanish for *hope*, completely recovered. The use of ECMO for neonatal diseases progressively evolved by improving survival from 10% (first experience) up to 75%. In 1985, Bartlett and colleagues published a hotly debated prospective randomized controlled study of the use of ECMO to treat newborns with respiratory failure based on a "randomized play the winner" statistical method. In this adaptive randomized design that is occasionally used in clinical trials, if one treatment is more successful, then more patients are randomly assigned to that treatment.[8] A group of 12 infants were included in the study. One patient was randomly assigned to conventional treatment (the patient died); 11 patients were given ECMO (all survived).[9] An important subsequent randomized controlled trial was performed by Dr. Pearl O'Rourke and published in 1989.[10] By demonstrating a significantly higher survival rate in children treated with ECMO (97% versus 60%), this study showed the superiority of extracorporeal assistance versus standard treatment until the scientific community and lay press declared that randomization to standard therapy without ECMO would be unethical. Finally, in 1996, the definitive proof of ECMO efficacy in the neonatal setting was published in the *Lancet* journal by UK Collaborative ECMO Trial Group.[11] A total of 185 newborn infants with severe respiratory failure (persistent pulmonary hypertension attributable to meconium aspiration, congenital diaphragmatic hernia, isolated persistent fetal circulation, sepsis, and idiopathic respiratory distress syndrome) were enrolled in the study. The study demonstrated the clinical efficacy of ECMO in neonates with potentially reversible respiratory insufficiency when performed in a well-staffed and organized neonatal ECMO service. The growing interest in ECMO and its worldwide diffusion led to the creation of an organization with the aim of collecting data on ECMO use, comparing outcomes, and sharing different experiences and expertise. The Extracorporeal Life Support Organization (ELSO) was founded in 1989. In 1991 the first European symposium on extracorporeal lung support held in Paris was associated with the foundation of the European ELSO (Euro-ELSO). ELSO is the epicenter for the development, definition, and delivery of indications, guidelines, and recommendations in the field of ECMO assistance, not only for neonates but also for pediatric and adult patients. A case series published in the 1990s suggested the feasibility and efficacy of ECMO in pediatric respiratory failure.[12] Green and colleagues in 1996[13] performed a study on 41 pediatric patients admitted to the ICU with acute respiratory failure. The patients were treated with conventional mechanical ventilation, high-frequency ventilation, or ECMO. The results demonstrated the superiority of ECMO

in improving the survival rate, especially in patients in the 50th to 75th percentile mortality risk group. (Stratification was based on oxygenation index [OI] and Pediatric Risk of Mortality score.)

In contrast to neonatal applications, the demonstration of the benefits of ECMO in adult patients has been slower and more difficult. The first adult trial, directed by Zapol and published in *JAMA* in 1979, demonstrated a very poor survival rate for patients with respiratory failure (90 patients from 9 centers) treated only with VA ECMO.[14] The study was heavily criticized, primarily for factors including the selection of moribund patients, the lack of experience of the centers involved in the study, excessive anticoagulation (attributable to the use of heparin-coated circuits) leading to hemorrhagic complications, and because the ECMO group did not receive lung-protective ventilation. Nonetheless, the results caused the use of ECMO for adult respiratory failure to be avoided for many years. A further confirmation of the paucity of benefit from ECMO in adults came from a randomized clinical trial performed by Alan H. Morris and colleagues.[15] The study included 40 patients with acute respiratory distress syndrome (ARDS) treated with VA assistance (carbon dioxide [CO_2] removal) or conventional ventilation strategy by using a computerized protocol, but it did not demonstrate differences in outcome between groups. The study by Morris and colleagues was criticized because of the poor experience with extracorporeal assistance in some centers included in the data collection. From 2001 to 2006, an ambitious trial on safety, clinical efficacy, and cost effectiveness of ECMO for adults was conducted in the United Kingdom and published in the *Lancet*: the conventional ventilatory support versus ECMO for severe adult respiratory failure (CESAR) trial.[16] The study evaluated a strategy of allocation to a single center (ECMO center), and the patients who were randomized to the control group were conventionally treated at designated treatment centers. A total of 180 adults were randomized in a 1:1 ratio to receive continued conventional ventilation ($n = 90$) or referral to consideration for treatment by ECMO ($n = 90$). The primary endpoint, combining mortality or severe disability 6 months after randomization, was lower for the patients randomized to the ECMO group ($P = .03$). Although burdened by some critical aspects (22 patients randomized to ECMO treatment died before receiving ECMO, no specific protocol for lung-protective ventilation was applied to the control group), the results of the study were of great interest, especially because it coincided with the worldwide pandemic H1N1 virus influenza (influenza A). The capacity of H1N1 infection to induce a particularly severe form of ARDS contributed to a renewed interest in ECMO assistance for adults. In fact, many ECMO centers from several parts of the world have published their experiences with treatment of pulmonary complications secondary to influenza A infection.[17] Over the past 10 years, the use of ECMO in the different types of patient populations—neonatal, pediatric, and adult—has progressively increased. According to the last ELSO Registry Report/ International Summary, data from a total of 50,667 patients have been collected with a mean ECMO survival rate of 73% (http://www.elsonet.org/). The Extracorporeal Membrane Oxygenation for Severe Acute Respiratory Distress Syndrome (EOLIA) trial, a large multicenter trial evaluating the efficacy of ECMO in patients with severe ARDS, is now ongoing (EOLIA trial), and many physicians are eagerly awaiting the results from this large study because it will offer more detailed outcome data, indications, and contraindications for the appropriate use of ECMO.*

RENAL REPLACEMENT THERAPY

In 1977, Peter Kramer described the first continuous form of dialysis specifically dedicated to patients with critical illnesses: continuous AV hemofiltration (CAVH).[18] At that time, RRT in the ICU was a last-chance therapy for patients with acute kidney injury (AKI); it was mostly performed with adapted machines with disparate dialytic protocols and was difficult to use in unstable patients who were critically ill. In CAVH, blood flow in the circuit was driven by the existing AV pressure gradient, and spontaneous ultrafiltration (UF) occurred, depending on the transmembrane pressure (TMP) gradient. The AV pressure gradient was dependent on the mean arterial pressure of the patient and the intrinsic resistance of the circuit; the spontaneous UF was determined by the hydrostatic pressure drop inside the filter and the negative suction provided by the ultrafiltrate column from the patient level to the ground. CAVH provided a slow continuous fluid removal, maintaining steady solute concentrations and preventing peaks of toxic substances. CAVH was one of the first examples of artificial renal support applied to patients who were critically ill. It was capable of overcoming the problems associated with hypotension attributable to rapid fluid removal and rapid reduction of plasma osmolality, arrhythmias caused by electrolyte changes and intravascular volume shifts, and cerebral edema in patients with head injuries. CAVH, however, had some serious limitations. It required both arterial and venous accesses, sometimes difficult to achieve and causing more morbidity. Solute clearance was limited by the low UF rates and the pure convective nature of CAVH. UF limitation is caused by the relatively low blood flow in the circuit and by the low TMP gradient in the most hemodynamically unstable patients. The lowest clearances were achieved and had the most clotting in the circuit. CAVH rarely exceeded 20 mL/min of clearance, hardly sufficient to meet the need of severely catabolic patients.

To overcome such technical limitations, new filters were designed with increased cross-sectional area and inner hollow fiber diameters that reduced unit length and lowered the resistance to blood flow. As a result of these improvements, the phenomenon of filtration pressure equilibrium and easy clotting caused by poorly optimized UF profiles was diminished, if not avoided. Another option explored in those days was the use of highly biocompatible membranes mounted on parallel plat devices. These filters presented lower intrinsic resistance, ensuring higher extracorporeal blood flows at a given AV pressure gradient and they were equipped with a second port in

*http://www.clinicaltrials.gov/ct2/show/NCT01470703?term=eolia&rank=1. (Accessed November 18, 2013)

the filtrate compartment, enabling the countercurrent dialysate flow to be programmed in the newly conceived continuous AV hemodiafiltration with dialysis (CAVHD) mode.

The logical evolution was to apply a peristaltic pump to the extracorporeal circuit. In the past, the use of a blood pump in the ICU was considered proprietary technology of the dialysis team (nurses and nephrology consultants) and a technology that required a specific expertise. Eventually, the knowledge of pumped systems began to be disseminated in the critical care world, making VV hemofiltration a reality. The need of *hardware* evolution in CAVH was not limited to blood pumps; it was also extended to fluid delivery systems and UF control mechanisms, permitting the delivery of dialysate or replacement solutions with an acceptable degree of accuracy.

Another step toward continuous VV renal replacement therapies was the advent of double-lumen catheters that made possible the puncture of a single vein, thus decreasing the high rate of complications attributable to the need of both venous and arterial cannulation. The driving force then resulted from the mechanical action of the roller pumps. Blood flows could finally be programmed and delivered with adequate precision. The new continuous VV therapies required negative-pressure measurement and alarms in the arterial line before the pump, as well as positive-pressure measurements and alarms in the venous return line. A bubble trap had to be inserted in this line to prevent air embolism. (A bubble trap was not necessary in CAVH within which the circuit operated at positive pressure along the entire length of the system). The higher blood flows induced higher filtration rates and the possibility to exploit higher clearances because of increased flow rates. For this reason, roller pumps were also applied to the dialysate or fluid replacement delivery section of the circuit, and external scales had to be frequently used to provide sufficiently accurate fluid balance during treatment. The benefits induced by the new adaptive technology were still counterbalanced by the gross inaccuracy of the systems and the limited integration between the extracorporeal circuit and the fluid balance devices. Safety and performance were definitely not optimized. Blood pumps were often inaccurate, circuit tubing was damaged over time, and filtration fractions were uncontrolled because of pressure and flow fluctuations. Consequently, intrafilter hematocrit and platelet count increased beyond safe values, and filter clotting typically occurred. Accurate UF control is mandatory in modern RRT. Early machines did not have scales or pumps, and when volumetric pumps started to be used to drive dialysate and ultrafiltrate in and out from the filters, inaccuracies close to 10% were observed, an unacceptable error rate for 24 hour–long therapies. Furthermore, when the membrane clogged and approached failure, the ultrafiltrate volumetric pump increased its inaccuracy because of the wide fluctuation in the membrane UF coefficient. Finally, the need of obtaining additional information or for performing additional functions induced physicians and nurses to include in the system several other devices, often poorly integrated, with the final result of a cumbersome "Christmas tree–like effect." It soon became evident that an ideal extracorporeal circuit should have incorporated continuous pressure measurements of inlet and outlet lumens of the catheter inlet and outlet of the filter and ultrafiltrate and dialysate ports. This information and the integration of adequate alarms was of crucial importance to the development of modern machines that allow the ICU staff to maintain filter efficiency and circuit patency, to detect potential sources of clotting, and to ensure patient safety.[19]

TECHNICAL ASPECTS AND MODES OF EXTRACORPOREAL SUPPORT

EXTRACORPOREAL MEMBRANE OXYGENATION

How to Deliver Artificial Gas Exchange

The main purpose of ECMO application is to guarantee adequate oxygen delivery (DO_2) [(DO_2 = cardiac output × arterial oxygen content)] and CO_2 clearance in proper proportion to systemic needs. In fact, the overall goal of cardiorespiratory care is to keep DO_2 at least twice oxygen consumption (VO_2) [(VO_2 = cardiac output [arterial venous oxygen content)]. If medical treatment is unable to maintain this equilibrium and/or the risk of ongoing ventilator- or vasopressor-induced iatrogenic injury arises (i.e., the treatment required is, itself, contributing to organ failure), then ECMO may be indicated to provide life support, allowing time for diagnosis and treatment until the cardiorespiratory system is restored. In general, when only respiratory assistance is required, the use of VV ECMO is advisable, whereas if cardiocirculatory support is necessary, then the VA assembly is used. The AV mode is a particular type of passive (pumpless) lung assistance primarily for decarboxylation (see later discussion). Therefore ECMO can be considered a modified cardiopulmonary bypass circuit to provide short-term respiratory and potentially circulatory support to patients with cardiorespiratory failure (Fig. 107-1). It involves the use of mechanical devices including a pump, a circuit, and an artificial lung (see Fig. 107-1 and see later discussion). The technique is performed by draining venous blood and pumping it through an artificial lung where CO_2 is removed and oxygen is added. The *arterialized* blood is then returned into the systemic circulation via a vein (VV configuration) or via an artery (VA configuration). In the VV mode, native and artificial lungs are in series, whereas in the VA mode, they are in parallel. In both configurations, the native lung can be totally or partially replaced, but only in the VA mode is the cardiocirculatory system supported. If total support has to be achieved, then the blood flow through the artificial lung should be equivalent to the total cardiac output in both modes, requiring a system (cannulas, pump, circuit, artificial lung) that drains 60 to 100 mL/kg/min. In the VA configuration, if venous blood is not totally drained (partial VA bypass), then the circulating blood is a mixture of two separate components: (1) blood that passes through the native lungs and is ejected by the left ventricle into the aorta, and (2) blood oxygenated

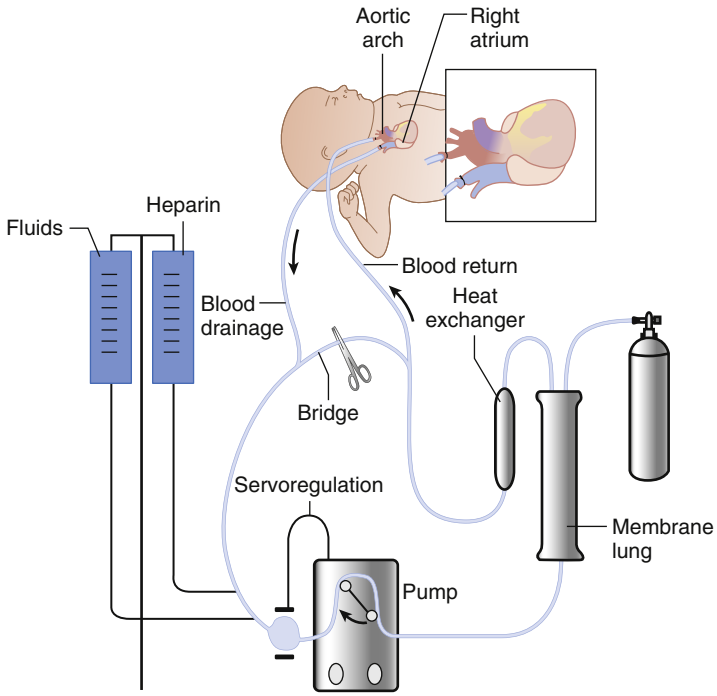

Figure 107-1. Schematic representation of the extracorporeal membrane oxygenation (ECMO) system. Venoarterial ECMO with jugular-carotid approach is more common in pediatric patients.

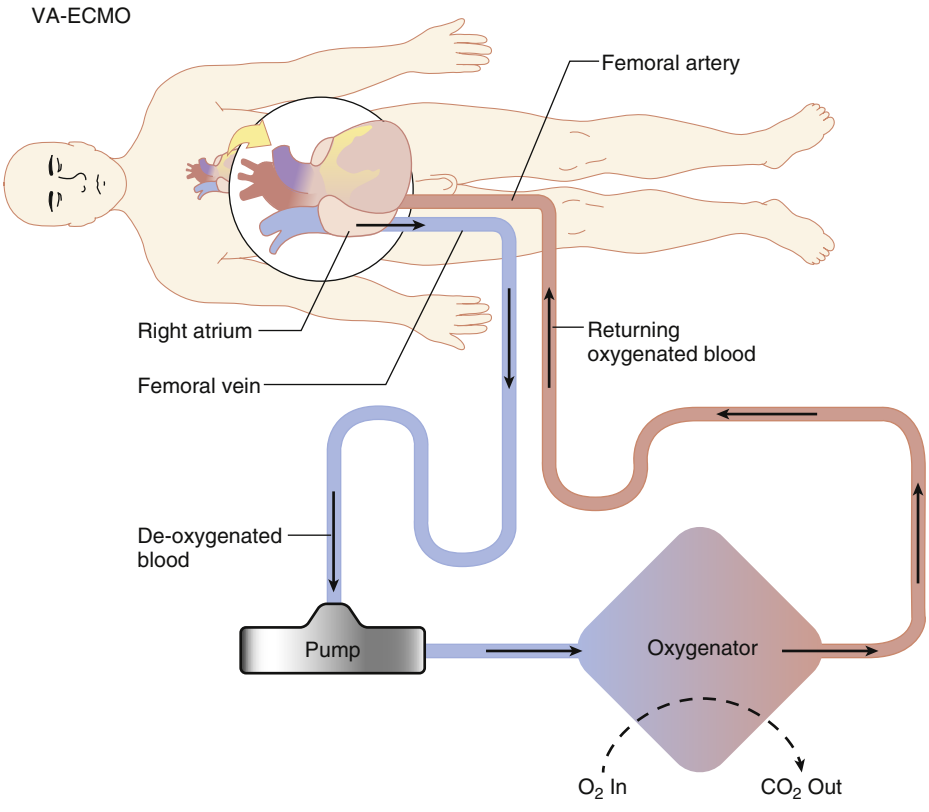

Figure 107-2. Schematic representation of venoarterial extracorporeal membrane oxygenation (ECMO) with femorofemoral approach.

and CO_2 cleared by the artificial lung and pumped into the aorta (usually via a femoral artery) by an artificial pump (Fig. 107-2). In the VV configuration (Fig. 107-3), the blood that passes the artificial lung is pumped into the venous system (right atrium) and mixes with blood coming from the systemic circulation. Different technical modalities can be adopted for VV modes using single cannulas with multiple lumens for drainage (inflow superior vena cava and inferior vena cava port) and infusion (outflow right atrium port) or two or three different cannulas (Fig. 107-4; and see later discussion). In this mode of assistance, the amount of blood pumped into the right ventricle (preload) is equivalent to the drained blood.

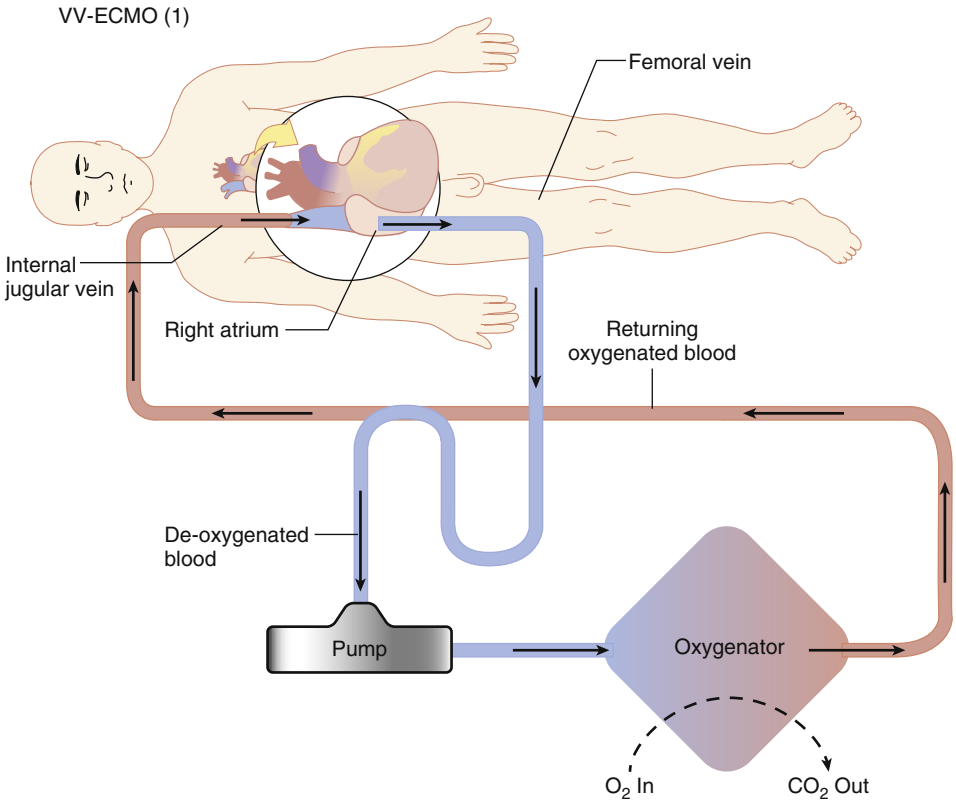

Figure 107-3. Schematic representation of venovenous extracorporeal membrane oxygenation (ECMO) (two cannulas) with the femorojugular approach.

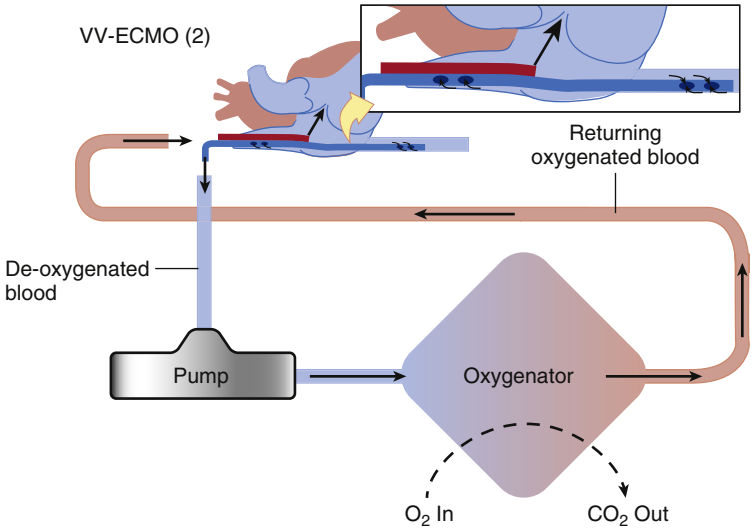

Figure 107-4. Schematic representation of venovenous extracorporeal membrane oxygenation (ECMO) and Avalon cannula *(detail)* with single-vein venovenous approach. CO_2, Carbon dioxide; O_2, oxygen.

Oxygen Delivery and Carbon Dioxide Clearance

During ECMO, oxygen delivery depends on a combination of four elements acting simultaneously:

1. Blood oxygenation in the artificial lung
2. Blood flow through the artificial lung
3. Blood oxygenation in the native lung
4. Blood flow through the native heart

Therefore blood oxygenation depends, in turn, on the technical characteristics of the membrane (e.g., geometry, thickness of the blood film, materials, red blood cells, transit time, hemoglobin concentration, inlet saturation, FiO_2), oxygen saturation in the ECMO drainage cannula (coming from the patient), hemoglobin concentration, and blood flow in the ECMO circuit. In practice, when blood oxygenation is almost completely dependent on VV ECMO (e.g., in patients with severe ARDS), systemic partial arterial pressure of oxygen (PaO_2) is never in the normal range (95% to 100%) and the air-oxygen mixture flow rate (FiO_2 ECMO) and the blood flow through the artificial lung should be adjusted to obtain the most appropriate PaO_2 level (at least 55 mm Hg) and/or arterial oxygen saturation of more than 88% and normal $PaCO_2$.[20] FiO_2 on the ventilator should be reduced to the minimal

value to avoid oxygen toxicity and to keep arterial saturation at more than 88%. To increase partial alveolar pressure of oxygen (P_AO_2), blood flow through the circuit must be increased. Moreover, when oxygenated blood reaches the pulmonary circulation, hypoxic vasoconstriction may be reduced with a further worsening of systemic oxygenation.[21] In some centers, circuit flow is titrated to achieve an arterial oxygen saturation (Sao_2) greater than 80%.[21] Differently from the oxygenation issue, CO_2 clearance is more effective than oxygenation because of its greater solubility (Fick principle) and the relatively linear shape of the CO_2 dissociation curve. Therefore the CO_2 clearance can be obtained with adequate fresh gas through the oxygenator but only 0.5 to 1.5 L/min (10 to 15 mL/kg/min) of blood flow through the artificial lung. To obtain adequate oxygenation, 50 to 60 mL/kg/min are usually necessary, although depending on cardiac output and recirculation in the circuit (see the discussion that follows), 80 to 100 mL/kg/min may be required. Practically, fresh gas flow can be initiated at the same rate as circuit blood flow and then adjusted to maintain $Paco_2$ in the normal range.[21] As a result, the rate of fresh gas flow primarily determines $Paco_2$, whereas PaO_2 is strictly derived from blood flow rate through the artificial lung.[21]

During ECMO, mechanical ventilation should be set to minimize the risk of traumatic injury, such as ventilator-induced lung injury (VILI), by maintaining the lungs open. An ultraprotective mechanical ventilation setting should be applied in all patients under ECMO assistance: inspiratory pressure less than 25 to 30 cm H_2O, positive end-expiratory pressure (PEEP) 10 to 20 cm H_2O (to prevent alveolar collapse), rate 4 to 6 breaths per minute, and FiO_2 as low as possible to maintain peripheral oxygen saturation (SpO_2) greater than 88%. In those patients with predicted long-term respiratory support, early tracheostomy under ECMO should be considered.[22]

Circuit Components

Consistent technologic improvements in ECMO devices for circuits (heparin-coated), pumps, and oxygenators have occurred during the past years. The ECMO circuit consists of four main components: (1) tubing and cannulas, (2) pump, (3) gas exchanger (artificial lung), and (4) heat exchanger (see Fig 107-1). These parts can be completed with pressure monitoring sites, access for therapies, hemofiltration, RRT, and other accessories that monitor for blood parameters (e.g., pH, PaO_2, $Paco_2$, potassium, oxygen saturation, hematocrit, temperature, hemoglobin concentration, base excess, bicarbonate concentration). Circuit dimension and design may partially vary, depending on patient size, clinical purposes, and institutional habits and practice. In the VA mode (for lung and heart support), the general rules are that the circuit has to guarantee a blood flow rate of 100 mL/kg/ min for pediatric patients and 60 mL/kg/min for adult patients. While in the VV mode (for lung assist), the target should be 120 mL/kg/min for neonates to 60 to 80 mL/kg/min for adults.[23] If the clinical purpose is only CO_2 removal, then the circuit may be set in VA, VV, or AV modes. This last configuration does not need an artificial pump (pumpless), because it uses the AV pressure gradient to generate flow through a low-resistance membrane (e.g., the NovaLung Interventional Lung Assist [iLA] Membrane Ventilator; NovaLung Gmbh, Heilbronn, Germany) (Fig. 107-5). A low flow (up to 1 L/min) through the membrane is usually sufficient for clearance of approximately 3 to 6 mL/kg/min of CO_2.[23] The venous cannula (drainage side) and blood tubing are the major limiting components for flow through the circuit. According to the Poiseuille equation, resistance to flow depends on the length and radius (fourth power) of the cannula. Therefore shorter and larger (internal diameter) cannulas placed into the right atrium allow a higher flow of blood into the circuit. For example, if 100 mm Hg pressure gradient is applied to 1 m tube (diameter ⅜"), then the blood flow will be approximately 5 L/m.[23]

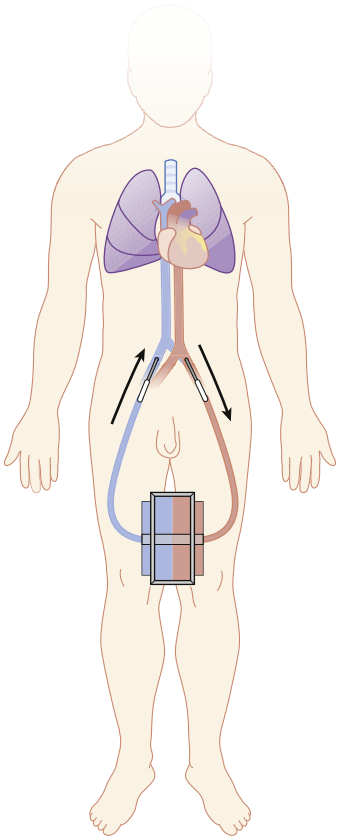

Figure 107-5. Schematic representation of the NovaLung Interventional Lung Assist (iLA) Membrane Ventilator (NovaLung GmbH, Heilbronn, Germany) pumpless arteriovenous system.

Two types of main pumps are currently used for ECMO circuits: roller pumps and centrifugal pumps. Roller pumps were the only type used during the first few decades of ECMO support, but their popularity has recently fallen as a result of improvements in centrifugal pumps. Roller pumps consist of tubing located inside a curved raceway. The raceway is placed at the travel perimeter of rollers mounted on the ends of rotating arms that compress the tubing, pushing the blood ahead and producing continuous blood flow. The output of the pump is determined by the revolutions per minute (rpm) of the pump and the volume contained in the tubing (Fig. 107-6). The main problems with roller pumps are: (1) a cumbersome heavy motor is required; (2) tubing can be damaged by the pump's arms; (3) excessive negative inlet (prepump) pressure and positive outlet (postpump) pressure can develop; and (4) careful

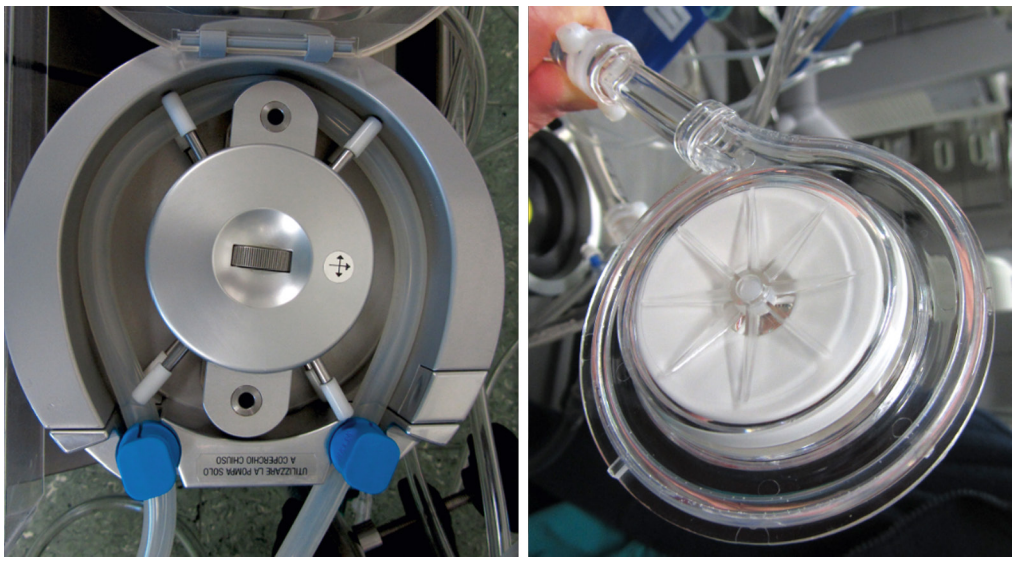

Figure 107-6. Roller pump *(left)* and centrifugal pump *(right)*.

monitoring is needed. At many institutions, the centrifugal pumps have replaced roller pumps for routine ECMO assistance (see Fig 107-6). Centrifugal pumps consist of an impeller arranged with either vanes or a nest of smooth plastic cones inside a plastic holder. The impeller couples magnetically with a small and light motor. The impeller spins at 2000 to 5000 rpm, creating a constrained vortex that suctions blood into the pump head and propels it out toward the gas exchanger. The magnet inside the disposable pump head creates a centrifugal force that directs blood forward to the outlet (i.e., a negative pressure at the inlet port of the pump pulls blood into the pump holder, creating a positive pressure at the outlet port). Problems with centrifugal pumps are blood stagnation and heating in the pump head increases the risk of thrombosis formation, cavitation (formation of cavities (i.e., air bubbles in the blood), and hemolysis when the inlet line is occluded. However, the limitation of revolutions per minute and new design have dramatically reduced the occurrence of these risks.[24] Centrifugal pumps are preload and afterload dependent; therefore the blood flow decreases when the blood volume coming from the draining vein is reduced and when the postpump pressure increases. Recently manufactured pumps for VA assistance provide pulsatile flow, which may be better than continuous nonpulsatile flow. Centrifugal pumps have several advantages over the roller pumps: (1) priming volumes are smaller, (2) gravity drainage is not required, and, (3) very importantly, they operate for weeks, minimizing the incidence of material damages.

Modern oxygenators have microporous membrane lungs, which are significantly more efficient than the older silicon rubber membranes. Moreover, these new components are easier to prime and manufacture. Plasma leakage (the main disadvantage of these membranes) has been addressed by coating the fibers with a very thin skin of gas-permeable membrane. This newer device is called a *hollow-fiber oxygenator* and has several advantages: (1) less platelet and plasma protein consumption, (2) more effective gas exchange, (3) lower resistance to blood flow (facilitating the use of centrifugal pumps), and (4) minimal requirement for priming volumes.[25] An air-oxygen mixture flow, delivered to the oxygenator, maintains the diffusion gradients for oxygen delivery and CO_2 removal. Oxygen concentration (flow FiO_2) has to be adjusted to obtain a PaO_2 of at least 55 mm Hg and/or Sao_2 greater than 88%. The gas flow rate determines the partial pressure of CO_2 (Pco_2) in postoxygenator blood, and its rate is set to maintain the physiologic $Paco_2$.

Finally, body temperature is maintained by hot water circulating in the heat exchanger, an effective system that puts the circuit and the water bath in contact. Therefore patients on ECMO are usually kept normothermic, and ECMO can be used to rewarm cold patients. An anticoagulant has to be administered because the different biomaterials and plastics can induce thrombosis. Bleeding complications remain more problematic than thrombosis, because current generation circuits and oxygenators are heparin-coated or coated with biocompatible materials. Heparin should be titrated to obtain an activated partial thromboplastin time of 40 to 55 seconds or 1.2 to 1.8 times normal. Alternatively, 1.5 times normal activated clotting time can be considered.[22] Maintaining a hemoglobin (Hb) level of at least 7 to 15 g/dL (depending on hypoxemia and patient comorbidities), is considered good practice, but a general consensus concerning the optimal Hb concentration has not been reached.[25] Platelet transfusion is considered if the platelet count goes below 75,000/mm^3, but some centers avoid platelet administration except in cases of bleeding attributable to thrombocytopenia.[25] In general, when the platelet count is greater than 100,000/mm^3 and in the absence of bleeding complications, aspirin may be administered. Finally, sedatives, analgesics, and pain killers should be administered at the smallest doses, whereas neuromuscular blocking drugs are usually only used in the early phase after ECMO initiation.[26] Some patients are mobile while receiving ECMO.

Vascular Access

In this light, vascular access is a key feature of all ECMO types.[27] In the adult setting, cannulation is usually percutaneously accomplished using the Seldinger technique. The use of vascular ultrasound should always be

performed to better identify venous vessel access, following the guidewire into the vessels to the right atrium avoiding coiling in proximal vessels. An alternative approach is the surgical exposure of the vessels, which is more common in the pediatric department. However, cannulation techniques vary, depending on the type of support needed and the patient's age, size, and clinical situation. For instance, for VA ECMO the most common approach in infants and children is the surgical exposure of the right jugular vein and common carotid artery, whereas adult patients are usually managed with percutaneous or surgical exposure and cannulation of the femoral vein and artery. In VA ECMO in adults, the femoral vessels are usually the first choice, and only in particular conditions (e.g., burns, open wounds, significant peripheral vascular disease) has the axillary artery been successfully used. To limit the probability of limb ischemia in adults, small shunting catheters can be placed distally to the arterial cannula or, as an alternative, the femoral artery can be approached by anastomosing a polytetrafluoroethylene (PTFE) vascular graft (end-to-side) to create a bidirectional flow.[28] In specific circumstances, such as patients who have failed to wean from cardiopulmonary bypass (also see Chapter 67), the ascending aorta and right atrium can be directly cannulated (transthoracic approach). Two main venous drainage modes can be considered when VV ECMO assistance is planned: (1) two cannulas can be placed, one for drainage and one for inlet (see Fig. 107-3); or (2) one cannula, the Avalon cannula (see Fig. 107-4), can be inserted. In the first case, the most common femoral-jugular approach is performed by a single large multiperforated drainage cannula inserted via a femoral vein into the right atrium, close to the cavoatrial junction (cannula size 23 to 29 French [Fr]). Then a single-stage catheter, as the return cannula, is inserted in the right internal jugular vein to the superior vena cava (21 to 23 Fr). A supplementary cannula (in the other femoral vein) can be placed to increase the drainage flow. When the blood is pushed by the pump through the artificial lung, a significant increase in pressure related to high resistance is expected. Pressures as high as 300 mm Hg are considered safe, although the higher the pressure, the greater the risk of blood leak and membrane damage. With the Avalon cannula (Avalon Laboratories, LLC, Rancho Dominguez, Calif), a single cannula with a double lumen (13 to 31 Fr) and three holes (two for drainage and one for reinfusion) is inserted via the right internal jugular vein; the Avalon tip must reach the inferior vena cava where the blood is drained together with that coming from the superior vena cava.[29] After passing through the gas exchanger, the blood returns into the right atrium toward the second lumen (see Fig. 107-4) that runs the blood to the third hole, facing the tricuspid valve. In this way, a single cannula is used to drain bi-caval blood and push it in the right ventricle after oxygenation, usually with minimal blood recirculation. Using fluoroscopy or echocardiography, or both, to place the cannula is important to allow the inlet and outlet access to be in the correct position.[30] Pressure and flow diagrams are used for selecting the most appropriate setting according to the patient's need.

RENAL REPLACEMENT THERAPY CIRCUIT: EXTRACORPOREAL MEMBRANE OXYGENATION FOR THE KIDNEYS

The goal of continuous RRT (CRRT) is to achieve blood purification as close as possible to that obtained by the native kidney. Blood is driven in a VV manner through a semipermeable membrane to remove water and solutes. Third-generation machines used in the ICU are currently designed to meet the dialysis dose requirements and the strict safety features that are recommended in every modern ICU.[31] Modern devices generally implement four to five roller pumps (blood, dialysate, reinfusion, UF-effluent, accessory), three to four scales, and pressure sensors (inlet, outlet, filter, effluent) to monitor the entire circuit conditions. These machines allow a fluid load from 20 to 40 kg to reduce nursing workload and to decrease downtime as a result of bag changes. In the meantime, maximal flow rates have increased up to approximately 450 mL/min for blood pumps and to approximately 8 to 10 L/hr for dialysate-replacement pumps. The effluent pumps are able to increase up to 20 to 25 L/hr. Accuracy of the roller blood pumps has increased to achieve a wide flow rate range, keeping flow errors below 2%. New algorithms allow an hourly update of the net UF prescribed and delivered gap and to correct the UF in the next hour to further reduce actual fluid loss discrepancies. An interesting safety feature of third-generation machines is the possibility of setting a limit of accepted UF error within a predetermined time frame, after which the session is automatically interrupted and operator intervention is required.[32] This feature seems important in light of the possible lethal human mistakes that might occur if overriding of UF error alarms is prolonged and uncontrolled.

CRRT machines are now designed with user-friendly interfaces with big screens and clear alarm signals and warnings; most importantly, monitoring circuit pressure trends in the previous 24 hours or possibly longer and eventually visualizing these trends in a graph are possible. With these features, therapy prescription has become flexible and safe, easily ranging from high volume to slow, low-efficiency hemodialysis to standard CRRT. Furthermore, modalities can be switched during the course of a treatment session[33] to be truly tailored to patients with rapidly changing clinical conditions or to modify CRRT prescriptions according to circuit conditions (i.e., increasing the rate of predilution hemofiltration or switching to dialysis if early signs of clotting are present).

CRRT filters are a key feature of blood purification in patients who are critically ill. In all cases, synthetic highly biocompatible membranes are currently used. These filters are made up of groups of hollow fibers with different total surface areas (from 0.1 to over 2 m^2) to meet the needs of treatment of different-sized patients. Such fibers have a generally high porosity (30 to 50 A°) and are used for both diffusive and convective treatments (see the discussion that follows). Polyacrylonitrile, polysulfone, and polymethyl methacrylate are the most used types of membranes currently available on the market; they allow a high UF coefficient (over 20 mL/hr/mm Hg) and high diffusive and convective performance.

Anticoagulation

The need for anticoagulation of the CRRT circuit arises from the fact that the contact between blood and the tubing of the circuit and the membrane of the filter induces activation of the coagulation cascade. This extracorporeal activation inevitably results in filter or circuit clotting (see also Chapter 67). Anticoagulation strategies vary, depending on the prescribed RRT schedule, being a priority feature of continuous treatments, during which blood–artificial surface interaction is maximized. Aims of anticoagulation are to: (1) maintain the extracorporeal circuit and dialyzer patency, as well as reduce off treatment (down) time that might have a clinical impact in the overall RRT clearance; (2) reduce treatment cost by using the fewest materials as possible; and (3) achieve these goals with minimal risk for the patient. This last concept should be the first to rule anticoagulation management—under no circumstances should the patient be at risk of bleeding to prolong the life of the circuit.

Circuit Set-Up Optimization and No Anticoagulation

Several technical features of the RRT circuit are likely to affect the success of any anticoagulant approach. Vascular access has to be of adequate size, tubing kinking should be avoided, blood flow rate should exceed 100 mL/min, pump flow fluctuations must be prevented (in modern machines this event is mainly attributable to circuit increased resistances rather than flow rate inaccuracies), and venous bubble trap, in which air and blood contact occurs, must be accurately monitored. In this light, another component of circuit set-up has to be addressed: plasma filtration fraction should be kept as far as possible below 20% and, when possible or considered correct, predilutional hemofiltration should be selected. When set-up is perfectly optimized, anticoagulants are only a relatively minor component of circuit patency; in fact, when patients have risk factors for bleeding (prolonged clotting times, thrombocytopenia), RRT can be safely performed without using any anticoagulant.[34]

Unfractionated Heparin

Unfractionated heparin (UFH) is the most commonly available anticoagulant. It is easy to use, and an antidote is available (protamine). Heparin doses might range from 5 to 10 IU/kg/hr. In patients with limited circuit duration, UFH can also be used in combination with protamine (regional heparinization) with a 1:1 ratio (150 IU of UFH per milligram of protamine) and strict monitoring of activated prothrombin time (aPTT). The problems with the use of UFH are its relative unpredictable bioavailability, the necessity for antithrombin III (ATIII) levels optimization, and the occurrence of heparin-induced thrombocytopenia (HIT).

Low-Molecular-Weight Heparins

Some centers have gained experience with this relatively new kind of anticoagulant, low-molecular-weight heparin (LMWH) for RRT. Prospective studies have not yet shown LMWH to be superior in prolonging circuit life. These molecules appear to have a better bioavailability than UFH and a lower incidence of HIT with a 10% increased cost.

Prostacyclin

Prostacyclin (prostaglandin PGI_2) is a potentially useful drug for RRT anticoagulation being a potent inhibitor of platelet aggregation with a short half-life. PGI_2 is infused at a dose of 4 to 8 ng/kg/hr with or without the addition of low-dose UFH. Larger doses of PGI_2 might induce hypotension. Some studies have demonstrated PGI_2 efficacy, but its high cost and harmful side effects might limit the use of this agent to patients with short circuit duration.[35]

Citrate

Citrate is a form of regional anticoagulation that depends on the ability of citrate to chelate calcium. The chelation of calcium prevents clot formation. Briefly, a calcium-free, sodium citrate–containing replacement solution or dialysate solution, or both, is prepared and administered at the appropriate rate to achieve the desired aPTT (60 to 90 seconds). Calcium chloride is then administered to replace chelated-dialyzed calcium and to maintain normocalcemia. This approach is effective in maintaining excellent filter patency and compares favorably with heparin. It also avoids the risk for HIT and does not lead to systemic anticoagulation. Relative drawbacks of this anticoagulation management include the risks of hypocalcemia, metabolic alkalosis, and the cumbersome replacement-dialysate fluid preparation.[36,37]

Other Strategies

Alternatives to the techniques previously presented are listed in Table 107-1.

VASCULAR ACCESS

The fundamental role played by vascular access must be emphasized. In fact, circuit failure is more often attributable to vascular access inadequacy than to insufficient anticoagulation. Thus the optimal dialysis catheter can save the patient from an inappropriate increase of anticoagulation dose. VV RRT relies on the use of a temporary double-lumen catheter. Such catheters are inserted in a central vein and available in different brands, shapes, and sizes. The site of insertion of double-lumen catheters implies a number of considerations such as clinician expertise, body habitus of the patient, and the presence of other intravenous catheters. The femoral vein is generally the first choice of vascular access; internal jugular or subclavian accesses are often associated with inadequate performance, and the inguinal puncture is safer and easier to perform in patients who are coagulopathic and critically ill. A valid alternative may be achieved by cannulation of the right internal jugular vein with the tip of the catheter reaching the right atrium. Circuit blood flow rates with this approach can reach 300 mL/min. Catheter size for adult patients ranges from 12 to 14 Fr and the length from 16 to 25 cm; the bigger and shorter the catheter, the higher the level of its performance. Nonetheless, when the femoral vein is selected, a 20-cm long catheter has its tip positioned close to the inferior vena cava, allowing optimal flows within the circuit. When an inadequate blood flow or a catheter malfunction is suspected, venous and arterial lumens should be flushed with saline with

TABLE 107-1 ANTICOAGULATION STRATEGIES

Drug	Pro	Contra
No anticoagulation	High risk of bleeding	Relative short circuit life span
Unfractionated heparin	Routine	HIT
Low-molecular-weight heparin	Routine (alternative to unfractionated heparin)	HIT
Prostacyclin	Very short circuit life span	Hypotension
Citrate	Routine; very short circuit life span	Hypocalcemia
Danaparoid	HIT	Insufficient data available
Argatroban	HIT	Insufficient data available
Irudine	HIT	Insufficient data available
Nafamostat mesilate	HIT	Insufficient data available
Heparin-coated circuits	Routine	Insufficient data available

HIT, Heparin-induced thrombocytopenia.

the goal of testing resistance to injection and aspiration. Limb clotting of the line versus kinking attributable to the patient's position must be distinguished. In the first case, a switching of arterial and venous limb can be attempted. This maneuver increases circuit recirculation, and the clinical consequences are negligible. In the second case, a heparin or urokinase lock can be tried for a few hours or, lastly, a catheter (guidewire) exchange can be attempted.

HOW TO DELIVER ARTIFICIAL BLOOD PURIFICATION: DIFFUSION VERSUS CONVECTION

Renal replacement consists of blood purification by semipermeable membranes. Blood flows into hollow fibers made up of porous biocompatible synthetic materials. A wide range of substances (water, urea, low-, middle-, and high-molecular-weight solutes) can be transported across such membranes, from the blood to the effluent side of the hollow fibers, by the mechanism of diffusion (solutes) and convection (water and solutes) (Fig. 107-7).

During diffusion, the movement of solutes depends on their tendency to reach the same concentration on each side of the membrane; the practical result is the passage of solutes from the compartment with the highest concentration to the compartment with the lowest concentration. Other components of the semipermeable membrane deeply affect diffusion—thickness and surface area, temperature, and diffusion coefficient. Dialysis is a modality of RRT and is predominantly based on the principle of diffusion: a dialytic solution flows through the filter countercurrently to blood flow to maintain the highest solute gradient from inlet to outlet port. Diffusion is the solute transport method that is applied during continuous VV hemodialysis (CVVHD) (Fig. 107-8).

During convection, the movement of solute across a semipermeable membrane takes place in conjunction

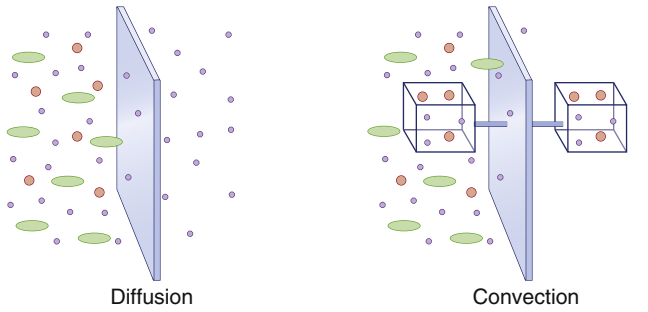

Figure 107-7. Diffusion and convection are schematically represented. During diffusion, solute flux (Jx) is a function of solute concentration gradient (dc) between the two sides of the semipermeable membrane, temperature (T), diffusivity coefficient (D), membrane thickness (dx), and surface area (A) according to the following equation:

$$Jx = D \times T \times A \ (dc/dx)$$

Instead, convective flux of solutes (Jf) requires a pressure gradient between the two sides of the membrane (transmembrane pressure [TMP]) that moves a fluid (plasma water) with its crystalloid content, a process called *ultrafiltration*, whose entity is also dependent on membrane permeability coefficient (Kf). Colloids and cells will not cross the semipermeable membrane, depending on the pores' size.

$$Jf = Kf \times TMP$$

where TMP = Pb – Pd – π, and Pd is blood hydrostatic pressure, Pd is hydrostatic pressure on ultrafiltrate side of the membrane, and π is blood oncotic pressure.

Schematic representation of the most common continuous renal replacement therapy (CRRT) set-ups. *Black triangles* represent blood flow direction; *gray triangles* indicate dialysate-replacement solutions flows. *CVVH*, continuous venovenous hemofiltration; *CVVHD*, continuous venovenous hemodialysis; *CVVHDF*, continuous venovenous hemodiafiltration; *Di*, dialysate in; *Do*, dialysate out; *Qb*, blood flow; *Qd*, dialysate solution flow; *Qf*, replacement solution flow; *Quf*, ultrafiltration flow; *Rpost*, replacement solution postfilter; *Rpre*, replacement solution prefilter; *SCUF*, slow continuous ultrafiltration; *Uf*, ultrafiltration; *V*, vein; *VV*, venovenous.

with significant amounts of UF (water transfer across the membrane). In other words, as the solvent (plasma water) is pushed across the membrane in response to the TMP by UF, solutes are carried with it, as long as the porosity of the membrane allows the molecules to be sieved from the blood. The process of UF is governed by the UF rate (Qf), the membrane UF coefficient (Km), and the TMP gradient generated by the pressures on both sides of the hollow fiber, according to the following formula:

$$Qf = Km \times TMP$$

The hydrostatic pressure in the blood compartment is dependent on blood flow (Qb). The greater the Qb, the greater the TMP. In modern RRT machines, UF control throughout the filter is obtained by applying a pump, which generates control of the UF rate. Modern systems are designed to maintain a constant Qf; when the filter is "fresh," the initial effect of UF pumps is to retard spontaneous UF production, generating a positive pressure on the UF side. As the membrane fibers foul, a negative pressure is necessary to achieve a constant Qf. In this case a progressive increase of TMP can be observed up to a maximal level in which clotting is likely and solute clearance may be significantly compromised. In fact, if it is true that the molecules cleared during convection are physically dragged to the UF side, then it is also true that the protein layer that progressively closes fiber pores tends to limit solute transport significantly.[38] A peculiar membrane capacity, defined as *adsorption*, has been shown to play a major role in higher molecular weight toxins[39]; however, it should be considered that membrane adsorptive capacity is generally saturated in the first treatment hours. This observation marks the scarce impact of the adsorption component on solute clearance and suggests relying only on the relatively minor effects of mass separation processes such as diffusion and convection.[40] As UF proceeds and plasma water and solutes are filtered from blood, hydrostatic pressure within the filter is lost and oncotic pressure is gained because blood concentrates and hematocrit increases. The fraction of plasma water that is removed from blood during UF is called *filtration fraction*; it should be kept in the range of 20% to 25% to prevent excessive hemoconcentration within the filtering membrane and to avoid the critical point during which oncotic pressure is equal to TMP and a condition of filtration-pressure equilibrium is reached. Finally, replacing plasma water with a substitution solution completes the hemofiltration process and returns purified blood to the patient. The replacement fluid can be administered after the filter, with a process called *postdilution hemofiltration*. Otherwise, the solution can be infused before the filter to obtain *predilution hemofiltration*. Although postdilution allows a urea clearance equivalent to therapy delivery (i.e., 2000 mL/hr; see later discussion), predilution, despite theoretic reduced solutes clearances, allows prolonged circuit life span by reducing hemoconcentration and protein-caking effects that occur within filter fibers. Conventional hemofiltration is performed with a highly permeable membrane with a surface area of approximately 1 m^2, steam sterilized, with a cutoff point of 30,000 daltons (30 kD). The difference between the volume of ultrafiltered plasma water and reinfused substitution solution gives the net UF, which is the fluid that is eventually removed from the patient for fluid control. Net UF prescription is based on patient needs and can range from more than 1 L/hr (pulmonary edema in a patient with congestive heart failure and who has diuretic-resistant AKI) to zero (septic patient in a catabolic state with increased creatinine levels and conserved diuresis). A net UF rate must be added to dialysis to achieve fluid balance control during diffusion that does not allow water movements.

Convection is applied during slow continuous UF (SCUF) and continuous VV hemofiltration (CVVH) (see Fig. 107-8).

The application of both convection and diffusion configures continuous VV hemodiafiltration (CVVHDF) (see Fig. 107-8).

Nomenclature

Intermittent hemodialysis (IHD): IHD is a common diffusive treatment in which blood and dialysate are circulated in countercurrent mode; generally, a low-permeability, cellulose-based membrane is used. Dialysate must be pyrogen free but not necessarily sterile, since dialysate–blood contact does not occur. The UF rate is equal to the scheduled weight loss. This treatment can be performed typically in 4 hours, three times weekly or daily. Blood flow (Qb): 150 to 300 mL/min; dialysate solution flow (Qd): 300 to 500 mL/min.

Peritoneal dialysis (PD): PD is a predominantly diffusive treatment during which blood, circulating along the capillaries of the peritoneal membrane, is exposed to dialysate. Access is obtained by inserting a peritoneal catheter, which allows the abdominal instillation of dialysate. Solute and water movement is achieved by means of variable concentration and tonicity gradients generated by the dialysate. This treatment can be continuously or intermittently performed.

Slow continuous ultrafiltration (SCUF): SCUF is a technique in which blood is driven through a highly permeable filter via an extracorporeal circuit in VV mode. The ultrafiltrate produced during membrane transit is not replaced, and it corresponds to weight loss. It is used only for fluid control in patients with overload (i.e., patients with congestive heart failure who do not respond to diuretic therapy). Qb: 100 to 250 mL/min; ultrafiltration flow (Quf): 5 to 15 mL/min (see Fig. 107-8).

Continuous venovenous hemofiltration (CVVH): CVVH is a technique in which blood is driven through a highly permeable filter via an extracorporeal circuit in VV mode. The ultrafiltrate produced during membrane transit is replaced in part or completely to achieve blood purification and volume control. If replacement fluid is delivered after the filter, then the technique is defined as *postdilution hemofiltration*. If it is delivered before the filter, the technique is termed *predilution hemofiltration*. The replacement fluid can also be delivered both prefilter and postfilter. Clearance for all solutes is convective and equals the UF rate. Qb: 100 to 250 mL/min; Quf: 15 to 60 mL/min (see Fig. 107-8).

Continuous venovenous hemodialysis (CVVHD): CVVHD is a technique in which blood is driven through a low permeability dialyzer via an extracorporeal circuit in VV mode, and a countercurrent flow of dialysate is

delivered on the dialysate compartment. The ultrafiltrate produced during membrane transit corresponds to the patient's weight loss. Solute clearance is mainly diffusive, and efficiency is limited to small solutes only. Qb: 100 to 250 mL/min; Qd: 15 to 60 mL/min (see Fig. 107-8).

Continuous venovenous hemodiafiltration (CVVHDF): CVVHDF is a technique in which blood is driven through a highly permeable dialyzer via an extracorporeal circuit in VV mode and a countercurrent flow of dialysate is delivered on the dialysate compartment. The ultrafiltrate produced during membrane transit is in excess of the patient's desired weight loss. A replacement solution is needed to maintain fluid balance. Solute clearance is both convective and diffusive. Qb: 100 to 250 mL/min; Qd: 15 to 60 mL/min; replacement solution flow (Qf): 15 to 60 mL/min (see Fig. 107-8).

Hemoperfusion (HP): The patient's blood is circulated on a bed of coated charcoal powder to remove solutes by adsorption. The technique is specifically indicated in cases of poisoning or intoxication with agents that can be effectively removed by charcoal. This treatment may cause platelet and protein depletion.

Plasmapheresis (PP): PP is a treatment that uses specific plasma filters. Molecular-weight cut-off of the membrane is significantly higher than that of hemofilters (100 to 1000 kD). Plasma as a whole is filtered, and blood is reconstituted by the infusion of plasma products such as frozen plasma or albumin. This technique is performed to remove proteins or protein-bound solutes.

High-flux dialysis (HFD): HFD is a treatment that uses highly permeable membranes in conjunction with an UF control system. Because of the characteristics of the membrane, UF occurs in the proximal part of the filter that is counterbalanced by a positive pressure applied to the dialysate compartment, which causes a phenomenon called *backfiltration* in the distal part of the filter from convective passage of the dialysate into the blood. Diffusion and convection are combined; because of the use of a pyrogen-free dialysate, replacement is avoided.

High-volume hemofiltration (HVHF): HVHF is a treatment that uses highly permeable membranes and hemofiltration with a high-volume setting: Qb: >200 mL/min; Qf: >45mL/kg/hr.

RENAL REPLACEMENT THERAPIES DOSE AND PRESCRIPTION

Similar to other therapies managed in the ICU, dialysis should be administered in an appropriate amount. The conventional view of RRT dose is that it is a measure of the quantity of blood purified of waste products and toxins achieved by means of renal replacement. Because this wide and still incompletely known family of substances is too difficult to measure and quantify, the operative view of RRT dose is generally reduced to the measure of the elimination of a representative marker solute. This premise has two major flaws: (1) the marker solute cannot and does not represent all the solutes that accumulate during AKI because kinetics and volume of distribution are different for each solute; and (2) its removal during RRT is not necessarily representative of the removal of other solutes, which is true both for end-stage renal failure and AKI. Nevertheless, despite all of these limitations, a significant body of data[41] suggests that single-solute marker assessment of the dose of dialysis appears to have a clinically meaningful relationship with patient outcomes and therefore clinical utility. In addition, the concept of RRT dose is useful also for practical purposes. Similar to antibiotics, vasopressors, antiinflammatory drugs, and mechanical ventilation, the administration of an extracorporeal treatment for blood purification requires the operators to know exactly when, how, and how much treatment should be prescribed and delivered.

During RRT, clearance depends on circuit Qb, Qf, or Qd, solutes' molecular weights, and hemodialyzer type and size. Qb, as a variable in delivering the RRT dose, is primarily dependent on vascular access and operational characteristics of the machines used in the clinical setting. Filtration fraction strictly links Qf to Qb during convective techniques. Filtration fraction does not limit Qd, but when the Qd:Qb ratio exceeds 0.3, it can be estimated that the dialysate will not be completely saturated by blood-diffusing solutes. The search for specific toxins to be cleared, furthermore, has not been successful, despite years of research; urea and creatinine are generally used as reference solutes to measure renal replacement clearance for renal failure. Although available evidence does not allow direct correlation of the degree of uremia with outcome in chronic renal disease, clearances of urea and creatinine blood levels are used to guide treatment dose in the absence of a specific solute. During UF, the driving pressure jams solutes, such as urea and creatinine, against the membrane and into the pores, depending on membrane-sieving coefficient (SC) for that molecule. SC expresses a dimensionless value and is estimated by the ratio of the concentration of the solutes in the filtrate divided by that in the plasma water or blood. An SC of 1.0, as is the case for urea and creatinine, demonstrates complete permeability, and a value of 0 reflects complete rejection. Molecular size over approximately 12 kD and filter porosity are the major determinants of SC. The clearance during convection is measured by the product of Qf times the SC. Thus, differently from diffusion, a linear relationship exists between K and Qf, the SC being the changing variable for different solutes. During diffusion the linear relationship is lost when Qd exceeds approximately one third of Qb. As a rough estimate, during continuous slow efficiency treatments, a direct expression of Qf or Qd, independent of which solute must be removed from blood, can be considered the RRT dose. During continuous treatment in the ICU, the goal is to deliver at a minimum a urea clearance of 2 L/hr. Some clinical evidence suggests that 35 mL/kg/hr may be the best prescription (i.e., approximately 2.8 L/hr in a patient weighing 70 kg; see later discussion).[42] Others suggest a prescription based on patient requirements, urea generation rate, and catabolic state of the single patient. It has been shown, however, that during continuous therapy a clearance less than 2 L/hr will almost certainly have insufficient results in the adult patient who is critically ill.

The dose of RRT can also be described by a fractional clearance of a given solute:

Kt/V

where K is dialysis clearance, t is the time of dialysis administration, and V is the solute marker volume of distribution. Kt/V is an established marker of adequacy of dialysis for small solutes correlating with medium-term (several years) survival in patients who are chronically ill and on hemodialysis. Urea is typically used as a marker molecule in end-stage kidney disease to guide treatment dose, and a Kt/V_{UREA} of at least 1.2 is currently recommended. As an example, the case of a 70-kg patient who is treated 20 hours per day with a postfilter hemofiltration of 2.8 L/hr at a zero balance is considered: The patient's K_{UREA} will be 47 mL/min (2.8 L/hr = 2800 mL/60 min) because ultrafiltered plasma water will drag all urea across the membrane during postfilter hemofiltration, making its clearance identical to UF flow. The patient's treatment time (t) will be 1200 minutes (60 minutes for 20 hours). The urea volume of distribution will be approximately 42,000 mL (60% of 70 kg; 42 L = 42,000 mL), which is roughly equal to total body water. Simplifying this patient's Kt/V_{UREA}, [47 × 1200] ÷ 42,000 = 1.34. However, Kt/V_{UREA} application to patients with AKI has not been rigorously validated.[43] In fact, although the application of Kt/V to the assessment of dose in AKI is theoretically intriguing, many concerns have been raised because problems intrinsic to AKI can hinder the accuracy and meaning of such dose measurement. These concerns include the lack of a metabolic steady state, uncertainty about the volume of distribution of urea (V_{UREA}), a high protein catabolic rate (PCR), labile fluid volumes, and possible residual renal function, which dynamically changes during the course of treatment. Furthermore, delivery of prescribed dose in AKI can be limited by technical problems such as access recirculation, poor blood flows with temporary venous catheters, membrane clotting, and machine malfunction. Finally, clinical issues such as hypotension and vasopressor requirements can be responsible for solute disequilibrium within tissues and organs.

These observations highlight the gross inadequacies of applying end-stage renal failure paradigms to patients with AKI. They also indicate that, unlike in the field of chronic hemodialysis, only major changes in the application of dose (e.g., changing from second daily to daily dialysis) can truly deliver a *different* therapy in the setting of AKI. More subtle adjustments such as prescribing a calculated Kt/V of 1.0 versus 1.2 can easily be criticized as being within the calculation error around each prescription and not necessarily representing a reliable change in dose delivery. Nonetheless, the crucial merit of specific-dose prescription, calculation, and delivery is the avoidance of underdialysis and the improved monitoring and awareness of effective delivered therapy.

Finally, the therapeutic needs that can be or need to be affected by the dose of RRT are not only the simple control of small solutes as represented by urea. They include control of acid-base, tonicity, potassium, magnesium, calcium, phosphate, intravascular volume, extravascular volume, temperature, and the avoidance of unwanted side effects associated with the delivery of solute control. In the patient who is critically ill, it is significantly more important to administer 10 units of fresh frozen plasma, 10 units of cryoprecipitate, and 10 units of platelets rapidly (e.g., in the setting of coagulopathic bleeding after cardiac surgery) without inducing excessive intravascular volume (because 1.0 to 1.5 L of ultrafiltrate are removed in 1 hour) than for Kt/V to be of any particular value. Dose of RRT is about prophylactic volume control. In a patient with right ventricular failure, AKI, and ARDS who is receiving lung-protective ventilation with permissive hypercapnia and with acidemia inducing a further life-threatening deterioration in pulmonary vascular resistance, the dose component of RRT that immediately matters is acid-base control and the normalization of pH 24 hours per day. The Kt/V (or any other solute-centric concept of dose) is almost simply a by-product of such dose delivery. In a young man with trauma, rhabdomyolysis, and rapidly rising serum potassium already at 7 mmol/L, the dialysis dose, to begin with, is all about controlling hyperkalemia. In a patient with fulminant liver failure, AKI, sepsis, and cerebral edema awaiting urgent liver transplantation and whose cerebral edema is worsening because of fever, the RRT dose is all about lowering the temperature without any tonicity shifts that might increase intracranial pressure. Finally, in a patient with pulmonary edema after an ischemic ventricular septal defect requiring emergency surgery, AKI, ischemic hepatitis, and the need for inotropic and intraaortic balloon counterpulsation support, the RRT dose is all about gently and safely removing fluid to ensure that the extravascular volume falls while the intravascular volume remains optimal. Solute removal is simply a by-product of fluid control. These aspects of dose must be explicitly considered when discussing the dose of RRT in the patient with AKI. Although each and every aspect of this broader understanding of dose is difficult to measure, clinically relevant assessment of dose in patients who are critically ill with AKI should include all dimensions of such dose. To date, no evidence in the acute field confirms that such solute control data are more relevant to clinical outcomes than volume control or acid-base control or tonicity control.

Tables 107-2 and 107-3 show potential flow charts that could be followed each time an RRT prescription is indicated.

CONTINUOUS VERSUS INTERMITTENT RENAL REPLACEMENT THERAPY

Blood purification can be achieved in the ICU by both CRRT and intermittent RRT. Currently, approximately 80% of patients who are critically ill are treated with CRRT. However, no specific recommendation is currently provided by the major critical care societies, and the choice is primarily left to institutional protocols and expertise. When the critical parameter of dialysis efficacy is metabolic control, an acceptable mean blood urea nitrogen level of 60 mg/dL, typically obtainable after some days with a 2 L/hr CVVH in a 100-kg patient, in a computer-based simulation, has been shown to be extremely difficult to reach, even by intensive IHD regimens.[44] In addition to the benefits specifically pertaining to the kinetics of solute removal, increased RRT frequency results in decreased UF requirements per treatment. The avoidance of volume swings related to rapid UF rates may also represent another dimension of dose where comparability is difficult.

Nevertheless, despite the development of new membranes, new catheters for vascular access, sophisticated dialysis machinery, and tailored dialysate composition,

TABLE 107-2 ALGORITHM FOR RENAL REPLACEMENT THERAPY PRESCRIPTION

Clinical Variables	Operational Variables	Settings
Fluid balance	Net ultrafiltration	Continuous management of negative balance (100-300 mL/hr) is preferred in patients who are hemodynamically unstable. In case blood purification is the main issue, 2000-3000 mL/hr K (or 25-35 mL/kg/hr) for CRRT should be targeted; for modality choice first consider CVVHDF. If IHD is selected, an everyday, 4-hr prescription is recommended with a Kt/V >1.2.
Adequacy and dose	Clearance and modality	2000-3000 mL/hr K (or 25-35 mL/kg/hr) for CRRT; first consider CVVHDF. If IHD is selected, then an everyday, 4-hour prescription is recommended. A Kt/V >1.2 is prescribed.
Acid-base	Solution buffer	Bicarbonate-buffered solutions are preferable to lactate-buffered solutions in patients with lactic acidosis and/or hepatic failure.
Electrolyte	Dialysate and replacement	Consider solutions without K^+ in case of severe hyperkalemia. Manage accurately with $MgPO_4$.
Timing	Schedule	Early and intense RRT is suggested.
Protocol	Staff/machine	Well-trained staff should routinely use RRT monitors following predefined institutional protocols.

CRRT, Continuous renal replacement therapy; *CVC,* central venous catheter; *CVVHDF,* continuous venovenous hemodiafiltration; *ECG,* electrocardiogram; *IHD,* intermittent hemodialysis; *K,* clearance; *RRT,* renal replacement therapy; *S-G,* Swan Ganz catheter.

TABLE 107-3 SCHEMATIC EXAMPLE OF A POSSIBLE PRESCRIPTION FOR CONTINUOUS TREATMENT*

	Estimated Urea Clearance (K_{CALC})†	Notes	Value of Q to Obtain 35 mL/kg/hr	Value of Q to Obtain a Kt/V of 1
CVVH postdilution	K_{CALC} = Qrep	Always keep filtration fraction <20% (Qb must be five times Qrep)	Qrep: 41 mL/min or 2450 mL/hr	Qrep: 29 mL/min or 1750 mL/hr
CVVH predilution	K_{CALC} = Quf/[1 + (Qrep/Qb)]	Always keep filtration fraction <20% (Qb must be five times Qrep)	For a Qb of 200 mL/min: Qrep: 53 mL/min or 3200 mL/hr	For a Qb of 200 mL/min: Qrep: 35 mL/min or 2100 mL/hr
CVVHD	K_{CALC} = Qdo	Keep Qb at least three times Qd	Qdo: 41 ml/min or 2450 mL/hr	Qdo: 29 ml/min or 1750 mL/h
CVVHDF postdilution (50% convective and diffusive K)	K_{CALC} = Qrep + Qdo	Consider both notes of CVVH and CVVHD	Qrep: 20 mL/min + Qdo: 21 mL/min	Qrep: 14 mL/min replacement solution + Qdo: 15 mL/min

Urea volume of distribution: V (L) = patient's body weight (kg) × 0.6.
Estimated fractional clearance: (Kt/V_{CALC}) = K_{CALC} (mL/min) × prescribed treatment time (min)/V (mL).
35mL/kg/hr roughly corresponds to a Kt/V of 1.4. A Kt/V of 1 approximately corresponds to 25 mL/kg/hr.
Filtration fraction calculation (postdilution): Qrep/Qb × 100.
Filtration fraction calculation (predilution): Qrep/Qb + Qrep × 100.
CVVH, Continuous venovenous hemofiltration; *CVVHD,* continuous venovenous hemodialysis;*CVVHDF,* continuous venovenous hemodiafiltration; *Qb,* blood flow rate; *Qdo,* dialysate solution flow rate; *Qnet,* patient's net fluid loss; *Qrep,* replacement solution flow rate; *Quf,* ultrafiltration flow rate (Quf = Qrep + Qnet).
*70-kg patient, V_{UREA}, 42 L, during an ideal session of 24 hours (time, 1440 minutes)
†Net ultrafiltration (patient fluid loss) is considered zero in K_{CALC} for simplicity.

a clear relationship between frequency of RRT delivery (CRRT versus intermittent RRT) and mortality has not been fully established. Most recently, the Surviving Sepsis Campaign guidelines for the management of severe sepsis and septic shock[45] concluded that, based on present scientific evidence, CRRT should be considered equivalent to IHD for the treatment of AKI. Vinsonneau and colleagues[46] recently conducted a large, prospective, randomized multicenter study in 21 ICUs over a 3.5-year period. The primary endpoint was the 60-day mortality after the randomization of 360 patients with acute renal failure (ARF) to either CVVHDF or IHD in centers that were familiar with both techniques. The eligibility criteria changed after 8 months as a result of the recruitment rate being too low. No differences in 28- or 60-day mortality rates (CVVHDF, 33%; IHD, 32%) or in 90-day mortality rates between the two groups were found, and the authors concluded that all patients with ARF as part of multiorgan dysfunction syndrome can be treated with IHD. The study was well conducted and, at the moment, is the best example of randomized controlled study effectively comparing the two techniques. Nonetheless, the study started several years ago, during which time the practices in both CVVHDF and IHD have changed considerably. As stated by Vinsonneau and colleagues, this study may have led to changes in investigator practices during the study period, particularly with respect to the delivered dose of renal support. This possibility, however, is hard to ascertain, considering that the investigators, by protocol, started therapy with initial standardized settings and then adapted these settings to meet individual patient requirements to obtain the metabolic control objectives. Interestingly, the

mortality decreased in the IHD arm of the study over the time of recruitment, which reflected a change in practice toward an increase in dialysis prescription. Considering the lack of control regarding the dosage in both arms of the study, definitive conclusions are difficult to make regarding treatment. As remarked in the accompanying editorial,[47] the question of which treatment is better is influenced by the nature of the task. CRRT might be better in terms of total water and solute removal over 24 hours and hemodynamic tolerance, but IHD can remove significantly more water and solute per hour and does not require continuous anticoagulation or complete patient immobilization. Furthermore, the advantages of continuous therapies are largely supported when administered without prolonged interruptions. Again, unfortunately the study by Vinsonneau did not provide this information. Finally, if all patients with AKI as part of multiorgan dysfunction syndrome can be treated with IHD, then they can also be safely treated by CVVHDF.

Other reports have drawn similar conclusions.[48,49] One of the common key points of these recent trials, however, can be that IHD has become safer and more efficacious with contemporary dialytic techniques. Furthermore, a liberal and extended use of CRRT may have become less safe and/or efficacious than previously considered or expected. Over the past 2 decades, however, technical advances in the delivery of IHD have dramatically decreased the propensity of IHD to cause intradialytic hypotension. These advances include the introduction of volume-controlled dialysis machines, the routine use of biocompatible synthetic dialysis membranes, the use of bicarbonate-based dialysate, and the delivery of larger doses of dialysis. Schortgen and colleagues demonstrated that the rate of hemodynamic instability was lower and outcomes were better after the implementation of a clinical practice algorithm designed to improve hemodynamic tolerance to IHD.[50] Recommendations included priming the dialysis circuit with isotonic saline, setting dialysate sodium concentration at above 145 mmol/L, discontinuing vasodilator therapy, and setting dialysate temperature to below 37° C. Thus the original rationale for the widely held assumption that CRRT is a superior therapy may have dissipated over time.

In conclusion, the question of the superiority of a modality for renal support might be artificial. In routine clinical practice, as designed by the Vinsonneau protocol, a change from one approach to another seems reasonable when clinical status changes (e.g., from CRRT to IHD when hemodynamics improve or the patient is extubated, and vice versa), even if this common sense approach has never been scientifically validated.[51] Randomizing patients to receive one therapy or the other, regardless of the conditions, might yield results that are difficult to generalize to clinical practice.

Hybrid techniques have developed over time as a feasible compromise solution to this eternal dispute. These techniques have been given a variety of names such as slow low-efficiency extended daily dialysis (SLEDD),[52] prolonged daily intermittent RRT (PDIRRT),[53] extended daily dialysis (EDD),[54] or simply extended dialysis,[55] depending on the variations in schedule and the type of solute removal (convective or diffusive). Theoretically speaking, these therapies were developed to enhance the advantages offered by either CRRT or IHD, including efficient solute removal with minimum solute disequilibrium, reduced UF rate with hemodynamic stability, optimized delivered to optimal prescribed-to-delivered dose ratio, low anticoagulant needs, diminished cost of therapy delivery, efficiency of resource use, and improved patient mobility. Initial case reports have shown that these hybrid approaches are feasible and do have high clearances. A single short-term single center trial comparing hybrid therapies with CRRT has shown satisfying results in terms of dose delivery and hemodynamic stability.[56] Recently, Baldwin and co-workers randomized 16 patients to 3 consecutive days of treatment with either CVVH (8 patients) or extended daily dialysis with filtration (EDDf) (8 patients) and compared small solute, electrolyte, and acid-base control.[56] They did not find significant differences between the two therapies for urea or creatinine levels over 3 days. All electrolyte derangements before treatment were corrected as a result of treatment, except for one patient in the CVVH group who developed hypophosphatemia (0.54 mmol/L) at 72 hours. After 3 days of treatment, a mild but persistent metabolic acidosis in the EDDf group was observed, compared with the CVVH group.

Generating ultrapure replacement fluid and administering it in the ICU at a lower cost than CRRT, in greater amounts and for shorter periods, is now possible. Hemofiltration may be combined with diffusion, or pure diffusion can be selected at any chosen clearance for a period that can encompass the daytime period with the maximum staff availability or the night-shift period. Thus the choices are now almost limitless: 3 or 4 hours of IHD with standard settings or CRRT at 35 mL/kg/hr of effluent flow rate can be selected. SLEDD at blood and dialysate flow rates of 150 mL/min for 8 hours during the day or SLEDD for 12 hours overnight can be considered an alternative. Otherwise, why not combine CRRT for the first 2 or 3 days when the patient is in the hyperacute phase with SLEDD thereafter as recovery takes place?

CLINICAL APPLICATIONS

EXTRACORPOREAL MEMBRANE OXYGENATION

Starting Extracorporeal Membrane Oxygenation (Venovenous and Venoarterial Configurations)

ECMO can be provided in two different ways or configurations: VV ECMO that provides respiratory support or VA ECMO for respiratory and cardiocirculatory support. Since venous blood is oxygenated and returned to the aorta (usually via the femoral artery and alternatively to the aortic arch via the right common carotid artery), the VA ECMO technique provides mechanical circulatory support for patients with cardiogenic shock.

In the VA configuration, ECMO has been successfully used as a bridge to myocardial recovery, long-term ventricular assist devices, cardiac transplantation after myocardial infarction, cardiomyopathy, myocarditis, postcardiotomy cardiac failure, and cardiac arrest.[57] A key issue that must be taken into consideration is that in

VA ECMO, the blood pumped by the machine (highly oxygenated) mixes with the blood coming from the left ventricle (poorly oxygenated), resulting in a possible hypoxemia of the upper body (including the coronary circulation and the brain) and an optimal oxygenation of the lower part (Harlequin syndrome). In light of this issue, the blood from the right radial artery should be carefully monitored and its oxygenation measured. This important issue can be faced by placing an additional cannula from the inflow side into the right internal jugular vein, creating a venous-arterial-venous (VAV) ECMO. A further problem related to the VA ECMO is the high left atrial pressure attributable to the increased afterload on a failing left ventricle. Draining the left atrium by means of a transseptal catheter, venting the left ventricle from the apex (left thoracotomy), or directly venting the left atrium can manage this problem.

Patients with severe hypoxic respiratory failure, without cardiac dysfunction, should receive percutaneous peripheral VV ECMO. Recourse to VA ECMO in the presence of preserved cardiac function may cause severe brain and heart hypoxia and expose patients to severe complications such as systemic thromboembolism, limb ischemia, and increased left ventricular wall tension. As a general rule, echocardiography should be performed before VV ECMO initiation to diagnose left ventricular dysfunction, which might necessitate the use of VA ECMO. In VV ECMO, blood is drained from one or both vena cava via the jugular or femoral veins (drainage), pumped through the artificial lung and then into the right atrium (inflow). Pulmonary blood flow is maintained and systemic delivery is provided by the left ventricle. Several advantages can be attributed to VV ECMO in comparison with VA ECMO: (1) the arterial system is not included in any technical maneuver without any risk of ischemia or thrombosis; (2) pulmonary blood flow is maintained with oxygenated blood, promoting vasodilation; (3) pulsatile blood flow to organs is maintained; and (4) an increase in left ventricle afterload attributable to the retrograde pump flow is avoided.

ECMO has been proposed for patients suffering from several forms of respiratory failure—ARDS refractory to conventional mechanical ventilation, lung trauma, severe asthma, pulmonary embolism, patients awaiting lung transplantation, and many other causes involving neonatal and pediatric populations.[58]

Indications and Contraindications for Venovenous Extracorporeal Membrane Oxygenation

Adults. The exact indications for adult VV ECMO have not been the subject of large trials. Nonetheless, it is recommended that ECMO should be considered in patients with hypoxic respiratory failure attributable to any cause (primary or secondary) when mortality is predicted to be 50% or greater and is indicated when higher than 80%, despite the optimal use of traditional therapies.[†] A mortality risk of 50% can be identified by a PaO_2/FiO_2 less than 150 mm Hg on FiO_2 greater than 90% and/or a Murray score of 2 to 3; an 80% mortality risk can be identified by a PaO_2/FiO_2 less than 80 mm Hg on FiO_2 greater than 90% and a Murray score of 3 to 4. Other indications are CO_2 retention attributable to asthma or permissive hypercapnia with a $Paco_2$ greater than 80 mm Hg or an inability to achieve safe inflation pressures (Pplat ≤30 cm H_2O) or severe air leakage. In general, ECMO approach should be used when less invasive therapies fail but before VILI or sustained cerebral hypoxia occurs. Certain institutions proposed stricter criteria after the H1N1 pandemic emerged in the spring of 2009. In Australia, for example, the New South Wales Department of Health recommended in its guidelines for ECMO initiation immediate consultation for VV ECMO in case of refractory hypoxemia or hypercarbia ($Paco_2$ >100 mm Hg, with PaO_2/FiO_2 <100). The French Réseau Européen de Recherche en Ventilation Artificielle (REVA) group proposed that ECMO should be initiated in cases of hypoxemia (PaO_2/FiO_2 <50 mm Hg), despite high PEEP (10 to 20 cm H_2O) and high FiO_2 (>80%) ventilation when plateau pressure reached 35 cm H_2O, despite decreases to 4 mL/kg in tidal volume.[59]

According to ELSO, there are no absolute contraindications for VV ECMO in adults. However, there are conditions that are known to be associated with a poor outcome, despite ECMO; these should always be considered before initiating ECMO assistance. These conditions are injurious mechanical ventilation for 7 days or longer, major pharmacologic immunosuppression (absolute neutrophil count <400/mL^3), and central nervous system hemorrhage that is recent or expanding. Specific patient conditions should also be considered. Although no specific age is a contraindication, increasing age is considered to increase the risk; weight over 125 kg can be associated with technical difficulties and the risk of not being able to achieve an adequate blood flow, based on patient size; and comorbidities should also be taken into consideration.

Bridging to lung transplant is being evaluated in some transplant centers.[†] It is a matter of fact that the role of ECMO in many of the conditions regarded as contraindications in the past (e.g., sepsis, trauma, malignancy, pulmonary hemorrhage) has recently been reappraised by many experienced centers. Furthermore, renewed interest for *the new era* of ECMO has allowed the implementation of modern techniques, more reliable devices, and effective training programs, which have significantly extended ECMO indications with respect to the *rescue utilization* adopted in the past.

Neonates. According to ELSO, VV ECMO should be considered in the neonate when the OI is 20 and should be indicated when the OI is 40. The calculation of OI is as follows:

$$[\text{mean airway pressure (MAP)} \times FiO_2] \div [\text{postductal } PaO_2 \times 100]$$

Lethal chromosomal disorders, irreversible brain damage, and grade III or greater intraventricular hemorrhage are contraindications for VV ECMO in neonates. Relative contraindications include irreversible organ damage (unless considered for organ transplantation), body weight less than 2 kg, and less than 34 weeks'

[†]See "Patient Specific Supplements to the ELSO General Guidelines." <http://www.elso.med.umich.edu/WordForms/ELSO%20Pt%20Specific%20Guidelines.pdf> (Accessed October 18, 2012)

postmenstrual age because of the increased incidence of increased intracranial hemorrhage (also see Chapter 95†).

Pediatric Patients. No absolute indications are known, but ECMO should be considered within the first 7 days of mechanical ventilation at high levels of support.†

Listed contraindications include recent neurosurgical procedures or intracranial bleeding within 10 days, recent surgery or trauma, and increased risk of bleeding. Grade II or III intracranial hemorrhage is a general contraindication.

Indications and Contraindications for Venoarterial Extracorporeal Membrane Oxygenation

The main VA ECMO indication in adult cardiac failure according to ELSO guidelines is the presence of cardiogenic shock associated with inadequate tissue perfusion, despite adequate intravascular volume and inotropes-vasoconstrictors administration. Intraaortic balloon counterpulsation should be considered before ECMO initiation, if appropriate. Typical conditions that are an indication for VA ECMO include acute myocardial infarction, myocarditis, peripartum cardiomyopathy, decompensated chronic heart failure, and postcardiotomy shock. Septic shock is an indication only in some centers. The American Heart Association guidelines for cardiopulmonary resuscitation (CPR) recommend consideration of ECMO to aid CPR in patients who have an easily reversible event and have had excellent CPR.†

In pediatric patients, ELSO suggests VA ECMO in early postoperative cardiac failure in the surgical unit if the patient is unable to come off bypass. In the ICU, VA ECMO should be considered in conditions of shock unresponsive to appropriate drug therapy. Moreover, VA ECMO can be considered after cardiac arrest from any cause with response to CPR but still unstable and no response to CPR direct massage underway for 5 minutes. Finally, VA ECMO can be considered in cases of myocardial failure unrelated to surgery such as myocarditis, cardiomyopathy, and toxic drug overdose.†

Management and Monitoring

New technologies with modern pumps, circuits, and oxygenators, and ICU nurses with additional training in ECMO technology and management ensure efficient care of both the ECMO device and patient. The circuit should be monitored several times daily by the medical and nursing team and at least once a day by a perfusionist or other ECMO specialist. Appropriate functioning, fibrin deposits, and clots should be carefully monitored in all components. Moreover, great care must be taken to search for any sign of inflammation and infection at the cannulation site.

Patients under ECMO assistance require careful monitoring of vital organs by means of electrocardiogram, airway pressure and flow, arterial blood pressure, and specific monitoring devices related to ECMO, such as the following:

- Blood flow delivered by the circuit is calculated by a flow meter.
- Transducers measure the pressures at different sites. The pressure before the membrane lung is extremely important; an increase in pressure levels may suggest thrombosis in the oxygenators.
- Oxygen saturation of the drained venous blood (superior vena cava, inferior vena cava, and coronary sinus) is a good indicator of DO_2:VO_2 ratio during VA ECMO.
- High oxygen saturation during VV ECMO may suggest venous blood recirculation (oxygenated blood recaptured by the circuit) attributable to cannula displacement.

Weaning From Extracorporeal Membrane Oxygenation

Improved lung function (and cardiocirculatory status for AV ECMO) is the *conditio sine qua non;* that is, it is the indispensable requisite or condition for starting a weaning protocol from VV ECMO. Improvements in lung mechanics, blood gases, and radiologic appearance are signs of progress toward autonomy. Although the ventilator is set to lung-protective mode, the gas flow to the oxygenator can be turned off and, if acceptable stability (cardiorespiratory function) is maintained for 1 to 4 hours, then the pump can be stopped and the cannulas removed. Lung recovery may take several weeks or months; recovery from ARDS has been reported after more than 50 to 100 days of ECMO support.[60] End-tidal CO_2 may be very low during the early phases of ECMO because pulmonary function is severely impaired. As lungs start recovering and blood flow to ventilated alveoli increases, end-tidal CO_2 increases as well. An end-tidal CO_2 close to normal values may suggest that a weaning trial could be considered. When VA ECMO is implanted for cardiac dysfunction, signs of recovery include increasing arterial pulse contour and, primarily, improving echocardiographic signs of heart contractility. In VA configuration, the tubing leading blood to the patient is clamped, but circulation within the circuit is maintained via a bypass. If cardiorespiratory functions are adequate, then the cannulas can be removed.

MANAGEMENT OF RENAL REPLACEMENT THERAPY

Indications to Start Renal Replacement Therapy

Whatever the technique of CRRT, the following clinical variables are typically compromised in the patient who is critically ill with AKI:

1. Continuous control of fluid status
2. Hemodynamic stability
3. Control of acid-base status
4. Ability to provide protein-rich nutritional support, while achieving excellent uremic control
5. Control of electrolyte balance
6. Control of phosphate and calcium balance
7. Prevention of swings in intracerebral water
8. Minimal risk of infection
9. High level of biocompatibility

†See "Patient Specific Supplements to the ELSO General Guidelines." <http://www.elso.med.umich.edu/WordForms/ELSO%20Pt%20Specific%20Guidelines.pdf> (Accessed October 18, 2012)

Even if clear guidelines or recommendations on when to start RRT exist, to date, a broad concept of timely intervention is generally accepted. When oliguria is associated with impairment of one or more of the clinical features previously listed, RRT should be started within 24 hours. The only urgent indications to dialysis are pulmonary edema refractory to high-dose diuretics and rapidly increasing kalemia. Fluid balance is a fundamental aspect to control in the patient who is critically ill with anuria. All patients who are critically ill need a high daily amount of volume infusions—blood and fresh frozen plasma, vasopressors and other continuous infusions, and parenteral and enteral nutrition, which should be delivered without restriction or interruption. It is not uncommon for patients with AKI and associated septic shock to receive large amounts of fluid resuscitation, leading to fluid overload. The consequent positive fluid balance and tendency to interstitial edema cause the necessity for water removal and, possibly, the achievement of a negative daily fluid balance. Extracorporeal RRTs are typically used for UF. Ultrafiltered water has a similar osmolarity to plasma water; for this reason, the process of *isolated UF* substantially corresponds to blood dehydration, with a possible increase of hematocrit values and the smallest modification of solutes concentrations.[61] CRRT slowly and continuously removes the patient's plasma water, mimicking urine output, whereas intermittent hemodialysis three times weekly must extract, in a few hours, the equivalent of 2 days of administered fluids plus excess body water that may be present in the patient with anuria. The intravascular volume depletion associated with excessive UF rate is due to both the high rate of fluid removal required and the transcellular and interstitial fluid shifts caused by the rapid dialytic loss of solute. The major consequence of rapid fluid removal is hemodynamic instability. In the case of a septic patient with AKI who is receiving a high amount of vasopressors because of hemodynamic instability and is needing appropriate fluid resuscitation, supplementation of nutrition, and blood product administration, the renal replacement modality of choice seems to be the one that warrants slow fluid removal that is prolonged for many hours per day to meet the highly variable required daily fluid balance. In particular, when volemic and uremic control is not a problem, an aggressive, protein-rich nutritional policy (1.5 to 2.5 g/day) can be implemented in the care of patients with AKI who are receiving CRRT, resulting in a significant improvement in daily nitrogen balance with possible favorable effects on immune function and overall outcome.[62] Safe prescription of fluid loss during RRT requires intimate knowledge of the patient's underlying condition, an understanding of the process of UF, and close monitoring of the patient's cardiovascular response to fluid removal. To preserve tissue perfusion in patients with AKI, optimizing fluid balance by removing the patient's excess water without compromising the effective circulating fluid volume is important. It is still a matter of controversy to determine which clinical parameters—actual patient weight or patient dry weight, MAP, central venous pressure, wedge pressure, systemic saturation, mixed venous saturation, bioimpedance, among others—or currently available monitorization—central venous catheter, Swan Ganz catheter, transesophageal echocardiography, and others—are to be used to define uniformly the concept of *volume overload*. In patients who are clinically fluid overloaded, however, accurately evaluating the amount of fluid to remove[63] in these patients is extremely important; one of the main features of slow and constant UF is the possibility for interstitial fluid to refill the *dehydrated* bloodstream slowly and constantly. This phenomenon is driven by hydrostatic and osmotic forces and allows for the elimination of high plasma water volumes each day with a reduced risk of hypovolemia and hypotension. In children who are critically ill, the correction of water overload is considered a priority; it has been shown and recently confirmed that restoring adequate water content in small children is the main independent variable for outcome prediction.[64] Similar results have been recently found in a large cohort of adult patients who are critically ill with AKI.[65]

Solute removal is a broad concept that is generally described by the elimination of a marker solute. This marker solute should be reasonably representative of all solutes that are normally removed from blood by the kidney. Unfortunately, a reference solute that represents all the solutes accumulating during AKI is not currently available because kinetics and volume of distribution are different for each molecule. As a result, *single-solute control* during RRT represents only a rough estimate of treatment efficiency. With these specifications, urea is generally used as an *imperfect* marker molecule, because of its accumulation in all patients with AKI and the ease of serum level measurement. Furthermore, despite its moderate toxicity, urea is the final product of protein metabolism; its accumulation describes the need for dialysis and its removal describes treatment efficiency. It is a small molecule, and its volume of distribution is similar to total body water. It is not bound to protein, and it freely passes through tissues and cell membranes. Creatinine has similar characteristics and is another commonly used marker solute.

Once RRT is indicated, a prescription on dialysis dose has to be made and the treatment carefully delivered. The intensity of a dialytic treatment can be roughly indicated by the amount of dialysis and hemofiltration flow delivered to the patient. After the milestone trial by the group of Vicenza in 2000,[66] such flow has been indexed to patient body weight, highlighting that this variable is of direct importance in patients with AKI. Two large multicenter randomized controlled studies published in 2009 (the randomized evaluation of normal versus augmented level [RENAL] replacement therapy study[67] and the Veterans Administration and the National Institutes of Health [VA/NIH] Acute Renal Failure Trial Network [ATN] study)[68] finally clarified the concept of optimal dialysis dose. The RENAL and ATN studies were designed to compare normal or less intensive renal support to an augmented or intensive therapy; in particular, the RENAL study compared 25 mL/kg/hr CVVHDF to 40 mL/kg/hr CVVHDF; the ATN study compared 20 mL/kg/hr CVVHDF or three times per week intermittent dialysis to 35 mL/kg/hr CVVHDF or daily intermittent dialysis. Surprisingly, both studies showed that increases in intensity of RRT dose did not improve patient outcomes, essentially negating a large

body of evidence coming from previous smaller trials. As a consequence, the definition of *normal dose* is now recommended in a range of 20 to 30 mL/kg/hr for continuous therapies or three times per week intermittent hemodialysis, or both.

Patients with oligo-anuric renal failure often have mild acidemia, secondary to increased unmeasured anions (strong ion gap [SIG] – 12.3 mEq/L), hyperphosphatemia, and hyperlactatemia. The alkalinizing effect of hypoalbuminemia attenuates this acidosis. The effect on acid-base balance of intermittent hemodialysis and CVVHDF has been evaluated; metabolic acidosis is common in both groups, and both intermittent hemodialysis and CVVHDF correct metabolic acidosis. However, the rate and degree of correction may significantly differ. CVVHDF normalizes metabolic acidosis more rapidly and more effectively during the first 24 hours than intermittent hemodialysis. Intermittent hemodialysis is also associated with a higher incidence of metabolic acidosis than CVVHDF during the subsequent 2-week treatment period. Accordingly, CVVHDF can be considered physiologically superior to intermittent hemodialysis in the correction of metabolic acidosis. In a comparison between CVVH and peritoneal dialysis, all patients randomized to CVVH achieved correction of acidosis with 50 hours of treatment, compared with only 15% of those treated by peritoneal dialysis ($P < .001$).[69]

Rocktaschel showed that once CVVHDF is commenced, acidemia is corrected within 24 hours. This change is associated with a decreased SIG and decreased phosphate and chloride concentrations. After 3 days of CVVHDF, patients develop alkalemia secondary to metabolic alkalosis attributable to a further decrease in SIG and a decrease in serum phosphate concentration in the setting of persistent hypoalbuminemia.[70]

Although considerable attention has focused on the perceived benefits of CRRT, the emphasis on the possibility that CRRT might confer increased risk has lessened. As a continuous extracorporeal therapy, CRRT often requires continuous anticoagulation, which can increase bleeding risk. Conversely, clotting of the extracorporeal circuit also frequently occurs with CRRT, which might contribute to blood loss and could exacerbate anemia in patients who are critically ill. The increased solute transfer associated with the use of CRRT might enhance the removal of amino acids, vitamins, catecholamines, and other solutes with a beneficial function in patients who are critically ill. Continuous therapies must be continuous to work. How many treatments really last more than 18 to 20 hours per day? Downtime attributable to filter-circuit-catheter clotting, circuit change, frequent replacement solution-bag substitution, and patient mobility (surgery, diagnostics) should be carefully monitored and might significantly affect the dialysis dose.[71,72] Also of concern are technical problems, including machine malfunction, medication errors, and compounding errors, that have been reported with the delivery of CRRT and might contribute to increased patient morbidity and mortality. Detection of safety problems, adverse events, or both, is particularly difficult when rates of expected morbidity and mortality are high in the population undergoing a procedure, as is the case with CRRT in patients who are critically ill with AKI. Currently, few studies in the nephrology literature provide substantive information on the safety or adverse effects of CRRT or IHD in the critically ill population. After the introduction of new technology and devices into medical practice, the natural tendency is to assume that the novel therapeutic approach is providing benefit, especially when the therapy becomes part of the typical equipment of an ICU bed and is applied 24 hours a day to a patient who is critically ill. The level of attention is probably greater when a dedicated dialysis nurse administers the therapy for few hours during the day shift. Nonetheless, a new generation of dedicated CRRT machines has been recently released with strict safety features and the possibility of a high range of prescriptions. In any case, the ideal therapy still does not exist, and specific ICU staff training is mandatory before such modern monitors are routinely used.

Indications to Stop Renal Replacement Therapy

A paucity of evidence can be found regarding when to wean RRT. Some insights may be gleaned from recent literature. One report from the Beginning and Ending Supportive Therapy (BEST) Kidney study group describes the current practice for the discontinuation of CRRT in a multinational setting to identify variables associated with successful discontinuation and whether the discontinuation of CRRT may affect patient outcomes.[73] In this study, 313 patients were weaned from CRRT for at least 7 days and were classified as the *success group*, and 216 patients were classified as the *repeat-RRT group*. Multivariate logistic regression analysis for successful discontinuation of CRRT identified urine output (during the 24 hours before stopping CRRT: odds ratio [OR], 1.078 per 100 mL/day increase) and creatinine (OR, 0.996 per mmol/L increase) as significant predictors of successful cessation. The predictive ability of urine output was negatively affected by the use of diuretic agents. As always happens with observational studies, establishing whether the *repeat-RRT* population would have achieved a different outcome by waiting for a better creatinine or urine output before stopping RRT is not possible. Risk factors for redialysis were also analyzed by the National Taiwan University Surgical ICU Acute Renal Failure Study Group.[74] In this study, RRT weaning of 94 postoperative patients was considered successful when prolonged for at least 30 days (21%) and was correlated with the Sequential Organ Failure Assessment (SOFA) score, age, dialysis duration, and, again, urine output. Interestingly, of the patients who remained RRT-free for 5 days after RRT discontinuation, more than two thirds remained RRT-free up to 30 days.

As a general recommendation, physicians should wait for adequate urine output (without diuretic therapy) and optimized creatinine values before weaning from RRT; the additional effect of patient glomerular filtration rate and treatment clearance should lead to normal or subnormal creatinine values while on RRT. Once

renal function appears close to the baseline or the *pre-AKI* level, interrupting the treatment without any specific weaning protocol seems reasonable. It is possible, on the other hand, that patients with signs of only partial renal recovery may benefit from more specific and prolonged weaning algorithms. Examples would be a decrease of the UF rate or prescription of intermittent treatments where the therapy was previously continuous. Future trials are needed to design, if possible, such protocols. Furthermore, evaluation of new renal biomarkers as prognostic factors is intriguing to explore if they can predict when patients have recovered sufficient renal function to allow them to remain RRT-free once RRT is stopped.

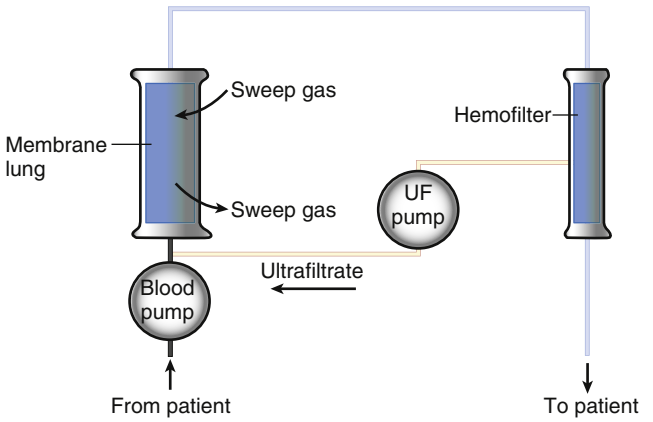

Figure 107-9. Blood is pumped through a membrane lung in series with a dialysis filter, and ultrafiltrate is returned to the blood before the membrane. *UF*, Ultrafiltrate.

ALTERNATIVE EXTRACORPOREAL SUPPORT TECHNIQUES

EXTRACORPOREAL CARBON DIOXIDE REMOVAL OR RESPIRATORY DIALYSIS

Lung protective ventilation is one of the main therapeutic issues for patients with different severity of respiratory insufficiency. Basic components of lung protective strategy include the administration of low tidal volume (<6 to 8 mL/ideal body weight) and the maintenance of low airway pressures (<30 cm H_2O plateau pressure) as evidence emerges that low tidal volumes reduce mortality in patients with ARDS who are mechanically ventilated. However, in low tidal volume ventilation, CO_2 clearance may be impaired, leading to problems related to hypercapnia. In the large ARDS network, it has been demonstrated that hypercapnia may complicate 14% of patients under lung protective ventilation strategy,[75] whereas all patients with ARDS ventilated with pressures lower than 28 cm H_2O may suffer from hypercapnia.[76] Hypercapnia may be undesirable because of its capability for harming injured lungs through immunosuppression and impaired pulmonary epithelial repair, worsening right heart failure and intracranial pressure in patients with elevated intracranial pressure.[77] When permissive hypercapnia cannot be applied for the aforementioned reasons, mechanical systems can be used to eliminate the CO_2 (extracorporeal CO_2 removal [ECCOR])[76]. Modern ECCOR devices have demonstrated improved survival when combined with ultraprotective ventilation ECCOR systems designed to eliminate CO_2 without providing significant oxygenation (differently from ECMO systems). CO_2 removal can be performed through a dedicated system (Fig. 107-9) that uses a pump-driven extracorporeal VV circuit with a neonatal membrane lung and a hemofilter coupled in series. Such a circuit requires a membrane lung to be coupled by a hemofilter. This is done to increase the pressure inside the membrane lung by adding the downstream resistance exerted by the hemofilter. This technical solution also reduces the risk of air bubble formation. Furthermore, the need for heparin is minimized by diluting the blood entering the membrane lung with the plasma water separated by the hemofilter. Finally, the performance of the extracorporeal CO_2 extraction is optimized as a result of the additional flow provided by ultrafiltered water recirculated into the membrane lung. The blood flow used for this device is not negligible (200 to 400 mL/min), and a normal dialysis vascular access is not adequate in this case.[77] An alternative system exploits cardiac output and arterial blood pressure to move the blood through a low-resistance artificial lung (AV pumpless CO_2 removal system; Interventional Lung Assist [iLA] Membrane Ventilator, NovaLung GmbH, Heilbronn, Germany) (see Fig. 107-5). Pumpless systems result in less blood trauma but require large-bore arterial cannulas and adequate blood flow and arterial pressure. General principles considered for ECMO are substantially valid for ECCOR with the basic difference that ECCOR systems work with lower blood flow rates (0.5 to 1.5 L/min) as a result of differences in CO_2 and oxygen kinetics (CO_2 is transported as dissolved bicarbonate and diffuses more readily than oxygen across extracorporeal membranes because of greater solubility).[22] Because lower blood flow is necessary, newer ECCOR devices use double-lumen cannulas similar to those used for dialysis (CO_2 dialysis).[78] For instance, the iLA Membrane Ventilator is designed with a pump capable of large flow rates (from 0.5 up to 6 to 7 L/min), coupled with different membranes and cannulas. This new field of pulmonary extracorporeal assistance is developing new devices to increase effectiveness and simplicity of use. With extended indications to VV decapneization, it is possible that the requirement of injurious ventilation will significantly decrease and the outcomes of patients who are critically ill will improve further in the next 10 years.

HIGH CUTOFF HEMOFILTRATION OR HEMODIALYSIS AND PLASMA THERAPY

A potentially useful strategy to increase mediator removal in septic patients with extracorporeal therapy is by using high-cutoff (HCO) membranes, which are porous enough to achieve the removal of larger molecules (approximately 15 to 60 kD) by diffusion. Such RRT using HCO membranes in sepsis-related AKI has a

widely accepted biologic rationale. Its ability to remove cytokines in ex vivo and in vivo studies has now been shown to be greater than that of any other technology to date[79] and has increased survival in experimental models of sepsis.[80] HCO therapy seems to have beneficial effects on immune cell function, and preliminary human studies using intermittent hemodialysis with HCO membranes have confirmed its ability to remove marker cytokines interleukin (IL)-6 and IL-1 receptor antagonist, with a decreased dose of norepinephrine in patients with sepsis.[81] HCO membrane–based blood purification has now been applied in at least four clinical studies to treat more than 70 patients with septic AKI with no reports of serious adverse effects. Predictably, albumin losses are significant but may be attenuated by using HCO membranes in a diffusive rather than convective manner while still preserving the effect on cytokine clearance.

The term *plasma therapy* actually encompasses two therapies: plasmapheresis and plasma exchange. In plasmapheresis, plasma separated from blood cells flows along one or more columns that contain different adsorbents, after which the processed plasma is reinfused back to the patient. Plasma exchange is a single-step process in which blood is separated into plasma and cells and the cells are returned back to the patient while the plasma is replaced with either donor plasma or albumin. Replacing volume lost with fresh-frozen plasma is also done to replete any factors needed to restore hemostasis or to correct the underlying disorder for which the plasma therapy was prescribed. With respect to sepsis, it has been argued that plasma therapy is most likely to be effective in patients with sepsis-associated thrombotic microangiopathy.[82] An emerging hybrid technology called *coupled plasma filtration adsorption* (CPFA) uses a resin cartridge placed downstream from a plasma filter, improving the removal of nonspecific septic mediators with promising results in early small trials.[83-85] CPFA is aimed at nonselectively reducing the circulating levels and activities of both proinflammatory and antiinflammatory mediators during sepsis and multiorgan failure. To overcome the shortcomings of plasma filtration and to improve removal efficiency, CPFA uses a specific sorbent cartridge placed in series with, but downstream to, the plasma filter. CPFA improves the removal of nonspecific mediators with promising results. Unfortunately, as reported in a personal communication by Livigni, the recent multicenter trial (Combining Plasma-Filtration and Adsorption Clinical trial) to verify the effectiveness of CPFA in improving mortality of patients with sepsis-related AKI has been completed without meeting its primary endpoint. Interestingly, a subgroup analysis revealed that the mortality rate of treated patients with sepsis-related AKI was reduced by a CPFA dose (volume of treated plasma) of more than 2 L/day. Furthermore, it is possible that improvement of the standard of care of patients who are critically ill decreased the mortality rate to the point such that a new trial on CPFA has been designed where mortality is not considered the primary endpoint.

CONTINUOUS RENAL REPLACEMENT THERAPY IN PATIENTS REQUIRING EXTRACORPOREAL MEMBRANE OXYGENATION

A peculiar and complex category of critically ill patients is the one requiring both RRT and ECMO. This clinical picture is frequently observed in the pediatric setting. AKI occurs to the vast majority of children requiring ECMO, who suffer from severe cardiac dysfunction (cardiorenal syndrome) or require aggressive mechanical ventilation (lung-renal syndrome). The CRRT circuit may be placed in parallel (blood flows in the same direction of the ECMO circuit) or in series (blood flows counter to the direction of the ECMO circuit). Santiago and coauthors described how to connect the CRRT device into the ECMO circuit[86]: the inlet (arterial) line of the CRRT circuit is connected after the ECMO blood pump by a three-way tap that is also used for the infusion of heparin, and the outlet (venous) line is connected to the circuit at another tap before the oxygenator. Contrary to what was suggested by the authors, the inlet of the CRRT machine may be connected after the ECMO pump and the filter outlet then returned to the ECMO circuit before the pump (into the reservoir, if present). The CRRT circuit, running countercurrent to extracorporeal assistance, allows the RRT blood to be aspirated from the arterial ECMO section (where blood returns to the patient) and then to be infused into the venous ECMO section (where the patient is drained).[87] This second set-up might reduce blood flow resistance and turbulence after the centrifugal pump and improve reservoir drainage when a roller pump is present. The blood recirculation induced by these circuit set-ups is negligible, considering that the CRRT:ECMO blood flow ratio is never superior to 0.1. Dr. Shaheen and colleagues[88] recently presented their experience with two different subgroups of children; one group required hemofiltration alone and the second group required hemofiltration and ECMO. Not surprisingly, the authors identified a higher mortality rate in those patients requiring CVVHDF and ECMO, compared with those patients requiring hemofiltration alone. The authors promoted the concept that certain therapies should be reserved to experienced teams. Performing CVVHDF in a heterogeneous population with large age and weight ranges poses significant clinical and technical challenges. The low frequency of CVVHDF used in ECMO, as well as the use of other extracorporeal therapies, also raises problems with maintaining nursing skills. Objective clinical and biochemical markers for commencing CVVHDF alone or in combination with ECMO remain to be defined. Several studies, however, have already showed safety and feasibility of this connection in the pediatric setting[89] and, even if some worries on such difficult interaction have been raised (i.e., fluid balance accuracy),[90] today, the application of CRRT to all patients requiring ECMO is claimed by some authors.[91] It has been shown in 15 patients matched with 46 historical controls that adding continuous hemofiltration to the ECMO circuit in newborns improves outcome by significantly reducing the time on extracorporeal assistance and on mechanical ventilation; such a strategy might improve fluid balance management and capillary

leak syndrome. Furthermore, according to these authors, fewer blood transfusions are needed and overall costs per ECMO run are lower.

CONCLUSIONS

In recent years, great technologic improvements have been made in the manufacture of extracorporeal circuits, rendering them simpler, safer, and more efficient for long-term assistance. The new ECMO and CRRT systems can be managed by one bedside nurse who is trained and experienced in circuit management, and it is now possible to assist patients for several weeks or even months without major complications.

Although recent studies suggest that ECMO might improve the outcomes of patients with respiratory failure or cardiogenic shock, or both, indications for ECMO use remain controversial. Interestingly, a similar parallel discussion could be conducted for RRT systems. Nonetheless, evidence and experience favoring lung protective ventilation strategies and timely continuous blood purification in patients who are critically ill with cardiorespiratory and/or kidney failure is accumulating apart from large trials showing unequivocal evidence. As a consequence, simpler, smaller, and less invasive extracorporeal devices are being developed and more and more frequently applied in ICUs.

In the future, ECMO, CRRT, extracorporeal CO_2 removal devices, hemoperfusion, adsorption, or plasmafiltration and adsorption (for either CPFA or liver support) will be integrated into a single multifunction machine with a user-friendly interface and flexibility in parameters and prescriptions, designed to respond to different medical needs with the use of different disposable layouts. Finally, advances in information technology should allow the fully integrated extracorporeal blood purification system to be connected to all electronic therapeutic devices (from simple syringe pumps to CRRT machines) to ultimately lead to an *artificial organ* in a more complete sense.

Chapter 108

Cardiopulmonary Resuscitation: Basic and Advanced Life Support

BRIAN P. MCGLINCH • ROGER D. WHITE

Key Points

- Circulation, airway, breathing (CAB) has replaced airway, breathing, circulation (ABC). The provision of uninterrupted, high-quality chest compressions after sudden cardiac arrest (SCA) is associated with better survival and neurologic outcomes than when airway interventions occur first with cardiac arrests in both adult and pediatric patients. Chest compressions should be immediately initiated on discovery of a suspected cardiac arrest.
- A single resuscitative shock should be delivered at the earliest possible opportunity after the recognition of cardiac arrest, followed immediately by the resumption of chest compressions without postshock cardiac rhythm analysis. Outcome studies have failed to demonstrate the benefit of a period of chest compressions before shock or for a series of stacked shocks.
- Advanced airway placement is no longer a priority intervention during cardiac resuscitation. Evidence demonstrating the benefit of tracheal tube placement on successful resuscitation from cardiac arrest is lacking.
- The use of vasopressor medications during resuscitation attempts for SCA has been de-emphasized in deference to providing uninterrupted, high-quality chest compressions. Epinephrine, vasopressin, and amiodarone have all demonstrated improved rates of resuscitation without affecting those surviving to hospital discharge.
- The use of ultrasound technology should be used, when available, for identifying potentially correctable sources of cardiac arrest, as well as for evidence justifying the termination of resuscitative efforts.
- Targeted temperature management (also known as *therapeutic hypothermia*) applied to comatose survivors of out-of-hospital cardiac arrests, resulting from shockable lethal cardiac dysrhythmias, has significantly improved the neurologic recovery in those surviving to hospital discharge. Increasingly, this therapy is being extended to those resuscitated from nonshockable lethal cardiac dysrhythmias.
- Pediatric resuscitation protocols have been simplified to improve rescue performance. Chest compressions should be performed at a rate of 100 per minute with two breaths interposed after every 30 compressions (consistent with adult resuscitation). Single rescuers should call for help before initiating resuscitation efforts. Chest compressions should be initiated if an infant is found with a pulse lower than 60 beats per minute.
- Children weighing more than 10 kg and experiencing lethal cardiac dysrhythmias can be defibrillated with adult defibrillation pads. At least 3 cm should separate the defibrillation pads. Infant defibrillation paddles are recommended for children younger than 1 year of age or weighing less than 10 kg. An initial defibrillation dose of 2 J/kg is recommended.
- Most deaths after SCA in both adults and children typically occur within the first 24 hours. Coordinated postresuscitation care involving access to coronary catheterization capabilities and intensive care management that includes targeted temperature management represents the best chance survivors of SCA have for optimal neurologic and cardiac recovery.
- Technologic advances augmenting native systemic circulation in low states of cardiac output, including cardiac arrest, is an active area of clinical research at this time. Although the results of several studies are hopeful, more consistent and reproducible evidence is necessary before new resuscitative technology is incorporated in resuscitation protocols.

Although the history of resuscitation can be traced to at least biblical times,[1] contemporary approaches to cardiopulmonary resuscitation (CPR) date back to 1966, when a National Academy of Sciences National Research Council conference generated consensus standards for the performance of CPR.[2] Since that time, successive conferences have reviewed the practice of CPR in light of available experimental and clinical data and have prepared revisions of previous standards.[3-10] The most recent recommendations, the *2010 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care* (*2010 AHA Guidelines for CPR and ECC*), represent the third internationally recognized resuscitation guidelines developed by experts from the American Heart Association (AHA) and the European Resuscitation Council (ERC); as such, these guidelines represent a variety of countries, cultures, and medical specialties.

Each intervention included in the new guidelines has undergone comprehensive evidence-based evaluation of the available scientific information supporting its uses in emergency cardiovascular care and resuscitation, as well as structured and transparent process for managing potential conflicts of interest. Both basic life support (BLS) and advanced cardiac life support (ACLS) are established on credible foundations and have enjoyed widespread acceptance in the emergency cardiovascular care community. Indicative of this acceptance is the widespread popularity of the AHA BLS and ACLS training programs and related training materials. The intent of this chapter is to review the premise, rationale, and techniques for the performance of both BLS and ACLS in light of current understanding and as published in the AHA textbooks on BLS[11] and ACLS.[12]

Modifications and reconsideration of the guidelines for emergency care of those in cardiac arrest have provided recommendations for interventions that have saved thousands of lives for nearly 50 years. Despite these careful reviews and the development of guidelines, survival to hospital discharge from witnessed out-of-hospital sudden cardiac arrest (SCA) attributable to ventricular fibrillation (VF) remains less than 10% worldwide.[13] The majority of patients experiencing sudden cardiac death cannot be resuscitated even when SCA is immediately recognized and resuscitation guidelines are closely followed.

Restating the performance of all BLS CPR procedures, which can be reviewed in the guidelines and also in the AHA BLS text, is not the intention of this chapter.[11] Rather, both BLS and ACLS are reviewed within the contexts of their application by anesthesia providers in operating rooms, intensive care units (ICUs), and other patient care environments.

SUDDEN CARDIAC ARREST AND CARDIOPULMONARY RESUSCITATION

SCA is a complex and dynamic process. Antegrade systemic arterial blood flow continues after cardiac arrest until the pressure gradient between the aorta and right heart structures reach equilibrium. A similar process occurs during cardiac arrest with antegrade pulmonary blood flow between the pulmonary artery and the left atrium.[14-16] As the arteriovenous pressure gradients dissipate, the left heart becomes less filled, the right heart becomes more filled, and the venous capacitance vessels become increasingly distended (Fig. 108-1). When the arterial and venous pressures equilibrate (approximately 5 minutes after cardiac arrest), coronary perfusion and cerebral blood flow stop.

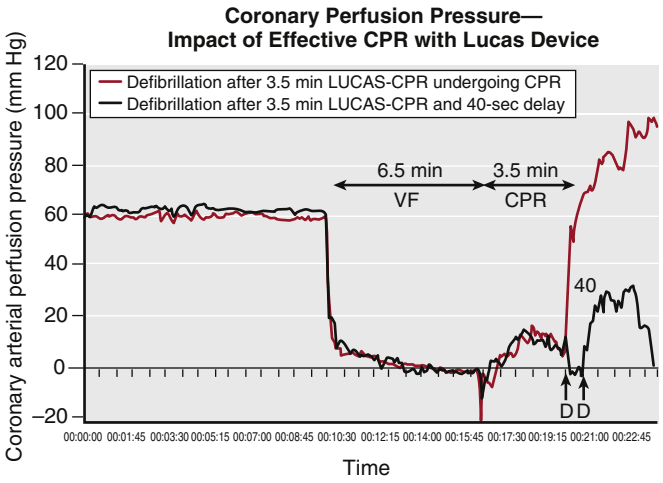

Figure 108-1. Coronary perfusion pressure. Impact of effective CPR with the LUCAS device. *CPR*, Cardiopulmonary resuscitation; *D*, defibrillation; *VF*, ventricular fibrillation. *(From Steen S, Liao Q, Pierre L, et al: The critical importance of minimal delay between chest compressions and subsequent defibrillation: A haemodynamic explanation, Resuscitation 58:249, 2003.)*

PHYSIOLOGIC CONSIDERATIONS

Since the early 1960s when CPR became a widespread clinical technique, blood was thought to be ejected as a direct result of actual compression of the heart between the sternum and the vertebral column and was commonly referred to as the *cardiac pump mechanism*. Transesophageal echocardiography during CPR in humans provides an opportunity for assessing changes in cardiac dimensions and valve positions during chest compressions, as well as the direction of blood flow. Observations made with echocardiography during CPR depict a reduction in left and right ventricular volume, closure of the tricuspid and mitral valves during chest compression, and ejection of blood into the arterial system, all of which are consistent with the cardiac pump mechanism (Fig. 108-2).[17-20]

Repeated, forceful coughing (cough CPR) can sustain consciousness during hypotensive events including VF for as long as 100 seconds when the arrhythmia (or any arrhythmia capable of rapidly compromising cardiac output) is immediately recognized and the patient can be verbally prompted to cough. This observation of maintaining consciousness with coughing suggests mechanisms other than direct cardiac compression may account for forward blood flow during cardiac arrest.[21] Vigorous coughing produces an arterial pressure pulse associated with forward blood flow that opens the aortic valve during pressure and flow generation.[22] This process is commonly referred to as the *thoracic pump mechanism* (see Fig. 108-2). The increasing intrathoracic pressure during chest compression equalizes intravascular pressure within the thorax. On the venous side, valve and venous collapse at the thoracic inlet limit the transmission of retrograde pressure or flow. The arterial system, which is relatively

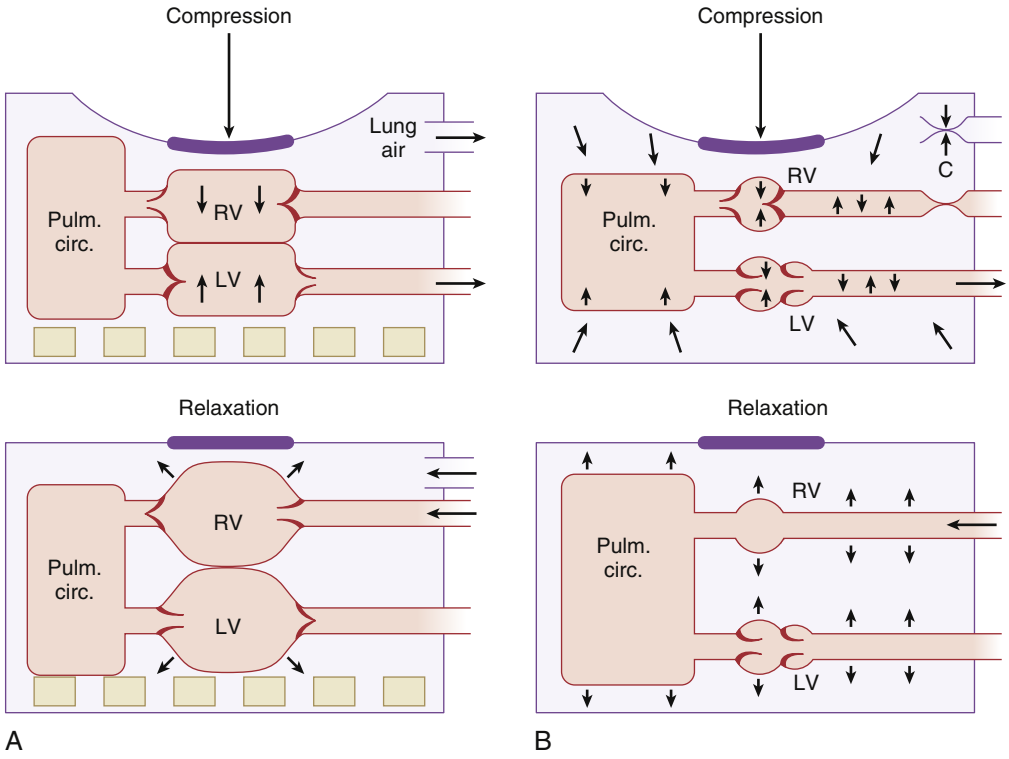

Figure 108-2. A, Systematic representation of cardiac compression pump. **B,** Intrathoracic pressure pump, representing the collapse *(C)* of airways and venous structures. *LV,* Left ventricle; *RV,* right ventricle.

resistant to collapse, transmits pressure and flow into the extrathoracic vascular system. Some studies suggest that during compression or vigorous coughing, the left side of the heart may act as a passive conduit for the transfer of pulmonary venous blood out into the peripheral arterial circulation. During compression, blood flows from the lungs through the left ventricle and toward the periphery. The pulmonary valve is closed, and the mitral and aortic valves are open during periods of high intrathoracic pressure when the chest is compressed.[23]

Both the cardiac pump and thoracic pump mechanisms exist at times during resuscitation attempts. Electrocardiography has confirmed the cardiac pump theory. Cough CPR is effective in maintaining consciousness, at least in the early period after the onset of a lethal arrhythmia, consistent with the thoracic pump theory. Chest compressions during cardiac arrest may initially promote a cardiac pump mechanism attributable to the presence of blood in the left side of the heart. As pressure gradients between the arterial and venous systems equilibrate during prolonged resuscitation, pulmonary blood volume increases and probably supports a thoracic pump mechanism.

Systemic, coronary, and cerebral blood flow during CPR is dependent on effective chest compressions but also on the venous blood return to the heart. At chest compression rates of 100 per minute, the chest compression-relaxation ratio approaches 50:50. The time available for blood return into the thorax is limited. Venous blood returns to the thorax at very low pressures during cardiac arrest. Modest increases in intrathoracic pressure, as might occur with overzealous ventilation during CPR, will impair venous return and negatively impact systemic, coronary, and cerebral perfusion and also reduce the chances of return of spontaneous circulation (ROSC).

Cardiac output during CPR with effective, uninterrupted chest compression is 25% to 30% of the normal spontaneous circulation. Systemic and pulmonary perfusion during CPR reflects the decreased cardiac output as demonstrated by weak carotid pulses with chest compression and low carbon dioxide excretion (addressed later in this chapter). In cardiac arrests without hypoxic causes (e.g., drowning, suffocation), oxygen content in the lungs at the time of cardiac arrest is usually sufficient for maintaining acceptable arterial oxygen content during the first several minutes of CPR. Rescue breaths are less important than initiating chest compressions immediately after the onset of SCA. Blood flow rather than arterial oxygen content is the limiting factor for oxygen delivery to coronary, cerebral, and systemic circulation during CPR.

BASIC LIFE SUPPORT

BLS involves the early recognition of a medical emergency, activation of an emergency response system (e.g., dialing 9-1-1 in the United States), and interventions made in response to SCA, heart attack, stroke, and foreign body airway obstruction (FBAO). No equipment is required for these interventions, except for access to a telephone or an automated external defibrillator (AED), or both. AEDs are included in BLS interventions because of their widespread availability in public spaces (e.g., airports, schools, shopping centers, hospitals, casinos, sporting arenas), their uncomplicated application, automated cardiac rhythm analysis, and administered shocks (if indicated, based upon AED cardiac rhythm analysis).

All BLS interventions (Table 108-1)[24] are time sensitive for preventing SCA, terminating SCA, or supporting circulation until spontaneous circulation is restored after

TABLE 108-1 SUMMARY OF KEY BLS COMPONENTS FOR ADULTS, CHILDREN, AND INFANTS

	Recommendations		
Component	**Adults**	**Children**	**Infants**
Recognition	Unresponsive (for all ages) No breathing or no normal breathing (e.g., only gasping) No pulse palpated within 10 seconds (HCP only)	No breathing, only gasping	
CPR sequence	CAB		
Compression rate	At least 100 per minute		
Compression depth	At least 2 inches (5 cm)	At least one-third AP depth; about 2 inches (5 cm)	At least one-third AP depth; about 1.5 inches (4 cm)
Chest wall recoil	Allow complete recoil between compressions. HCPs rotate compressors every 2 minutes.		
Compression interruptions	Minimize interruptions in chest compressions. Attempt to limit interruptions to less than 10 seconds.		
Airway	Head tilt–chin lift (HCP suspected trauma: jaw thrust)		
Compression:ventilation ratio (until advanced airway is in place)	30:2 one or two rescuers	30:2 single rescuer 15:2 two HCP rescuers	30:2 single rescuer 15:2 two HCP rescuers
Ventilations when rescuer is untrained or is trained but not proficient	Compressions only		
Ventilations with advanced airway (HCP)	One breath every 6-8 seconds (8-10 breaths per minute) Asynchronous with chest compressions Approximately 1 second per breath Visible chest rise		
Defibrillation	Attach and use AED as soon as available. Minimize interruptions in chest compressions before and after shock. Resume CPR beginning with compressions immediately after each shock.

SCA. In the 5-year interim between the 2005 and 2010, the AHA BLS recommendations, clinical evidence, and survivor outcomes after sudden cardiac death support making uninterrupted chest compressions the priority intervention, above airway management, rescue breathing, and pulse check.[24] Airway, breathing, circulation (ABC) has been replaced by circulation, airway, breathing (CAB) for both adult and child resuscitations.[24] Lay rescuers and health care professionals alike, frequently misinterpret agonal gasping respirations as spontaneous ventilation and fail to recognize the absence of a pulse early after the onset of SCA.[24,25] Because the breathing and pulse assessments are almost uniformly inaccurate, regardless of the rescuer's medical training,[24,26,27] and the need to initiate CPR as soon as possible after the onset of SCA to maximize the chances of successful resuscitation, chest compressions should be immediately initiated on recognizing unresponsiveness in a potential victim of SCA.[24] Thirty chest compressions conducted at a rate of 100 per minute are followed by two rescue breaths (30:2) in adults and children resuscitations.

"Push hard and push fast" remains the recommendation for chest compressions during CPR.[24] Although evidence from human studies that identify the ideal chest compression rate is insufficient, current recommendations are for chest compressions to occur at a rate of 100 per minute with minimal interruptions in both adult and childhood cardiac arrests. In adults, chest compressions should be at least 2 inches (5 cm) deep. In children, chest compressions should be one-third the depth of the thorax. In a large study evaluating the quality of CPR (i.e., depth of chest compressions as recommended in the 2010 AHA Guidelines for CPR and ECC) on survival from out-of-hospital cardiac arrest, compression depth and rate influenced resuscitation from cardiac arrest.[28] Although the majority of prehospital chest compressions did not meet the 2010 AHA chest compression depth recommendations (i.e., 50 mm), those patients with chest compression depth and rate nearer to the 2010 AHA Guidelines for CPR and ECC had more frequent survival rates than those with less optimal chest compressions.

Interruptions in chest compressions negatively affect coronary and cerebral perfusion, ROSC, and survival.[29,30] The 2010 AHA Guidelines for CPR and ECC reflect these observations with an increased emphasis on limiting interruptions in chest compressions, even for other resuscitative measures (e.g., rescue breaths, advanced airway placement, defibrillation, postshock rhythm analysis, pulse checks).[31] During single- and two-person CPR, the 2010 AHA Guidelines for CPR and ECC recommend compression:ventilation

ratios of 30:2 in both scenarios with minimal interruptions in chest compressions for rescue breaths. In the absence of native cardiac function and systemic circulation, CPR is performed until spontaneous circulation returns or the patient is pronounced dead. Although CPR is far less efficient than native circulation, when properly performed with limited interruptions, CPR can provide coronary circulation and cerebral blood flow sufficient to afford full recovery in many patients if ROSC can be re-established.

Compression-only resuscitation may be a potential mechanism for encouraging resuscitation in the general population when potential rescuers are uncomfortable or unwilling to provide rescue breaths. Without question, prompt initiation of chest compressions in the individual with SCA can be lifesaving. However, in a large study of 40,000 Japanese victims of SCA, those who received compression-only CPR had lower 1-month survival rates and lower improved neurologic recovery, compared with conventional CPR that included rescue breaths.[32] The authors also noted reduced survival when CPR was not promptly initiated, as well as a reduced neurologic recovery with advancing age, regardless of the CPR method. For the best chances of survival after SCA, conventional CPR is superior to compression-only CPR.

In a similar approach, Bobrow and associates[33] evaluated placing a close facemask with high flow oxygen on out-of-hospital patients in cardiac arrest during resuscitation as their initial airway intervention. They then compared survival to hospital discharge outcomes and neurologic recoveries of those provided close facemask oxygenation for patients receiving bag-valve-mask ventilation. Advanced airway placement was pursued after the initial 600 chest compressions in all patients. This novel approach, limiting interruptions in chest compressions only for cardiac rhythm analysis and defibrillation in the early course of resuscitation, provided insight into the value of ventilation and oxygenation in the early stages of resuscitation. They report survival to hospital discharge outcomes and neurologic recoveries were no different between ventilation groups for patients experiencing unwitnessed cardiac arrests or those for whom the initial cardiac rhythm was nonshockable. However, for patients with witnessed cardiac arrests and shockable initial arrhythmias, neurologic outcomes were improved in those receiving passive oxygenation rather than bag-valve-mask ventilation (38.2% versus 25.8%, adjusted odds ratio [OR] 2.5, 95% confidence interval [CI] 1.3-4.6). These results further establish the importance of high-quality, uninterrupted chest compressions, and a de-emphasis of airway interventions early in the resuscitative process.

Another example justifying the 2010 AHA Guidelines for CPR and ECC's emphasis on high quality, uninterrupted chest compressions comes from a large (N = 3960) observational study evaluating resuscitation and neurologic outcomes for out-of-hospital cardiac arrests from nonshockable cardiac arrhythmias.[34] During the 10-year period, the final 5 years' resuscitation and survival results were compared with the initial 5 years' results. During that time period, AHA resuscitation guidelines had been modified, resulting in improved quality of chest compressions and limited interruption in chest compressions for other resuscitative measures. Although survival from nonshockable cardiac arrhythmias remains significantly lower than shockable arrhythmias, the 2005 AHA Guidelines for CPR and ECC, with its emphasis on high quality, uninterrupted chest compressions, resulted in statistically significant improvements in ROSC (from 27% to 34%), discharge from hospital (4.6% to 6.8%), discharged with favorable neurologic outcomes (3.4% to 5.1%), survival to 1 month (4.1% to 6.2%) and survival to 1 year (2.7% to 4.9%).

Multiple modifications to standard CPR and mechanical adjuncts to improve circulation (e.g., interposed abdominal compression, mechanical chest compression devices, impedance threshold devices) have only shown modest benefit in re-establishing spontaneous circulation. However, none has demonstrated improved survival to hospital discharge when compared with standard CPR. What is certain is that CPR, regardless of the mechanism of blood flow and technique, is only a temporizing intervention in need of rapid supplementation with ACLS interventions, most critically, rapid defibrillation of the fibrillating heart. No device, other than a defibrillator, has been associated with consistently improved survival from cardiac arrest.

Shock First or Cardiopulmonary Resuscitation?

Previous guidelines recommended a period of CPR before attempting defibrillation in unwitnessed cardiac arrests or when CPR had been delayed longer than 4 minutes. However, evidence recommending routine delivery of CPR for 90 to 180 seconds before attempting defibrillation is insufficient, based on the results of two randomized control trials that failed to demonstrate a benefit to ROSC or hospital discharge when CPR was performed before defibrillation.[35,36] The results of a retrospective before-and-after study demonstrated improved 30-day and 1-year neurologic recovery if CPR is performed before defibrillation,[37] and the results of a large observational study demonstrated the probability of survival from out-of-hospital cardiac arrest was improved as the number of preshock chest compressions increased.[38] Practically, chest compressions should be immediately initiated upon encountering an individual in SCA and continued until an AED is applied, charged, and ready to defibrillate.

Automated External Defibrillators and Manual Defibrillation

The most frequent cardiac rhythm responsible for witnessed cardiac arrest in adults is VF, although the incidence of VF is decreasing.[39] VF is a highly metabolically active state for the myocardium. In the presence of VF, myocardial stores of oxygen and metabolic substrates are rapidly depleted. Chest compressions deliver oxygen and energy substrates to the myocardium, improving the chances for defibrillation. CPR prolongs the duration of VF but cannot convert the arrhythmia to an organized rhythm in most circumstances. Defibrillation is the process of delivering an electrical current between two pads placed on the chest with sufficient current passing between the pads and through the myocardium to interrupt disorganized cardiac activity and restore an organized cardiac rhythm or asystole for at least 5 seconds.[40] Defibrillation is not synonymous with resuscitation. Successful termination of VF requires effective chest compressions and prompt defibrillation.

The AHA has included early defibrillation with an AED as part of BLS training. The AHA has also endorsed the concept of public-access defibrillation (PAD), which encourages the policy of making defibrillation available to those in cardiac arrest through nonconventional providers, such as police, security guards, and others. The AED, when applied to an individual with possible SCA, is capable of analyzing the cardiac rhythm, detecting VF and rapid ventricular tachycardia (VT), then automatically attempts defibrillation. A trained rescuer's role is to apply the defibrillator pads to the patient's chest, activate the AED, and deliver the shock through the push of a button when prompted to do so by the AED. The entire sequence, AED application through discharge of energy and postdefibrillation rhythm analysis, should be conducted in the presence and with minimal interruption of chest compressions.

The first AED was introduced in 1979.[41] In 1986, the first microprocessor-based AED was introduced; the AED used three successive, nonescalating, 180-J monophasic damped waveform shocks. Advances in defibrillator technology, including conversion from monophasic to biphasic defibrillator waveforms, resulted in smaller, lighter units with more accurate rhythm analysis.

An issue faced by trained rescuers is the wide availability of AED devices encountered in both health care facilities and PAD settings. Considering the cost, longevity, and low-maintenance nature of AEDs, replacement of previous-generation devices programmed with outdated defibrillation protocols will probably have a low priority by those responsible for managing the devices. As a result, a rescuer applying an AED may find outdated rhythm analysis (prolonged interruption of chest compressions) and defibrillation protocols (e.g., three stacked shocks without interposed chest compressions). At this time, deferring to AED protocol, even if outdated, may be more helpful than attempting to circumvent the protocol and "trick" the AED into following more current protocols. A manual defibrillator should be obtained at the earliest opportunity if an outdated AED protocol interferes with resuscitation attempts.

In circumstances during which standard defibrillators rather than AEDs are used in resuscitation, the rescuer must recognize the technology inherent in the defibrillator. When a manual defibrillator is activated, the rhythm screen typically identifies the defibrillator technology as either monophasic or biphasic. The manual defibrillator should be managed with a protocol identical to current AED protocols: (1) emphasis is placed on delivering uninterrupted chest compressions while defibrillator pads are being applied and for periods when rhythm analysis is not occurring; (2) chest compressions are immediately resumed after shock delivery; (3) cardiac rhythm is reanalyzed as indicated after 2 minutes of chest compressions and rescue breathing; and (4) defibrillation is attempted only for VF and rapid VT. If a monophasic defibrillator is available, then defibrillation energy should begin at high energies (300 to 360 J).[42]

Single Versus Stacked Defibrillation

Beginning in 2005, the AHA recommended a single shock from an AED or manual defibrillator be administered, after which chest compressions and rescue breaths were immediately resumed for 2 minutes before repeating cardiac rhythm analysis. This approach was reaffirmed in the 2010 AHA Guidelines for CPR and ECC.[43] Chest compressions are continued until the defibrillator is ready to deliver the shock and is resumed immediately thereafter without waiting for cardiac rhythm analysis. In most instances, the heart is at least transiently "stunned" by defibrillatory shocks and benefits by a period of coronary blood flow delivered through chest compressions. In the event that a patient has invasive hemodynamic monitoring in place at the time of cardiac arrest and if an organized cardiac rhythm with a perfusing arterial waveform follows defibrillation, then chest compressions may not be indicated.

At this time, the only indications for multiple defibrillation attempts to be given without 2-minute periods of chest compressions and ventilation are for the very specific resuscitation efforts provided during cardiac surgery or in the cardiac catheterization laboratory.[40,43] These patients typically have existing invasive monitors and defibrillation pads at the time of VF or VT, and the onset of VF is immediately recognized. Only one series of stacked shocks is indicated during these resuscitations.

Biphasic Defibrillation Waveforms

Biphasic defibrillation waveforms deliver energy first in one direction and then reversed for the duration of the impulse. One of two biphasic waveforms is used in modern AEDs and defibrillators; biphasic truncated and rectilinear biphasic (Figs. 108-3 and 108-4).[40] Both waveforms are effective for terminating VF using energy levels specific to each. No randomized clinical trial has demonstrated superiority of one waveform over the other with respect to neurologically intact survival to hospital discharge. Impedance-compensated, nonescalating low-energy biphasic waveforms (150 J) were first introduced in 1996 and have been shown to be more successful in terminating VF than are traditional, escalating-energy monophasic waveforms (200 to 300 J) in the controlled setting of an electrophysiology laboratory.[44-46]

Impedance compensation allows the defibrillator to change waveform morphologic characteristics based upon impedance measured during shock delivery (typically 70 to 80 Ohms) to generate transthoracic current capable of defibrillation, regardless of patient weight.[47] Biphasic defibrillation waveforms and impedance compensation, together, allow effective defibrillation at lower energies than with monophasic, nonimpedance compensated monophasic waveforms.[48-51]

A high first-shock defibrillation rate can be expected after biphasic defibrillation shocks. If VF persists after a biphasic shock, then additional chest compressions should be delivered to replenish myocardial oxygen and metabolic substrates, rather than additional shocks.[40] Although the first biphasic waveform shock should not be less than 150 J regardless of waveform, Hess and associates[52] reported the performance of a rectilinear biphasic waveform during nonescalating energy protocols (120 J-120 J-120 J) demonstrating a frequent rate of shock success in terminating VF and unchanged ROSC or survival to hospital discharge when this lower, nonescalating energy approach was used.

In circumstances in which pediatric patients require defibrillation, modification of adult defibrillation procedures is necessary. If possible, pediatric defibrillator pads should be applied in the anteroposterior position. Initial energy levels should range from 2 J/kg to 4 J/kg. At this time, no information is available suggesting higher defibrillation energies in children are unsafe. These recommendations are unchanged from previous AHA resuscitation guidelines (also see Chapter 93).

Additional discussion related to cardioversion and defibrillation is included in the treatment algorithms for specific arrhythmias presented later in this chapter.

Implanted Cardiac Defibrillators

In some patients at risk for lethal arrhythmias, defibrillators are implanted to provide immediate, automatic defibrillation (also see Chapter 48). Implantable cardioverter defibrillators (ICD) are recognized as the most effective treatment for patients at risk for recurrent life-threatening arrhythmias that are not due to a transient, reversible cause.[53,54] Class I indications for ICD placement are shown in Box 108-1.[54] Class I indications for ICD placement for patients with congestive heart failure are shown in Box 108-2.[54] A number of class II indications for implantation of ICDs exist, primarily establishing guidelines for ICD use in patients believed to be at high risk for lethal arrhythmias without a history of cardiac arrest. Class III indications for ICD placement are typically related to patients with such severe underlying disease in whom survival beyond 12 months is unlikely with or without ICD placement.

For patients with ICD devices, any suggestion or confirmation of ICD activation warrants prompt clinical evaluation and ICD interrogation confirming the presence of an arrhythmia. If VF or VT has occurred, then one of three broad categories is likely to have occurred.[53] First, the ICD activation represents an isolated arrhythmia in a patient with modest heart disease and preserved functional capacity during which the ICD discharge corrected what is likely an isolated event. Long-term survival is likely. Second, the ICD activation represents an

BOX 108-1 ***Class I Indications for Implantable Cardioverter Defibrillator Placement***

- Survivors of cardiac arrest caused by ventricular fibrillation or hemodynamically unstable sustained ventricular tachycardia after evaluation to diagnose cause of event to exclude completely reversible causes
- Structural heart disease and spontaneous sustained ventricular tachycardia, whether hemodynamically stable or unstable
- Syncope of undetermined origin with clinically relevant, hemodynamically significant sustained ventricular tachycardia or ventricular fibrillation induced at electrophysiologic study
- Left ventricular ejection fraction <35% caused by prior myocardial infarction at least 40 days previously and New York Heart Association class II or III
- Nonischemic dilated cardiomyopathy with left ventricular ejection fraction ≤35% and New York Heart Association class II or III
- Left ventricular ejection fraction <30% caused by prior myocardial infarction at least 40 days previously and New York Heart Association class I
- Nonsustained ventricular tachycardia caused by myocardial infarction, left ventricular ejection fraction <40%, and inducible ventricular fibrillation or sustained ventricular tachycardia at electrophysiologic study

BOX 108-2 ***Class I Indications for Implantable Cardioverter Defibrillator Placement for Patients with Congestive Heart Failure***

- Secondary prevention to prolong survival in patients with current or prior symptoms of heart failure and reduced left ventricular ejection fraction who have history of cardiac arrest, ventricular fibrillation, or hemodynamically destabilizing ventricular tachycardia
- Primary prevention of sudden cardiac death to reduce mortality in patients with nonischemic dilated cardiomyopathy or ischemic heart disease at least 40 days after myocardial infarction, a left ventricular ejection fraction ≤35%, and New York Heart Association class II or III symptoms on optimal medical therapy, with expectation of survival with good functional status for more than 1 year
- May be used in patients receiving cardiac resynchronization therapy for New York Heart Association class III or ambulatory class IV symptoms, despite recommended optimal medical therapy

From Aronow WS: Implantable cardioverter-defibrillators, Am J Ther *17:e208, 2010.*

unfavorable change in previously stable cardiovascular disease. The arrhythmia may signal the onset of heart failure, myocardial infarction or ischemia, worsening valvular function, or an additional, serious medical condition. Third, in patients with significant or severe heart disease, ICD activation represents further progression of the underlying disease and represents a very poor prognosis. In most circumstances, ICD activation represents an important decline in a patient's underlying condition.

The ICD delivers defibrillation energy directly to the myocardium; usually 40 J. Patients with ICDs are usually aware of the ICD activation, prompting requests for help. When malignant arrhythmias are detected by the ICD, up to eight shocks are administered unless new arrhythmias are detected, sometimes resulting in more than eight shocks.[40] After any confirmed or suspected ICD firing, prompt interrogation of the unit is indicated.

An ICD shock should signal to rescuers the need to prepare for ACLS, including the placement of defibrillation pads, cardiac monitoring, and intravenous (IV) access. The placement of defibrillation pads should be away from the ICD (usually found under the left or right pectoralis muscle) to prevent damage to the ICD and to reduce the likelihood that pacing spikes from the ICD are misinterpreted by the AED (if manual defibrillators are not available) as QRS complexes. ICD activity can be suspended by applying a pacemaker magnet over the ICD in those circumstances where the ICD competes with manual interventions associated with the resuscitation.

Airway Management and Ventilation in Cardiac Arrest

Anesthesia providers know that ventilation is critical for ROSC and for organ preservation during cardiac arrest (also see Chapter 55). The AHA ACLS training program has effectively conveyed this treatment as a priority but after the initiation of chest compressions and with minimal interruption of chest compressions in accordance with the 2010 AHA Guidelines for CPR and ECC. The techniques for providing ventilation are dependent on the clinical situation. The head tilt–chin lift maneuver is recommended for initial airway control in most circumstances. The epiglottis, rather than the tongue, is the major cause of upper airway obstruction in the individual who is unconscious or sedated.[55] Because of its ligamentous attachments to the hyoid bone, the epiglottis can be lifted by manual maneuvers that anteriorly displace the hyoid bone. These observations provide anatomic confirmation of the efficacy of the head tilt–chin lift technique for opening an obstructed airway. The head tilt–jaw thrust maneuver accomplishes the same purpose in restoring airway patency.[56]

When rescue breathing is indicated for an individual in tracheal nonintubated cardiac arrest, 2 breaths are delivered after 30 chest compressions during one- and two-person CPR, providing that the rescuer(s) is(are) trained in CPR.[24] The 2010 AHA Guidelines for CPR and ECC excuse untrained rescuers from providing rescue breaths to ensure that uninterrupted chest compressions are provided until more qualified rescuers arrive. (Fig. 108-5).[24] When performed, rescue breaths should be provided with only enough force and volume to cause the chest to rise. Chest compressions are only minimally interrupted for the provision of rescue breaths (until a secure airway is established). Excessive ventilation force or tidal volume risks overcoming the esophageal opening pressure, contributing to gastric inflation,[57] the potential for regurgitation, and its consequences.[58,59] If tracheal intubation is performed, then ventilation can occur at a rate of 8 to 10 breaths per minute with small tidal volumes and without interrupting chest compressions. Optimal tidal volumes or respiratory rates in the setting of cardiac arrest are not known.

During the first few minutes after the onset of cardiac arrest, chest compressions are the priority intervention, unless the cardiac arrest is due to asphyxiation, drowning, or suffocation, which are the only circumstances that ventilation must be provided before chest compressions.[24] Oxygen delivery to tissues with CPR is limited more by blood flow and low cardiac output than arterial content.[60] Low cardiac output associated with CPR results in low oxygen uptake from the lungs that, in turn, reduces the need to ventilate the patient during this low flow state.[60] Rescuers must avoid hyperventilation during resuscitation. The increased intrathoracic pressure from ventilation impedes venous return to the heart, decreases cardiac output, and compromises resuscitation efforts.[61]

Advanced airway placement during cardiac arrest is no longer a priority and is not mandated in the 2010 AHA Guidelines for CPR and ECC.[61] Attempting to place endotracheal intubation frequently causes significant interruptions in chest compressions, particularly when the provider undertaking intubation is inexperienced or lacks proficiency with the intervention. Insufficient evidence demonstrates improved ROSC when an endotracheal tube is placed. However, in a large retrospective study of a 25,000 in-hospital cardiac arrest database, an endotracheal tube placed during the first 5 minutes of cardiac arrest resuscitation did not improve the rates of ROSC but was associated with an improved 24-hour survival.[62]

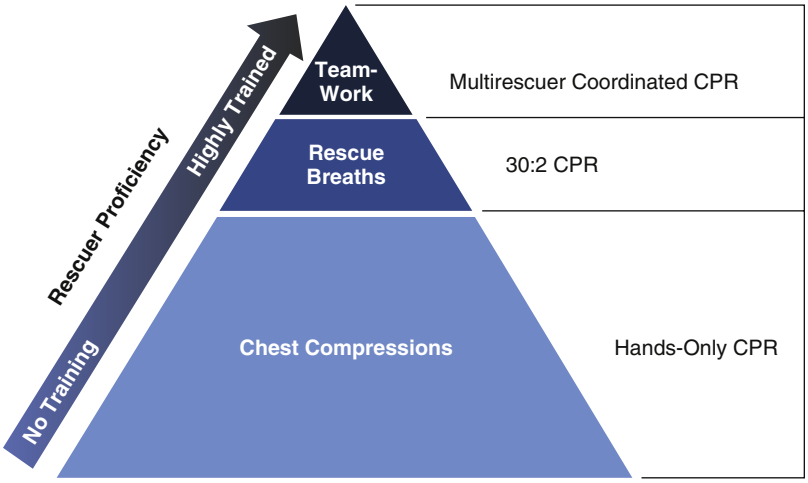

Figure 108-5. Building blocks of cardiopulmonary resuscitation (CPR). *(From Travers AH, Rea TD, Bobrow BJ, et al: Part 4: CPR overview: 2010 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care,* Circulation *122(18 Suppl 3): S678, 2010.)*

Those not proficient or experienced with endotracheal intubations should focus on proficiency with bag-valve-mask ventilation or placement of a supraglottic airway.

Supraglottic airways (e.g., laryngeal mask airway, King LT [laryngeal tube] Airway) are considered reasonable tools for advanced airway management in both out-of-hospital and in-hospital settings. These devices do not require visualization of the glottic opening and are inserted without interrupting chest compressions. Although, in most circumstances, supraglottic airways provide an open airway and effective ventilation, the airway is not secured in a fashion equivalent to an endotracheal tube; a cuffed tube is not placed in the trachea, protecting the airway from aspiration. Supraglottic airways are not equivalent to a properly placed endotracheal tube. They are reasonable airways for rescuers without advanced airway management expertise, as well as for those circumstances during which endotracheal intubation is found to be difficult. Partial pressure of end-tidal carbon dioxide ($PetCO_2$) can be monitored when supraglottic airways are in place, the importance of which is discussed in the next section.

Once an advanced airway is inserted, its placement must be confirmed by verification of breath sounds, chest rise, and the presence of carbon dioxide during ventilation. These parameters are assessed with each airway manipulation in elective surgical cases and represent a standard of care in the anesthesia environment. These parameters—breath sounds, chest rise, and the presence of carbon dioxide—are applicable and, because of the unstable and high-risk environment (either out-of-hospital or in-hospital) of a cardiac arrest, are mandatory assessments when an airway is placed outside the surgical department environment. Continuous monitoring of $PetCO_2$ is recommended during resuscitation attempts to ensure that the airway placement is secure, to guide compression quality, and to detect ROSC as demonstrated by a sudden increase in end-tidal carbon dioxide content.

In 1978, Kalenda[63] described the use of capnography as a guide to the effectiveness of external chest compressions. He demonstrated the value of monitoring $PetCO_2$ values in three patients in cardiac arrest and confirmed changes in $PetCO_2$ with ROSC. Kalenda proposed that when ventilation is constant, as during controlled mechanical ventilation, the expired carbon dioxide is a precise and continuous mirror of lung perfusion and, hence, of cardiac output.[63]

Despite the potential clinical importance of Kalenda's well-documented observations and conclusion, it was several years before monitoring $PetCO_2$ values during cardiac arrest and CPR was explored further. In 1984, using a porcine model of cardiac arrest, Grundler and colleagues[64] demonstrated a rapid decrease in $PetCO_2$ with the onset of cardiac arrest and its immediate increase with resuscitation. Based on these preliminary experimental observations, this group suggested that $PetCO_2$ monitoring may be a relatively simple and noninvasive guide to advanced life support interventions during CPR.[64,65] Severe reductions in pulmonary blood flow during cardiac arrest and CPR and therefore an acute failure in oxygen delivery to the lungs explained the observed very low $PetCO_2$ values and the increased partial pressure of carbon dioxide in mixed venous blood (Pv_{CO_2}).[66] Subsequent studies in dogs provided confirmation of the possible utility of $PetCO_2$ in that expired Pv_{CO_2} correlated very closely with coronary perfusion pressure, which itself was shown to be a determinant of survival from cardiac arrest in this model.[67,68] In a porcine model of VF, the onset of VF was associated with a rapid decline in $PetCO_2$ from a mean (plus or minus standard error of the mean [±SEM]) of 4.0% ± 0.2% to less than 0.7% ± 0.2%.[69] With external chest compression and constant-volume mechanical ventilation, $PetCO_2$ increased to 1.9% ± 0.3% with an immediate increase to 4.9% ± 0.3% after successful defibrillation and 12 minutes of CPR after defibrillation. Close correlation was found between changes in cardiac output and $PetCO_2$ during both closed- and open-chest CPR[69] (Table 108-2).

$PetCO_2$ monitoring has been reported in humans in cardiac arrest who are undergoing CPR.[17,70-73] In a study of 10 patients in whom spontaneous circulation returned, $PetCO_2$ values immediately increased on restoration of spontaneous circulation, from a mean (±SD) of 1.7% ± 0.6% to 4.6% ± 1.4%.[55] The rapid increase in $PetCO_2$ was often the first clinical evidence of the resumption of spontaneous circulation. In a larger retrospective study involving 575 patients, Heradstveit and colleagues[73] reported the value of $PetCO_2$ included 100% sensitivity and 100% specificity in identifying endotracheal tube positioning in the larynx, an indication of the effectiveness of chest

compressions, and the early detection of ROSC. Although the authors noted that patients resuscitated from cardiac arrest had higher $PetCO_2$, they caution against "cut-off values" for predicting ROSC since many factors were noted that influenced $PetCO_2$ (e.g,. cause of cardiac arrest, rescuer fatigue, duration of resuscitation).

In 10 patients who were critically ill, 9 of whom were in septic or cardiogenic shock at the onset of cardiac arrest, $PetCO_2$ decreased from a mean (±SD) of 1.7% ± 0.9% to 0.4% ± 0.4% shortly after the onset of cardiac arrest.[57] The very low pre-arrest value is indicative of low cardiac output and therefore low pulmonary blood flow. During external chest compression, this value increased to 1.0 ± 0.5%. In seven patients in whom circulation was restored, $PetCO_2$ rapidly increased from 1.3% ± 0.5% to 3.7% ± 2.1% and then declined to a stable volume of 2.4% ± 1.8% 4 minutes after resumption of spontaneous circulation. In patients with whom resuscitation failed to restore spontaneous circulation, $PetCO_2$ remained at 0.7% ± 0.4%.

The major determinants for $PetCO_2$ are carbon dioxide production, alveolar ventilation, and pulmonary blood flow.[61-64]

In the presence of constant-volume ventilation and apparently unchanged carbon dioxide production immediately after cardiac arrest, the changes in $PetCO_2$ observed both experimentally and clinically during cardiac arrest and CPR and during ROSC indicate that $PetCO_2$ reflects pulmonary blood flow and cardiac output.[17,70-72,74] Monitoring of both systemic arterial pressure by invasive monitoring and $PetCO_2$ with controlled ventilation should provide optimal hemodynamic assessment of the adequacy of the resuscitative effort. Assessment of both interventions, such as chest compression and the response to resuscitative medications, is also possible.[75]

Monitoring $PetCO_2$ values is a standard in anesthesia and intensive care settings (also see Chapter 44). The 2010 AHA Guidelines for CPR and ECC now endorse this monitoring technology as a class I recommendation for adults with SCA with an endotracheal tube or supraglottic airway in place. This technology has become available and is more reliable in the out-of-hospital setting and should be used whenever possible to ensure proper tracheal tube placement, as well as the detection of ROSC or monitoring effectiveness of chest compressions.[61]

ADVANCED CARDIAC LIFE SUPPORT

All physicians, particularly those involved with invasive procedures in which sedation or anesthesia is administered, should be capable of performing CPR and other resuscitative interventions. CPR almost invariably necessitates rapid progression to ACLS interventions and follow-up care. Biannual or even annual maintenance of certification in both BLS and ACLS is expected for physicians in clinical practice, ensuring up-to-date compliance with updated AHA resuscitation guidelines.

In a study using a computer program that simulates critical patient incidents such as cardiac arrest, only 30% of participants, who consisted of anesthesiology residents, faculty, and private practitioners, managed a simulated cardiac arrest in accordance with AHA ACLS guidelines.[76] The timing since the last ACLS training was recognized as an important predictor for the proper management of simulated cardiac arrest. Of those trained in ACLS within 6 months preceding the assessment, 71% successfully managed cardiac arrest scenarios and in accordance with AHA ACLS guidelines. Successful management decreased to 30% in those whose ACLS training occurred 6 months to 2 years earlier. No participant more than 2 years without ACLS training correctly used ACLS guidelines in the simulated resuscitation.[76] Skills, such as time to first defibrillation, defibrillation sequence, tracheal intubation, and administration of medications, decline in the first 6 months after ACLS training. These observations support the position that some form of periodic training and retraining in ACLS is necessary to maintain proficiency in the knowledge and skills that are essential for managing cardiac arrest in accordance with the contemporary principles as incorporated in the AHA ACLS training programs.

Monitoring and Recognition of Arrhythmia

Prompt recognition and treatment of potentially life-threatening (pre-arrest) cardiac arrhythmias are essential components of ACLS. Early recognition and immediate

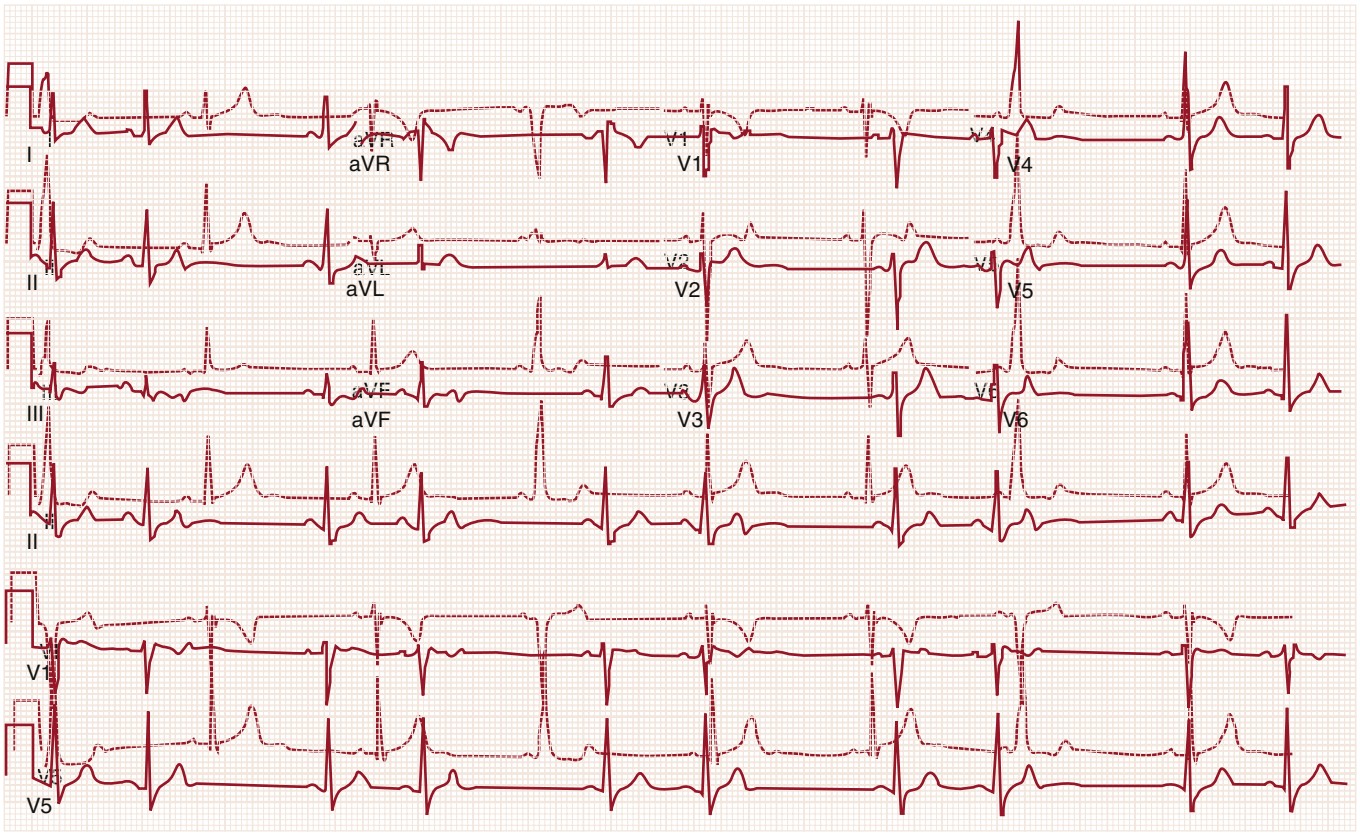

Figure 108-6. Sinus bradycardia with blocked premature atrial complexes.

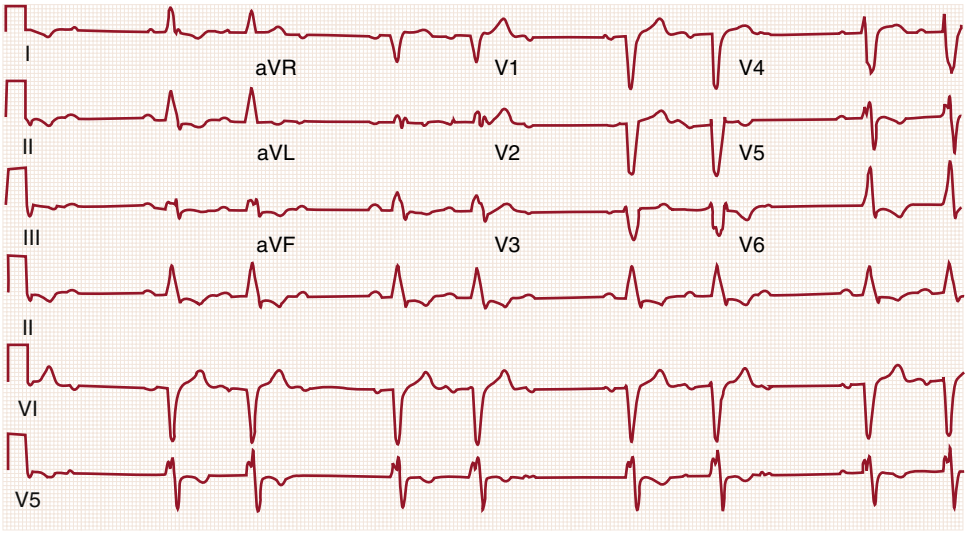

Figure 108-7. Normal sinus rhythm with first-degree atrioventricular blockade with Mobitz first- and second-degree heart block.

intervention for precardiac arrest signs and symptoms often prevents the onset of fatal arrhythmias, necessitating the application of BLS and ACLS. In this context, supraventricular arrhythmias that may cause hemodynamic compromise are discussed first, followed by the recognition and management of those that are ventricular in origin (also see Chapters 45, 47, and 48).

Supraventricular Bradyarrhythmias

Supraventricular bradyarrhythmias may be sinus or junctional in origin (Fig. 108-6), or they may be caused by second-degree (types I and II) (Figs. 108-7 and 108-8) or third-degree atrioventricular (AV) block (Fig. 108-9). Sinus (or junctional) bradycardia and type I (AV nodal) second-degree block are usually manifestations of increased vagal tone. Sinus bradycardia and type I second-degree AV block (Wenckebach phenomenon) may be observed during high-dose narcotic anesthesia.

During spinal anesthesia, reduced venous return and unopposed vagal tone may produce bradycardia and hypotension of sufficient severity to progress to cardiac arrest. Treatment is indicated whenever the bradycardia, regardless of the type, leads to a significant decrease in systemic arterial pressure, produces clinical

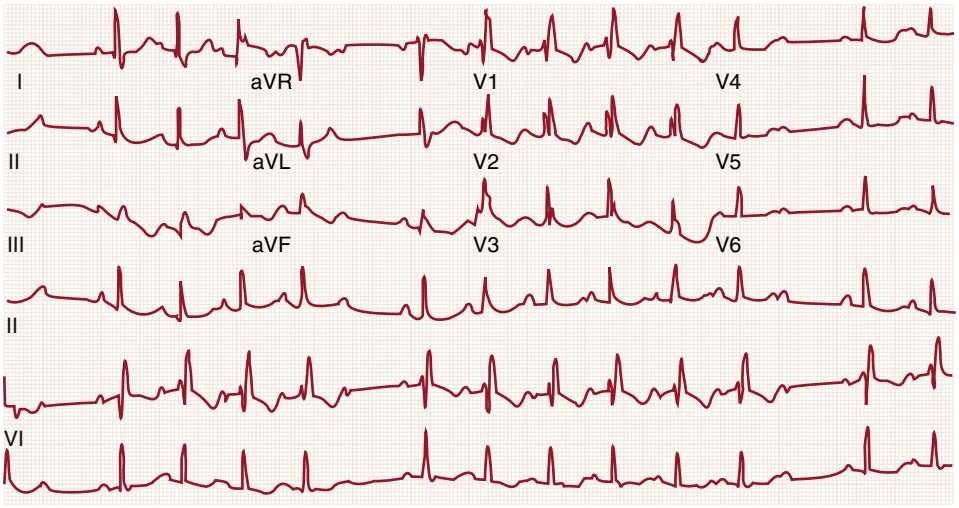

Figure 108-8. Sinus tachycardia with Mobitz II heart block and right bundle branch block.

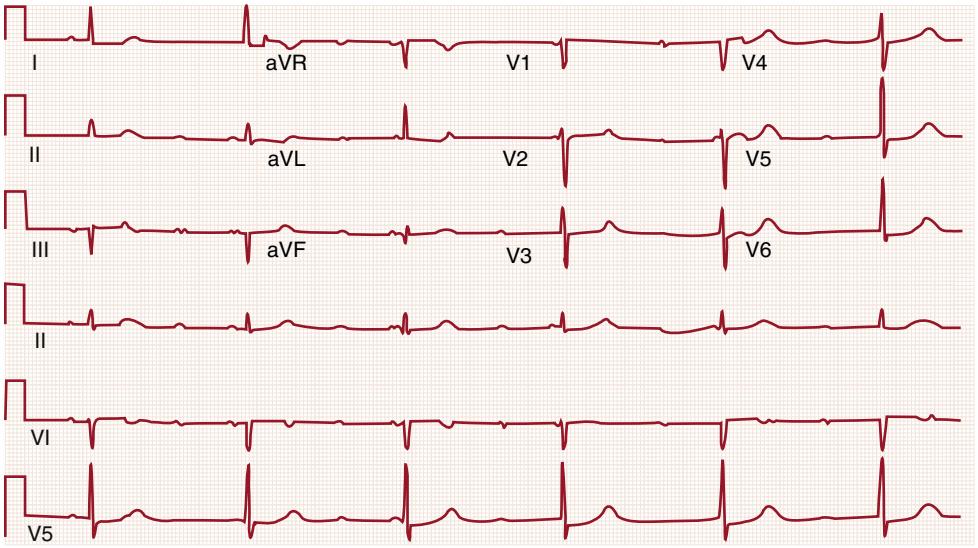

Figure 108-9. Type 3 complete heart block with sinus tachycardia and junctional escape rhythm.

signs of reduced cardiac output (or a decrease in measured output), or is accompanied by ventricular ectopic depolarization. Any of these signs should be considered as evidence of hemodynamic or electrophysiologic deterioration with the propensity to progress to lethal arrhythmias, either asystole or VF. IV atropine 0.5 to 1.0 mg should be the initial treatment, repeated as needed at 3- to 5-minute intervals to a total dose of 3 mg.[61] Atropine doses less than 0.5 mg in adults are associated with paradoxical slowing of the heart rate and should be avoided.[61]

The administration of atropine for symptomatic bradycardia should be accompanied by the application of transcutaneous pacing (TCP) pads. TCP for symptomatic bradyarrhythmias is painful for conscious patients and should be viewed as a temporizing measure, without strong clinical evidence supporting its use over pharmacologic interventions.[61] When bradyarrhythmias are refractory to atropine and TCP, IV infusions of dopamine (2 to 10 μg/kg/min) or epinephrine (2 to 10 μg/min) should be considered.

If pharmacologic methods and TCP are ineffective in producing an increase in heart rate and hemodynamic (increased systemic pressure, cardiac output, or both) or electrophysiologic improvement (elimination of ventricular ectopy), then alternative therapies include transvenous pacing or, during spinal anesthesia, low-dose (0.2 mg) IV epinephrine.[77,78] The availability of intraoperative cardiac pacing equipment (e.g., esophageal pacing probes, pacing pulmonary artery catheters) has diminished the need for agents such as isoproterenol infusions for the treatment of intraoperative bradyarrhythmias (also see Chapters 48 and 68).

Transesophageal atrial pacing can be effective in treating intraoperative supraventricular bradyarrhythmias such as sinus or junctional bradycardia.[79,80] This device is compatible with most external pacing devices and defibrillators. In its current configuration, transesophageal pacing is only effective at pacing the atria. Ventricular response to transesophageal pacing requires an intact AV node. Atrial fibrillation or AV conduction disturbances render this intervention ineffective in the treatment of symptomatic bradyarrhythmias.

Figure 108-10[61] depicts the bradyarrhythmias treatment algorithm recommended in the 2010 AHA Guidelines for CPR and ECC.

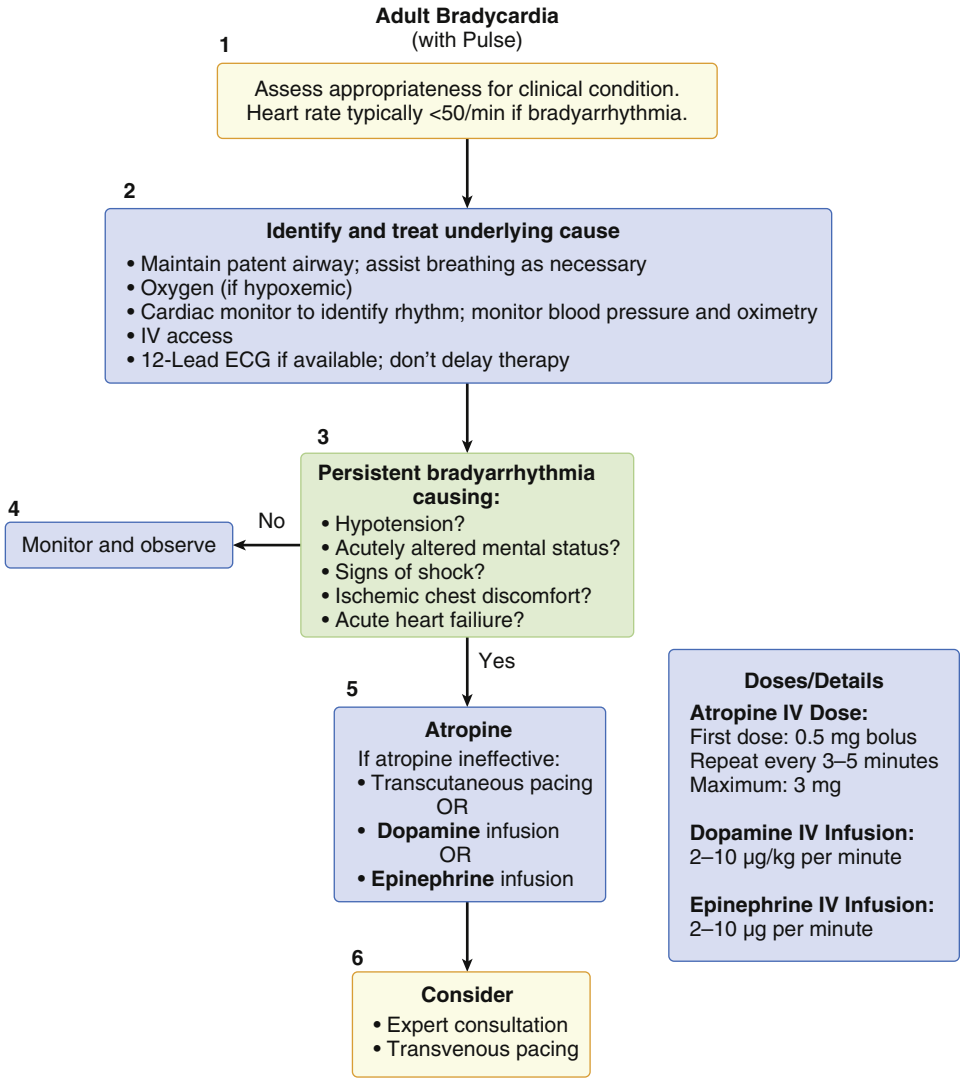

Figure 108-10. 2010 American Heart Association bradyarrhythmia treatment algorithm. *ECG*, Electrocardiogram; *IV*, intravenous. *(From Neumar RW, Otto CW, Link MS, et al: Part 8: adult advanced cardiovascular life support: 2010 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care,* Circulation *122(18 Suppl 3):S749, 2010.)*

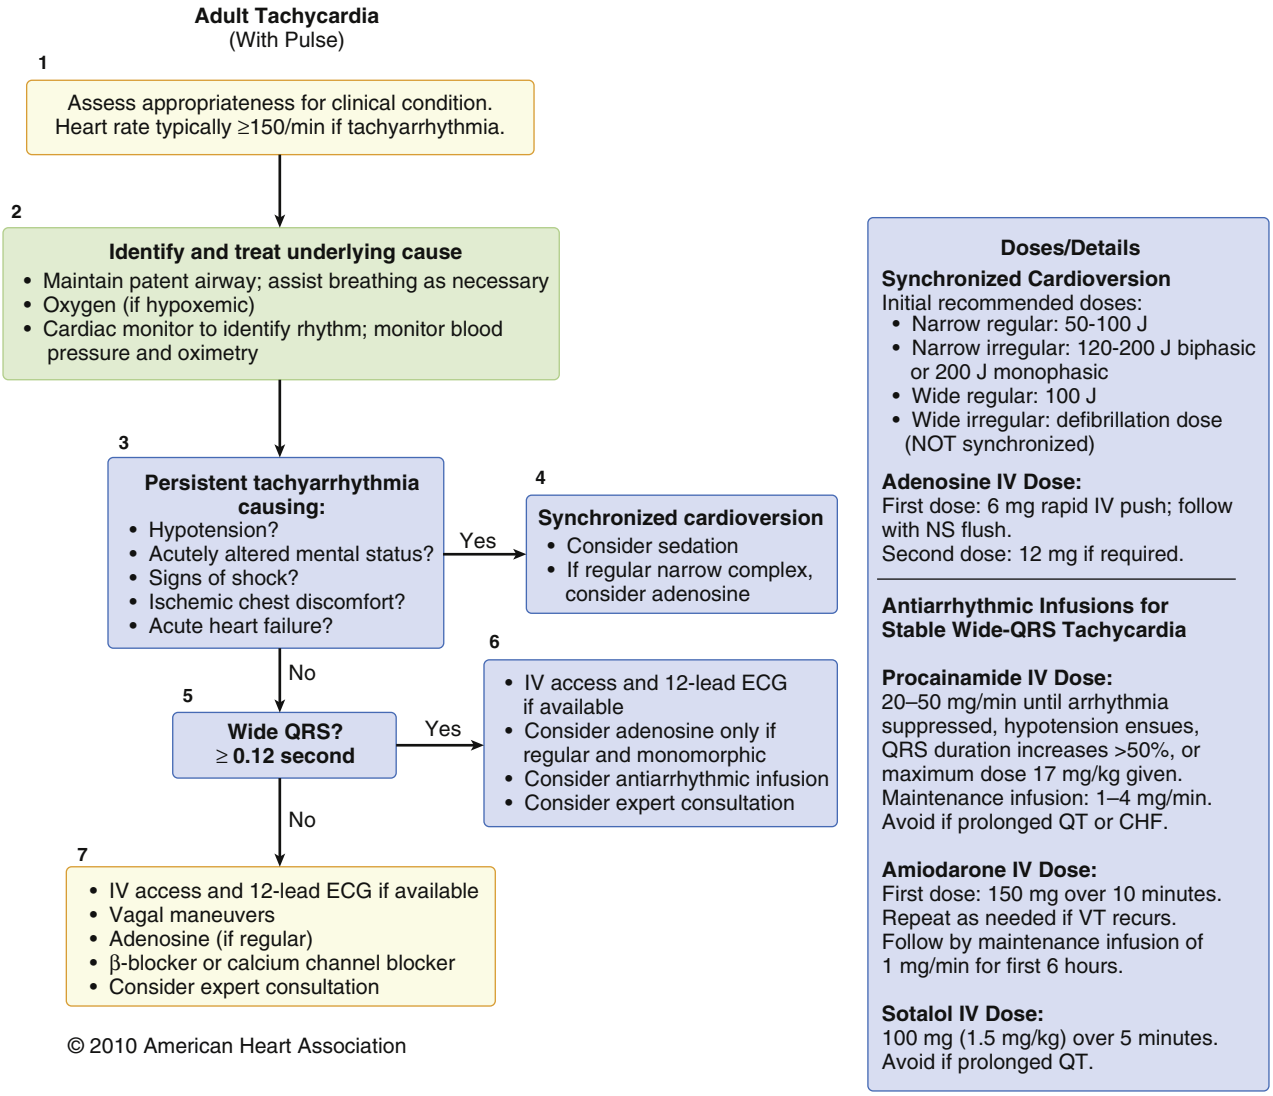
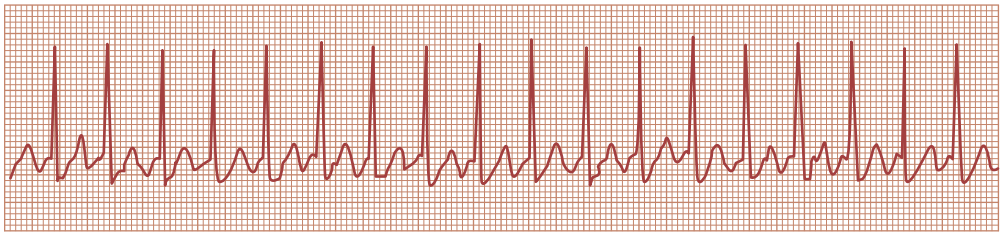
Supraventricular Tachyarrhythmia

Medical professionals should be able to recognize and differentiate between sinus tachycardias, narrow complex supraventricular tachyarrhythmias, and wide complex tachycardias. Supraventricular tachyarrhythmias include atrial flutter, atrial fibrillation, AV junctional tachycardia, multifocal atrial tachycardia, paroxysmal reentrant tachycardia, and other much less frequent arrhythmias (also see Chapter 68). Paroxysmal supraventricular tachycardia (PSVT), atrial fibrillation (or flutter) with rapid ventricular rates and multifocal atrial tachycardia are discussed; not only can they produce hemodynamic compromise, but they can also present diagnostic and therapeutic challenges. Considering the complexity of rhythm analysis and the implications for prompt intervention, two broad concepts are helpful: most wide complex tachycardias are ventricular in origin, and irregular narrow complex tachycardias are likely atrial fibrillation or multifocal atrial tachycardias. Figure 108-11[61] depicts the tachycardia treatment algorithm recommended in the 2010 AHA Guidelines for CPR and ECC.

An example of PSVT is shown in Figure 108-12, *A*. If such a tachyarrhythmia produces hemodynamic deterioration, then cardioversion is the treatment of choice. The recommended initial dose for cardioversion of atrial tachyarrhythmias is 100 J to 200 J if a monophasic defibrillator is used or 100 J to 120 J using a biphasic device. Energy can be increased as needed if the arrhythmia is resistant to initial electrical therapy. If the patient is hemodynamically stable, then vagal maneuvers can be attempted (e.g., Valsalva maneuver in awake patients) before initiating pharmacologic interventions. Vagal maneuvers alone will terminate approximately 20% to 25% of reentry supraventricular tachycardias (SVTs).[81] If vagal maneuvers are unsuccessful, then adenosine is the drug of choice for terminating organized rapid supraventricular arrhythmias. Adenosine slows sinoatrial and AV nodal conduction and prolongs refractoriness, which is very effective in terminating PSVT, the most common cause of which is reentry within the AV node.[82-85] The drug is diagnostically useful in revealing the underlying mechanism in tachyarrhythmias of uncertain origin (e.g., atrial fibrillation, atrial flutter) by inducing transient block of AV nodal conduction (Fig. 108-12, *B*).[86,87] Because of rapid cellular uptake and metabolism, adenosine must be rapidly injected into a venous catheter proximal enough to the heart to ensure





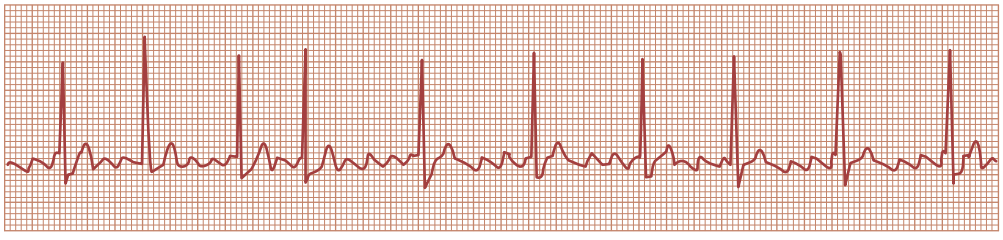


Figure 108-11. 2010 American Heart Association tachyarrhythmia treatment algorithm. *CHF*, Congestive heart failure; *ECG*, electrocardiogram; *IV*, intravenous; *NS*, normal saline; *VT*, ventricular tachycardia. *(From Neumar RW, Otto CW, Link MS, et al: Part 8: adult advanced cardiovascular life support: 2010 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care,* Circulation *122(18 Suppl 3):S751, 2010.)*

A

B

Figure 108-12. A, Supraventricular tachycardia at a rate of 180 beats per minute is present; the origin of the tachycardia is not evident. **B,** Supraventricular tachycardia after an injection of 6 mg adenosine. Atrial flutter waves are clearly visible, thus establishing the diagnosis.

delivery of a sufficient concentration of the drug at the AV node to induce an AV nodal conduction block. Adenosine can be initially used in a dose of 6 mg, and, if necessary, a second dose of 12 mg can be administered in 1 to 2 minutes. If a central venous catheter is used, then these doses can be reduced to 3 mg and 6 mg, respectively. If the drug is injected more distally and slowly (e.g., into a small-bore dorsal hand vein catheter), not only may therapeutic failure result, but transient acceleration of the tachyarrhythmia may also occur (Fig. 108-13, *A-B*).[88] This paradoxical acceleration of the rate is a manifestation of the increase in sympathetic nervous system traffic induced by adenosine in the presence of inadequate AV nodal blockade. Likewise, conversion of 2:1 or 1:1 conduction in atrial flutter has been observed.[89-91] This adverse effect indicates that an attempt to establish the diagnosis of atrial flutter should be electrophysiologically made, with vagal maneuvers used, if necessary, to unmask the flutter waves. Rate acceleration has also been observed after adenosine administration to patients with atrial fibrillation and preexcitation (Wolff-Parkinson-White syndrome).[91] As with verapamil in this setting, the rate acceleration is a result of the AV nodal block with diversion of fibrillation wave fronts through the accessory connection. Although the short half-life of adenosine may reduce this hazard, avoiding adenosine, as well as other AV node-blocking drugs, seems prudent in patients with atrial fibrillation and preexcitation. Immediate access to a defibrillator is recommended when adenosine is administered for tachyarrhythmias.

Adenosine's very short half-life (<5 seconds) is both advantageous and disadvantageous: side effects such as flushing, dyspnea, and chest pain are short lived, but the tachyarrhythmia may recur and necessitate the use of another drug or a repeat dose of adenosine. The AV nodal-blocking action of adenosine is antagonized by theophylline or related methylxanthines and is potentiated by dipyridamole and carbamazepine.[92,93] A suggested scheme for the use of adenosine, including dose adjustments, is presented in Box 108-3.

Bronchospasm has been described after the injection of adenosine, including intraoperatively.[94-97] This complication has occurred in patients with bronchial asthma or chronic obstructive pulmonary disease (COPD). The mechanism is unknown, but the bronchospasm may result from the stimulation of bronchial smooth muscle adenosine receptors or the stimulation of mast cell–derived mediators of bronchoconstriction. Aminophylline, an adenosine-receptor antagonist, has been successfully used intraoperatively to treat adenosine-induced bronchospasm.[97] In light of this experience, adenosine should not be used or should be used with caution in patients with a history of bronchial asthma or COPD with a bronchospastic component.

If the PSVT does not respond to adenosine or if it recurs, then verapamil is the drug of choice. A dose of 5 mg produces a more sustained block of AV nodal conduction. Verapamil can also be used to slow the ventricular response in atrial fibrillation or flutter.[98] However, it should not be used in patients with Wolff-Parkinson-White syndrome in whom atrial fibrillation or flutter develops. In this setting, verapamil-induced increases in conduction over the accessory pathway may produce alarming acceleration of the ventricular rate or VF.[99,100] If atrial flutter or fibrillation results in hemodynamic deterioration because of the rapid ventricular response, then cardioversion is the treatment of choice. Atrial flutter can be terminated with low-energy synchronized shocks.

Atrial flutter or fibrillation with a rapid ventricular response can cause rate-related hemodynamic compromise perioperatively expressed as hypotension, decreased

BOX 108-3 ***Administration of Adenosine****

Peripheral (antecubital)	6 mg, then 12 mg if needed
Central	3 mg, then 6 mg if needed
If taking theophylline-containing drugs	9 mg peripherally, 6 mg centrally
If taking dipyridamole	2 mg peripherally, 1 mg centrally

*Use with caution in patients with asthma and in those taking carbamazepine.

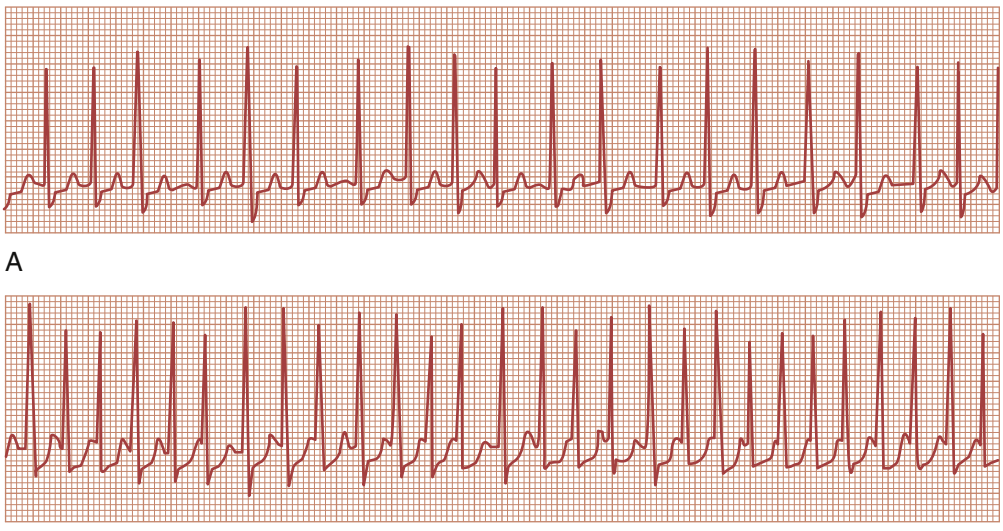

Figure 108-13. A, Atrial fibrillation with a rapid ventricular response of 190 beats per minute. **B,** After an injection of 6 mg adenosine, the ventricular response increased to 240 beats per minute. *(From White RD: Acceleration of the ventricular response in paroxysmal lone atrial fibrillation following the injection of adenosine, Am J Emerg Med 11:245, 1993.)*

cardiac output, or both. In patients who are hemodynamically unstable, cardioversion should be used. Recent-onset atrial flutter is typically very sensitive to low-energy shocks (e.g., 50 J, monophasic or biphasic waveforms). Atrial flutter can also be terminated by overdrive pacing with external generators that have this capability. For atrial fibrillation, the initial dose for cardioversion is 100 to 200 J with monophasic waveforms or 100 J to 120 J with biphasic waveforms. Escalation of energy doses for the second and subsequent doses is indicated.

In patients who are hemodynamically stable and with rapid ventricular rates secondary to atrial fibrillation or flutter, the treatment is pharmacologic. With the acute onset of these tachyarrhythmias, IV ibutilide has the most rapid onset of effect in restoring sinus rhythm.[101] Ibutilide is a class III antiarrhythmic drug that prolongs the action potential duration and effective refractory period without effects on the action potential upstroke. The dose is 1 mg given over a 10-minute period. A second dose can be administered 10 minutes after the first, if necessary. Conversion to sinus rhythm is more frequent in atrial flutter than in atrial fibrillation (63% versus 31%) and more frequent in atrial fibrillation of shorter duration.[101,102] Prolongation of the QT interval reflects the pharmacologic action of the drug, and polymorphic VT (PVT) accompanied by increases in the QT interval is seen in 8.3% of patients receiving ibutilide; consequently, clinicians should be prepared to manage this arrhythmia.

Alternative options for the treatment of supraventricular arrhythmias include diltiazem, verapamil, β-blocking medications, procainamide, and amiodarone. By slowing conduction and increasing refractoriness in the AV node, calcium channel blocking agents result in ventricular rate control in patients with atrial flutter, atrial fibrillation, and multifocal atrial tachycardia. Diltiazem is administered as a loading dose of 0.25 mg/kg over 2-minute period, followed, if needed, in 10 to 15 minutes by 0.35 mg/kg. An infusion at a rate of 5 to 15 mg/hr can be used to maintain rate control. If IV verapamil is used, 5 mg can be given and then 5 to 10 mg in 15 to 30 minutes as needed. β-Adrenergic-blocking medications are helpful in ventricular rate control when no contraindications to their use are present. Amiodarone is a complex agent with antiadrenergic effects in the presence of supraventricular arrhythmias and tachycardias resulting from accessory pathways or rapid AV node transmission of atrial impulses and in situations in which other agents have failed to control the heart rate. It is administered as a 150-mg IV bolus over a 10-minute period, followed by a 1 mg/min infusion for 6 hours to a maximum daily dose of 2 g. Although effective in terminating clinically significant SVTs, proarrhythmic agents (e.g., amiodarone, procainamide, sotalol, ibutilide) are less desirable first-line interventions, compared with adenosine and verapamil.

Multifocal (multiform) atrial tachycardia is a common tachyarrhythmia that is often misdiagnosed as atrial fibrillation.[103-105] Increased automaticity in multiple atrial foci results in a need for therapy different from that for reentrant supraventricular arrhythmias (e.g., atrial flutter, atrial fibrillation, PSVT). Multifocal atrial tachycardia is diagnosed by observing the presence of at least three morphologically different P waves in the same lead of a 12-lead electrocardiogram (ECG) and a ventricular rate more rapid than 100 beats per minute (Fig. 108-14).

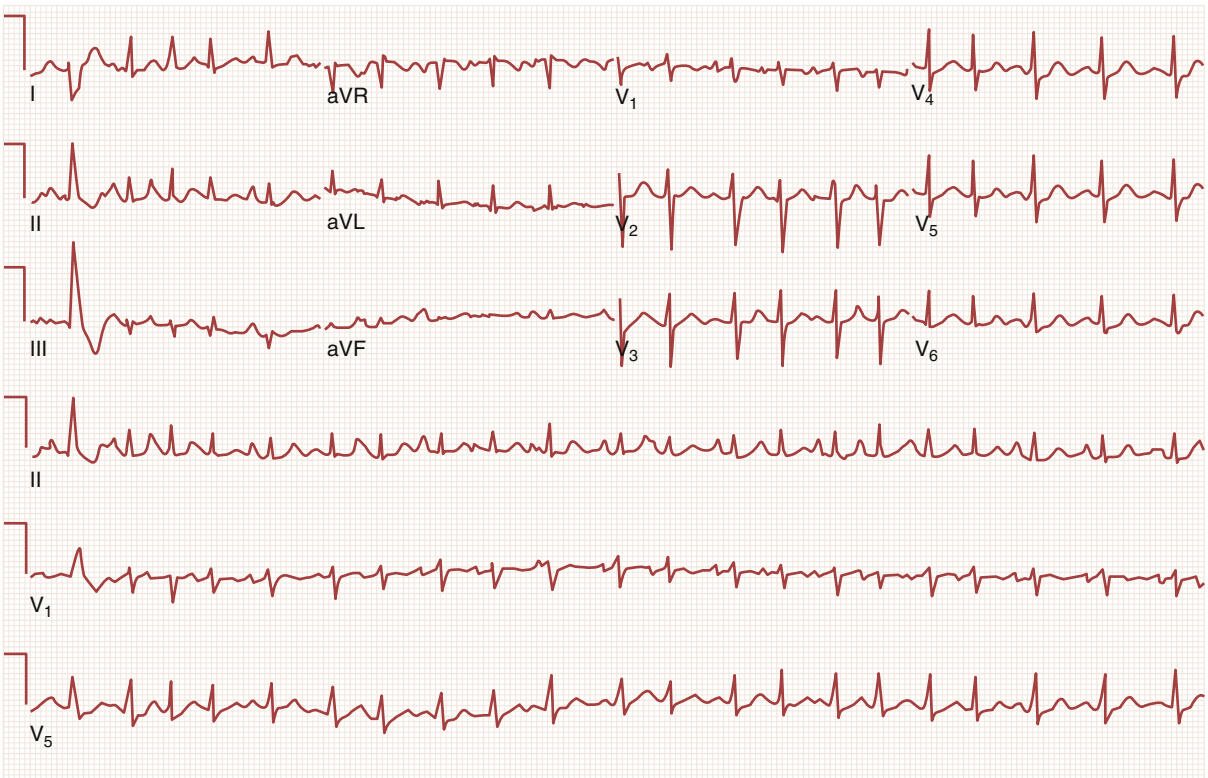

Figure 108-14. Multifocal atrial tachycardia. P-wave morphologic characteristics vary across the tracing. Each QRS complex is preceded by a single P wave.

Multifocal atrial tachycardia is usually described as occurring in patients with COPD, especially during exacerbations when ICU management is necessary. However, it occurs in other settings as well, such as hypokalemia, catecholamine administration, and acute myocardial infarction.[105,106] Treatment of underlying conditions probably contributing to myocardial irritability is important. Digitalization and cardioversion, sometimes helpful in other supraventricular arrhythmias, are ineffective in multifocal atrial tachycardia. Digitalis toxicity or repeated and futile attempts at cardioversion can follow misdiagnosis. Acceptable rate control treatment in patients with preserved ventricular function includes calcium channel blockers, beta-adrenergic blockers, and amiodarone. In the presence of impaired ventricular function, diltiazem and amiodarone may be useful.

Synchronized cardioversion is recommended for the treatment of unstable SVT, unstable atrial fibrillation with rapid ventricular response, unstable atrial flutter with rapid ventricular response, and unstable monomorphic VT.

Ventricular Bradyarrhythmias

In the setting of emergency cardiovascular care, the bradyarrhythmia arising within the ventricles that is in need of urgent treatment is complete heart block with a very slow idioventricular escape rhythm (e.g., 15 to 30 beats per minute) (Fig. 108-15). In this situation, atropine can be tried, but the treatment of choice is external or transvenous pacing as soon as it can be accomplished. If an external pacemaker is available, then pacing should be quickly instituted.

Ventricular (Wide Complex) Tachyarrhythmia

In the category of potentially life-threatening and sometimes pre-arrest arrhythmias, VT (Fig. 108-16) warrants urgent intervention. VT that produces cardiac arrest (pulseless VT) is discussed with VF. Treatable causes of VT should always be sought before or during pharmacologic or electrical interventions. Hypoxemia, hypercapnia, hypokalemia or hypomagnesemia (or both), digitalis

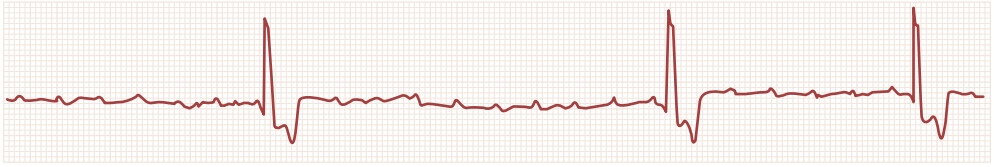

Figure 108-15. Slow (14 beats per minute) idioventricular escape rhythm in a patient with carotid sinus hypersensitivity. External or transvenous pacing is the treatment of choice for bradyarrhythmias such as this.

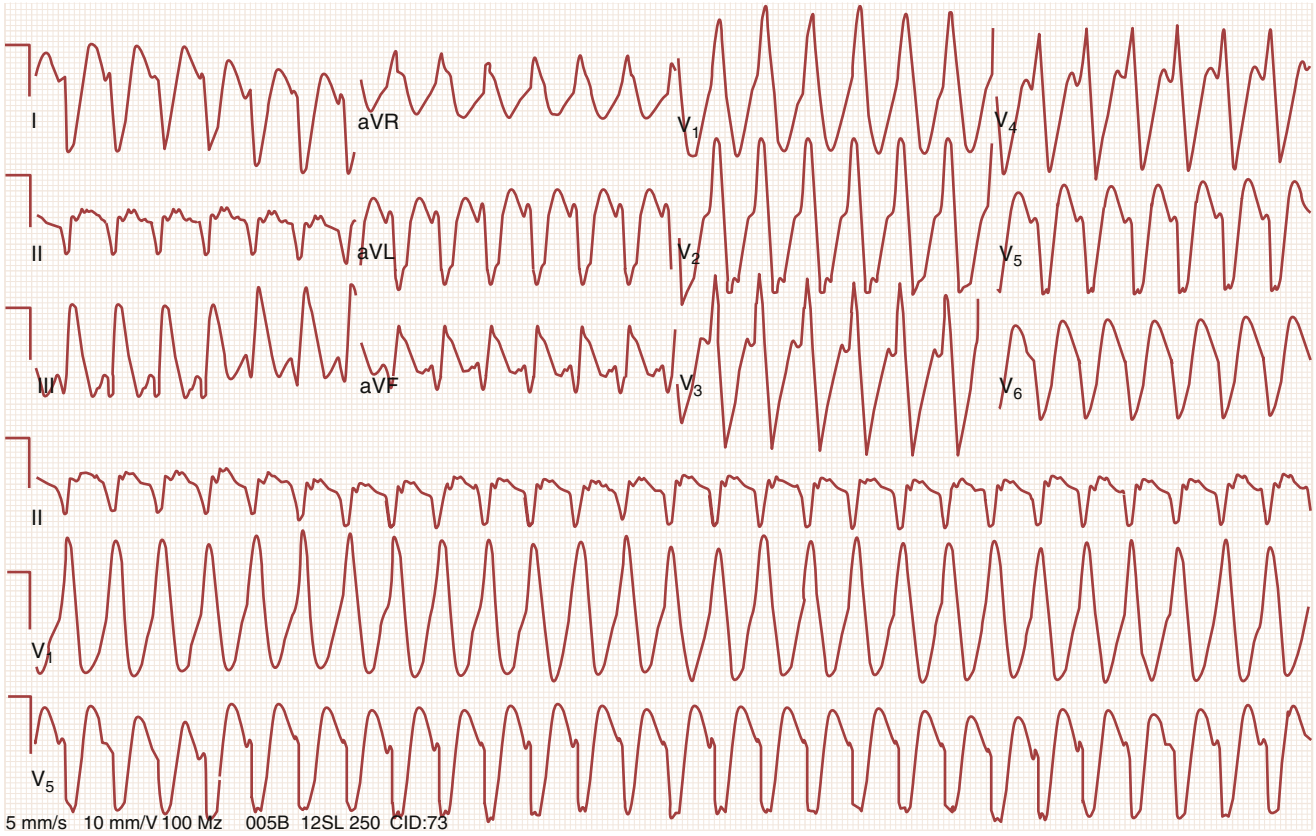

Figure 108-16. Ventricular tachycardia. The rate is 280 beats per minute, the QRS width is 160 msec, and three consecutive capture or fusion beats are demonstrated.

toxicity, and acid-base derangements are obvious causes for VT and should be quickly evaluated and corrected if present.

Treatment of VT is dependent on the degree of hemodynamic compromise induced by the tachycardia. If the patient remains stable and ventricular function is preserved (no evidence of pulmonary edema or a known history of left ventricular dysfunction), then procainamide and synchronized cardioversion are the treatments of choice. If cardioversion is chosen, then the energy levels are identical to those used in unstable patients. If antiarrhythmic therapy is pursued, procainamide (class IIa evidence), amiodarone (class IIb evidence), or sotalol (class IIb evidence) are recommended. Procainamide and sotalol should not be used in patients with prolonged QT intervals. Importantly, only one drug should be administered; a second drug should not be added without expert consultation. The loading dose for procainamide is 20 to 50 mg/min until the arrhythmia is suppressed, hypotension develops, the QRS prolongs by 50%, or a total dose of 17 mg/kg is administered. A maintenance dose of 1 to 4 mg/min should follow the loading dose. Sotalol can be loaded at a rate of 1.5 mg/kg over a 5-minute period. Amiodarone is administered as 150 mg over a 10-minute period, followed by an infusion of 1 mg/min for 6 hours and then a 0.5 mg/min maintenance dose over the subsequent 18-hour period. Hypotension is common with all three of these recommended medications.

In patients who are unstable, that is, those with systemic hypotension, pulmonary edema, or clinical or electrocardiographic signs of acute myocardial ischemia or infarction, synchronized cardioversion is the treatment of choice with either monophasic energy doses of 360 J or biphasic, nonescalating, impedance-compensated energy doses of 120 J (also see Chapter 47).

An atypical form of VT known as *torsade de pointes* ("twisting of the points") that was originally described in 1966 is characterized by twisting of the QRS axis around the baseline and a polymorphic appearance. The underlying electrophysiologic derangement in this arrhythmia is a striking and nonuniform delay in repolarization exhibited as a prolonged QT interval on the ECG. It typically begins with a characteristic long-short initiating sequence (Fig. 108-17). Torsades des pointes can be induced by drugs such as quinidine, procainamide, disopyramide, and phenothiazine, as well as by bradycardia, hypokalemia, hypomagnesemia, or acute ischemia or infarction. Although amiodarone produces significant prolongation of repolarization, it rarely causes torsades de pointes, possibly because the drug-induced prolonged repolarization is uniform (nondispersed), in contrast to the repolarization abnormality induced by other drugs.

Closely related to torsades de pointes is PVT (Fig. 108-18). The description of the tachycardia as PVT rather than torsades de pointes implies that the cause of the prolonged repolarization is not evident and the QT interval is not prolonged.[79,107-109] Because both PVT and torsade de pointes can be life threatening, a correct diagnosis is required. The critical therapeutic distinction is based on the presence or absence of a prolongation of the QT interval. If QT prolongation is present, then therapy is directed toward shortening the repolarization time (after withdrawing the offending drugs listed earlier or correcting abnormalities such as hypokalemia). In the past, drugs such as isoproterenol were used for this purpose, but definitive short-term therapy is overdrive ventricular or atrial pacing (preferably the latter) if AV conduction is intact.

If PVT (i.e., polymorphic wide complex tachyarrhythmia without evident QT prolongation) is present with hemodynamic instability, then immediate defibrillation is indicated. If PVT is present in a patient who is hemodynamically stable, then standard antiarrhythmic therapy for VT as outlined earlier can be tried. Magnesium sulfate should be considered early in the treatment of this form of PVT as well, particularly if torsades de pointes is suspected by history but QT prolongation cannot be confirmed by ECG. A 12-lead ECG is often needed to identify QT lengthening.

The 2010 AHA Guidelines for CPR and ECC provides a treatment algorithm for tachyarrhythmias (see Fig. 108-11) that encompasses those of both supraventricular and ventricular origin. The algorithm is simplified from previous versions to afford a more prompt and directed assessment and interventions.

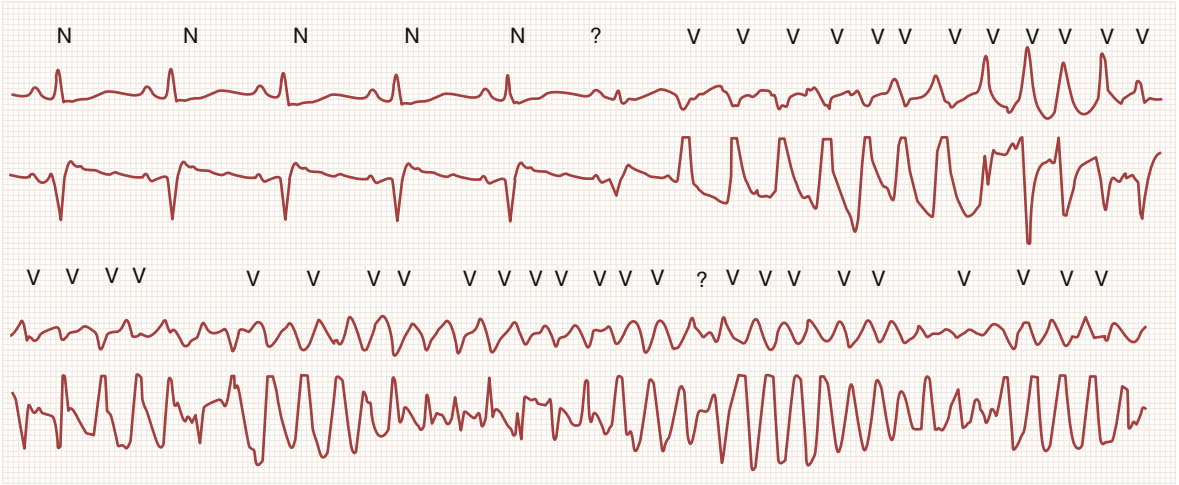

Figure 108-17. Polymorphic ventricular tachycardia. A prolonged QT interval during sinus rhythm suggests that the arrhythmia is torsades de pointes. This arrhythmia occurred in a patient after resuscitation from cardiac arrest.

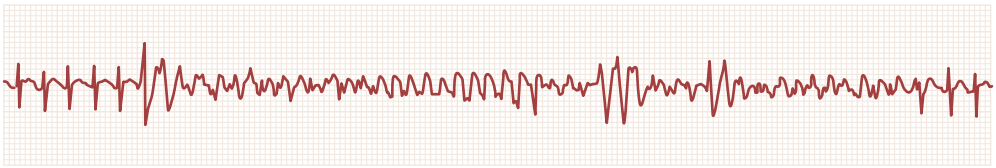

Figure 108-18. Polymorphic ventricular tachycardia. The QRS complexes have varying morphologic characteristics but without the "twisting of the points" torsades demonstrated in Figure 108-17. The tachycardia spontaneously terminated.*(From White RD, Wood DL: Out-of-hospital pleomorphic ventricular tachycardia and resuscitation: Association with acute myocardial ischemia and infarction, Ann Emerg Med 21:1282, 1992.)*

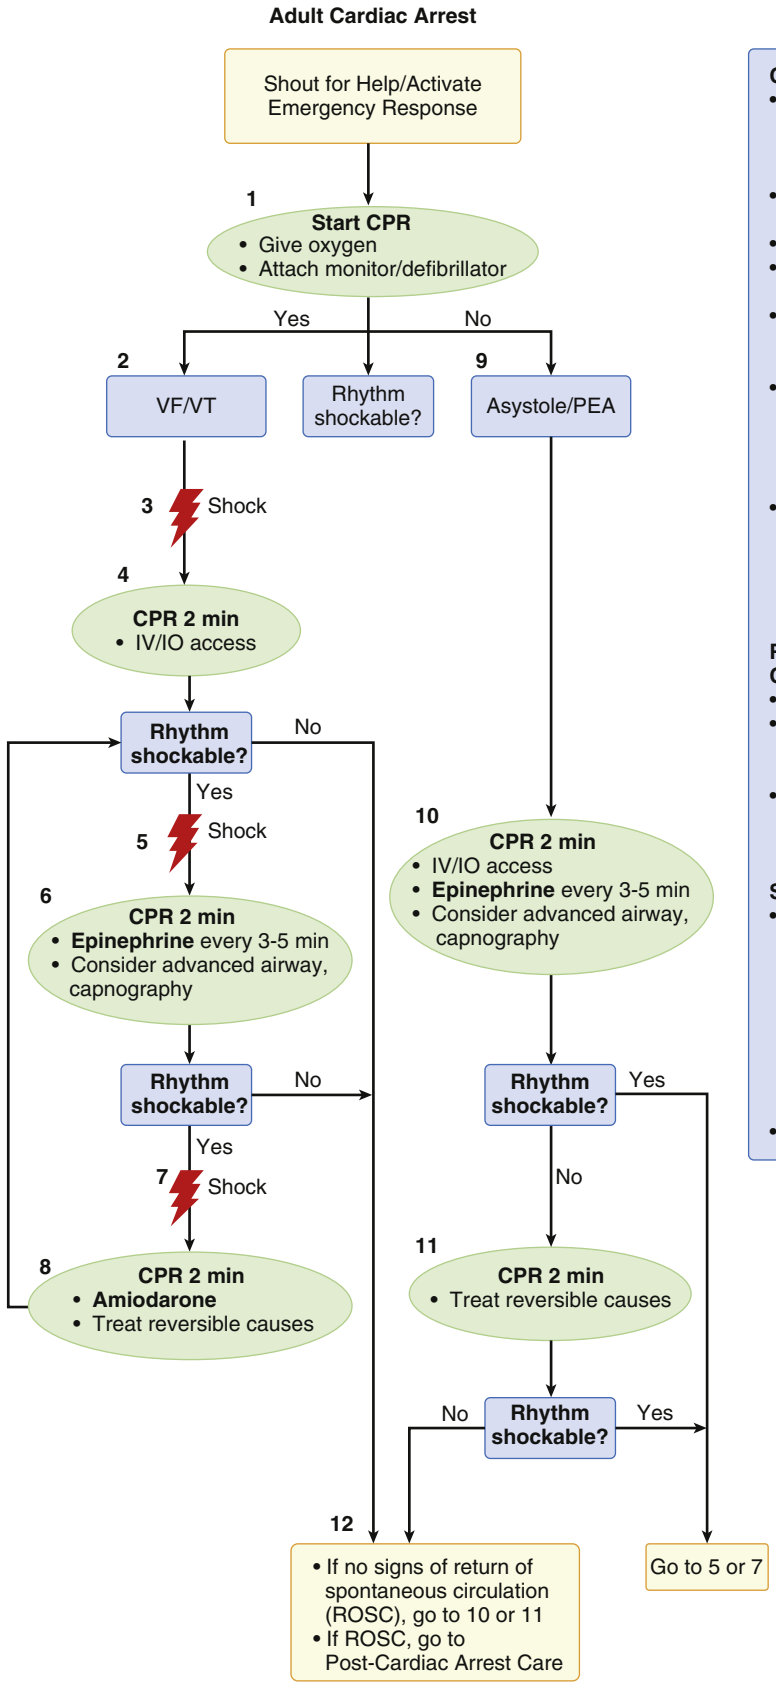
MANAGEMENT OF CARDIAC ARREST

This section reviews the interventions, both electrical and pharmacologic, used for treatment of the various forms of lethal cardiac arrhythmias (Fig. 108-19). A discussion of the major beneficial and adverse actions of the drugs used in ACLS is included. The clinical applications of some of these drugs have already been presented in the review of recognition and management before arrest or before potentially life-threatening events.

PULSELESS VENTRICULAR TACHYCARDIA OR VENTRICULAR FIBRILLATION

For therapeutic purposes, pulseless VT and VF are considered the same lethal entity in need of the same interventions, beginning with prompt defibrillation. Fortunately, these arrhythmias are the most treatable and yield the greatest likelihood of immediate and long-term survival in both in-hospital and out-of-hospital settings. Early defibrillation, not pharmacologic interventions, is responsible for the improved survival after VF cardiac arrest. As a result, PAD puts AEDs in public places so that defibrillation can occur at the earliest possible opportunity to individuals in cardiac arrest, regardless of rescuer training.

In operating rooms, ICUs, or other environments where continuous monitoring of cardiac rhythm is used and when a VT or VF arrest occurs, chest compressions should be immediately provided and defibrillation performed at the earliest opportunity. A period of chest compression before defibrillation is not recommended in the 2010 AHA Guidelines for CPR and ECC. If a monophasic defibrillator is available, then a single 360 J shock should be delivered. With biphasic defibrillators, biphasic truncated exponential waveforms should use 150 to 200 J for first shock, depending on the manufacturer's recommendation. Energy settings for rectilinear biphasic waveforms should use 120 J for the initial shock. For simplicity and improved decision-making during resuscitation efforts, if the rescuer is unfamiliar with the waveform used or the manufacturer recommendations, then the maximal available energy should be used as the default energy.[61] Chest compressions should be immediately resumed after the delivery of shock and continued for 2 minutes before reassessing the underlying cardiac rhythm, unless obvious evidence for ROSC occurs. The 2010 AHA Guidelines for CPR and ECC recommend three stacked shocks to be used only in the coronary catheterization laboratory or in the cardiac surgical operating rooms after weaning from cardiopulmonary bypass.[40,]



No evidence supports one biphasic waveform over another. All biphasic defibrillators available today are impedance compensated and adjust the delivered dose of energy in response to the measured transthoracic impedance (TTI) with each shock. (This technology has resulted in greater first-shock efficacy and is not used in monophasic defibrillators.) Defibrillation energies should be increased until VF is terminated or maximal defibrillator energy output is reached. In circumstances in which VT or VF is terminated with defibrillation but VT or VF recurs, defibrillation should use the previously successful energy level.

If ROSC has not occurred after an initial defibrillatory attempt, then five cycles of CPR consisting of 30 compressions to 2 ventilations should be performed before cardiac rhythm reanalysis. Placement of a supraglottic airway or endotracheal intubation can be considered in this interval. During this opportunity, peripheral IV access should be attempted if not already established.

VASOPRESSOR THERAPY IN CARDIAC ARREST

The 2010 AHA Guidelines for CPR and ECC de-emphasizes the use of medications in resuscitation attempts. Emphasis is placed on providing quality, uninterrupted chest compressions and defibrillation attempts every 2 minutes as needed for ongoing resuscitation efforts. Although epinephrine has been a mainstay of pharmacologic therapy in resuscitation efforts for many years, clinical evidence is lacking for improved survival and neurologic recovery after cardiac arrest when epinephrine is administered. Vasopressin and amiodarone are two other pharmacologic agents commonly administered during cardiac arrest. Just as with epinephrine, vasopressin and amiodarone lack convincing clinical evidence for improved hospital discharge and neurologic recovery when administered during resuscitation efforts. All three medications have demonstrated benefit in ROSC during cardiac arrest but no benefit on hospital discharge.

Epinephrine's benefit in cardiac arrest states arises from its potent α- and β-adrenergic stimulation effects, resulting from a 1 mg (10 mL of a 1:10,000 solution) IV dose. α_1– and α_2–receptor stimulation results in peripheral vasoconstriction, leading to increased aortic diastolic pressure. Increased aortic diastolic pressure improves coronary blood flow. The modest increase in aortic diastolic pressure might provide improved coronary blood flow during cardiac arrest or other low coronary blood flow states, resulting in ROSC. Epinephrine-induced β-adrenergic stimulation increases myocardial contractility. This consequence increases myocardial oxygen demand and probably further exacerbates subendocardial ischemia during the low-flow states of cardiac arrest (also see Chapter 16).

CPR Quality
- Push hard (≥2 inches [5 cm]) and fast (≥100/min) and allow complete chest recoil
- Minimize interruptions in compressions
- Avoid excessive ventiation
- Rotate compressor every 2 minutes
- If no advanced airway, 30:2 compression-ventilation ratio
- Quantitative waveform capnography
  – If $PetCO_2$ <10 mm Hg, attempt to improve CPR quality
- Intra-arterial pressure
  – If relaxation phase (diastolic) pressure <20 mm Hg, attempt to improve CPR quality

Return of Spontaneous Circulation (ROSC)
- Pulse and blood pressure
- Abrupt sustained increase in $PetCO_2$ (typically ≥40 mm Hg)
- Spontaneous arterial pressure waves with intra-arterial monitoring

Shock Energy
- **Biphasic:** Manufacturer recommendation (eg, initial dose of 120–200 J); if unknown, use maximum available, Second and subsequent doses should be equivalent, and higher doses may be considered.
- **Monophasic:** 360 J

Drug Therapy
- **Epinephrine IV/IO Dose:** 1 mg every 3-5 minutes
- **Vasopressin IV/IO Dose:** 40 units can replace first or second dose of epinephrine
- **Amiodarone IV/IO Dose:** First dose: 300 mg bolus. Second dose: 150 mg.

Advanced Airway
- Supraglottic advanced airway or endotracheal intubation
- Waveform capnography to confirm and monitor ET tube placement
- 8–10 breaths per minute with continuous chest compressions

Reversible Causes
- Hypovolemia
- Hypoxia
- Hydrogon ion (acidosis)
- Hypo-/hyperkalemia
- Hypothermia
- Tension pneumothorax
- Tamponade, cardiac
- Toxins
- Thrombosis, pulmonary
- Thombosis, coronary

@ 2010 American Heart Association

Figure 108-19. 2010 American Heart Association adult cardiac arrest algorithm. *CPR,* Cardiopulmonary resuscitation; *ET,* endotracheal; *IO,* intraosseous; *IV,* intravenous; *PEA,* pulseless electrical activity; *$PetCO_2$,* partial pressure of end-tidal carbon dioxide; *VF,* ventricular fibrillation; *VT,* ventricular tachycardia. *(From Neumar RW, Otto CW, Link MS, et al: Part 8: adult advanced cardiovascular life support: 2010 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care,* Circulation *122(18 Suppl 3):S736, 2010.)*

Vasopressin (40 units) was included in previous resuscitation guidelines based on observations that survivors of cardiac arrest had increased endogenous vasopressin levels. Vasopressin is an endogenous peptide hormone secreted by the posterior pituitary gland in response to hypovolemia or systemic hypoperfusion states. When intravenously administered, intense peripheral vasoconstriction results from the stimulation of V_1 receptors in the endothelium. Vasopressin lacks adrenergic stimulation and, as a result, has limited increases in myocardial contractility, myocardial and cerebral oxygen consumption, and metabolic demands. No survival benefit has been observed in humans when vasopressin was used with or without epinephrine in cardiac arrests.

Amiodarone was included in the ACLS algorithms because of its ability at an IV dose of 300 mg to terminate ventricular arrhythmias during cardiac arrest that were resistant to defibrillation after epinephrine administration. Amiodarone's antiarrhythmic effect occurs through sodium and calcium channel blockade, potassium efflux antagonism, and adrenergic (α- and β-) blocking effects, producing prolonged action potentials and increased refractoriness in all cardiac tissue. Similar to epinephrine, amiodarone improves the rate of ROSC but has no observed influence or benefit on hospital discharge or neurologic outcomes.

Epinephrine's role in cardiac arrest resuscitation has been questioned, particularly as greater emphasis is placed on interventions leading to improved cardiac arrest neurologic outcomes. Jacobs and colleagues[110] studied outcomes after cardiac arrest resuscitations during which 1 mg epinephrine versus a similar volume of saline placebo were administered. Survival to hospital discharge was not different between the groups; however, patients receiving epinephrine during their resuscitation efforts had a statistically higher rate of ROSC, compared with the placebo group. Although the number of patients experiencing cardiac arrests was quite large ($N = 4103$) in this study, only 601 underwent randomization, potentially biasing the results. Similar results were reported by Olasveengen and associates[111] in a study of IV access and medication administration during cardiac arrest; epinephrine was given if an IV line was placed or not given because of the lack of IV access. Similar to the Jacobs' study results, administration of epinephrine clearly demonstrated a benefit in establishing ROSC but had no statistically significant improvement in hospital discharge or neurologic outcomes. A study by Hagihara and colleagues[112] reported essentially the same findings; epinephrine is associated with significantly better ROSC after cardiac arrest, but hospital discharge and good neurologic outcomes are significantly worse.

Vasopressin's benefit in cardiac arrest has also come under greater scrutiny. Mentzelopoulos and colleagues[113] performed a large meta-analysis involving published randomized control studies in which vasopressin was administered during cardiac resuscitation (with or without epinephrine) and evaluated for its role in ROSC, as well as its role in long-term neurologic outcomes. The conclusion was that the use of vasopressin in patients in cardiac arrest was not associated with any significant benefit or harm. The only long-term survival benefit was observed when vasopressin was administered to patients who were in asystole. Although the theoretical advantages of vasopressin use during cardiac arrest are encouraging (intense peripheral vasoconstriction without β-adrenergic receptor stimulation), when used in clinical practice, vasopressin offers little benefit in cardiac arrest events. Substitution of one dose of IV epinephrine with 40 units IV vasopressin during resuscitative efforts in cardiac arrest is acceptable in the 2010 AHA Guidelines for CPR and ECC[61] (see Fig. 108-19).

Amiodarone is a first-line antiarrhythmic medication used in cardiac arrest events and is endorsed for use in the 2010 AHA Guidelines for CPR and ECC.[61] In the study, Amiodarone in Out-of-Hospital Resuscitation of Refractory Sustained Ventricular Tachycardia (ARREST), Kudenchuk and colleagues[114] reported the results of a randomized, prospective study in which 300 mg IV amiodarone or placebo was administered to patients in out-of-hospital cardiac arrest with persistent VF after three defibrillation attempts and 1 mg IV epinephrine. The study demonstrated significant increases in survival to hospital admission in the amiodarone-treated group but was unable to demonstrate any difference in hospital discharge rates. In the Amiodarone versus Lidocaine in Pre-Hospital Ventricular Fibrillation Evaluation (ALIVE) study, Dorian and colleagues[115] reported the results of a double-blind, controlled clinical trial comparing amiodarone with lidocaine in patients experiencing out-of-hospital cardiac arrest in Toronto, Canada. Their results demonstrated amiodarone's superiority to lidocaine in terminating persistent VF in the out-of-hospital setting. Similar to the ARREST study, the ALIVE study was able to demonstrate the improvement produced by amiodarone only in survival to hospital admission, not to discharge, when compared with lidocaine or placebo. Based on these studies, VF resistant to defibrillation and epinephrine therapy warrants amiodarone therapy to augment the attempts to terminate the arrhythmia, recognizing that a long-term benefit for such therapy is lacking.

During resuscitation efforts, 1 mg IV epinephrine should be administered as the initial pharmacologic drug in VF or PVT. This dose can be repeated every 3 to 5 minutes as long as cardiac arrest persists. Defibrillation should be attempted 2 minutes after epinephrine injection. For VF resistant to defibrillation attempts, 300 mg IV amiodarone should be considered and can be repeated once at a 5-minute period (if necessary) with a 150 mg IV dose. As with epinephrine, defibrillation should be attempted 2 minutes after amiodarone injection. No other vasopressors or antiarrhythmic medications should be administered than those studied and endorsed by the AHA in its resuscitation guidelines.

PULSELESS ELECTRICAL ACTIVITY

Pulseless electrical activity (PEA) refers to a heterogeneous group of cardiac rhythm disorders, all characterized by pulselessness in the presence of organized electrical activity. High priority must be given to identifying possible reversible causes of PEA (Box 108-4). Severe hypoxia in respiratory emergencies can result in PEA. In the traumatized patient, hypovolemia, cardiac tamponade, and

BOX 108-4 *Potentially Reversible Causes of Cardiac Arrest*

Hypovolemia	Tension pneumothorax
Hypoxia	Tamponade (cardiac)
Hydrogen ion (acidosis)	Toxins
Hypokalemia or hyperkalemia	Thrombosis (pulmonary)
Hypothermia	Thrombosis (coronary)

tension pneumothorax are possible causes of cardiac arrest and must be considered and acutely treated. Unanticipated cardiac arrest occurring in the intraoperative and postoperative periods should include acute massive pulmonary thromboembolism or air emboli as possible causes. In the pregnant woman, uterine compression of the inferior vena cava, amniotic fluid embolism, or uterine rupture are possible sources of PEA (also see Chapter 77). Idioventricular rhythms might accompany derangements such as severe hyperkalemia, metabolic acidosis, or drug (e.g., digitalis, β-blockers, calcium channel blockers, tricyclic antidepressants) overdose. In every circumstance, prompt initiation of chest compressions and the administration of 1 mg epinephrine are recommended as temporizing measures until more definitive therapy can be provided once the cause for the PEA is identified. Each of these scenarios has an associated intervention unique to that situation. Asystole or VF can develop if PEA is not corrected.

ASYSTOLE

Asystole is the complete and sustained absence of electrical activity and is often a terminal event. In most patients, asystole is irreversible, but a brief trial of resuscitation, beginning with oxygen therapy and IV epinephrine after effective chest compressions, is indicated particularly in the setting of witnessed cardiac arrest. Occult VF is more theory than reality. The concern that asystole is actually VF is unrealistic and should not prompt defibrillation attempts. Atropine is no longer recommended for treating asystole. When resuscitation efforts are pursued for patients found in asystole, oxygenation, at least 2 minutes of chest compressions, and IV epinephrine should be provided before cardiac rhythm analysis occurs, for ROSC assessment, or electrical activity resumes.

ECHOCARDIOGRAPHY IN CARDIAC ARREST

When PEA occurs, either as the presenting condition in cardiac arrest or after termination of ventricular arrhythmias, the 2010 AHA Guidelines for CPR and ECC recommend an assessment of the "5 Hs and 5 Ts" (see Box 108-4) to elucidate the reversible causes for the cardiac arrest. The presence of hypothermia, hypoxia, or electrolyte abnormalities can be readily assessed. However, other causes leading to cardiac arrest can often be identified with the use of echocardiography. Although not explicitly recommended in the 2010 AHA Guidelines for CPR and ECC, prompt echocardiographic evaluation for patients in PEA could result in prompt intervention for reversible conditions that might otherwise be undetected.

Ultrasound technology is readily available in most surgical departments and ICUs in the United States and is used for technical interventions from placement of regional anesthesia blocks to assessing cardiac function in the patient who is hemodynamically unstable (also see Chapter 46). During cardiac arrest, echocardiography might identify pulmonary emboli, significant hypovolemia, cardiac tamponade, and impaired cardiac function—even if clinicians with limited experience are interpreting these images.[116] The American Society of Echocardiography guidelines recommend that limited and focused transesophageal echocardiography be performed when intraoperative cardiac arrests occur.[117,118] Perhaps, most importantly, echocardiography can assist decision-making with respect to the termination of resuscitative efforts when PEA persists through resuscitative efforts.[119] As experience accumulates with the use of echocardiography during cardiac arrest states, greater emphasis may eventually be placed on using this technology for diagnosing the causes of PEA arrests, confirming the presence or absence of myocardial contraction in the presence of organized cardiac rhythm, as well as guiding resuscitation if ROSC occurs.

POSTRESUSCITATION INTERVENTIONS

EMERGENCY PERCUTANEOUS CORONARY INTERVENTION

In patients resuscitated from out-of-hospital cardiac arrest, emergency percutaneous coronary intervention (PCI) and angiography are recommended in the 2010 AHA Guidelines for CPR and ECC.[120] Approximately 90% of patients resuscitated from out-of-hospital cardiac arrest have evidence of coronary artery disease,[121] and 70% have at least one significant coronary lesion demonstrated by coronary angiography.[122,123] These findings are the basis for the recommendation endorsing early, urgent coronary angiography after resuscitation from cardiac arrest, even if 12-lead ECG is not suggestive of myocardial ischemia after resuscitation. Early coronary interventions that re-establish coronary blood flow improve myocardial recovery and electrical and hemodynamic stability. Fibrinolytic therapy provided to survivors of out-of-hospital cardiac arrest has not been shown to have favorable outcomes, particularly compared with PCI.[124,125] Attention must be directed toward facilitating early PCI in survivors of cardiac arrest as part of an advanced postcardiac arrest protocol, including those patients remaining comatose after resuscitation.

TARGETED TEMPERATURE MANAGEMENT

The median survival rate from out-of-hospital cardiac arrest is 8.4% (3.0% to 16.3%).[126,127] Only one-third of individuals in out-of-hospital cardiac arrest survive to hospital admission, and two-thirds of these survivors die before hospital discharge.[128] The majority of patients dying after successful ROSC die from ischemic neurologic injury.[129] In the setting of normothermia, cerebral blood flow less than 125 mL per minute and persisting for longer

than 7 minutes is associated with permanent neurologic damage[130] (also see Chapter 54). Improved survival from cardiac arrest might be possible if interventions are used in attenuating the effects cardiac arrest exerts on central nervous system tissues.

Cerebral ischemia induces an inflammatory response of platelet aggregation and degranulation, protein and enzyme denaturalization, and neutrophil and complement activation, all of which increase permeability and/or blood-brain barrier disruptions demonstrated by neuronal damage biomarkers.[131] Ischemic neurons become progressively acidotic in low-flow or no-flow states, leading to intracellular lactic acidosis and carbon dioxide retention. Intracellular acidosis inhibits enzymatic function, impairing neurotransmitter reuptake and depleting adenosine triphosphate (ATP) and adenosine diphosphate (ADP) stores. As adenosine accumulates, vasodilatation and neuronal edema result. As energy stores are depleted, sodium-potassium-ATPase dysfunction occurs in the neuronal membrane, resulting in extracellular hyperkalemia and intracellular hypercalcemia. Elevated intracellular calcium activates proteolytic and lipolytic enzymes, further disrupting neuronal membranes, resulting in massive liberation of excitatory neurotransmitters; glutamate is the most neurotoxic. Excess glutamate promotes overactivation of glutamate receptors and excitability of already stressed neurons, leading to a further influx of calcium into the neuron, resulting in neuronal death.

The cerebral inflammatory cascade might be attenuated, first, by improved blood flow as a result of effective and uninterrupted chest compressions during resuscitation efforts and, second, through induced hypothermia if ROSC is established and maintained. Drugs are ineffective in improving neurologic outcomes after cardiac arrest aside from their use to improve cerebral perfusion through improved cardiac output, to prevent hypotension, and to treat hyperglycemia.[127] Induced hypothermia might reduce cerebral metabolic rate and oxygen consumption, as well as attenuate the cerebral ischemia–induced inflammatory response associated with cardiac arrest states.

Since 2005, the AHA has endorsed targeted temperature management (i.e., induced core body temperatures 32° to 34° C) over 12 to 24 hours for patients who are hemodynamically stable and resuscitated from out-of-hospital VF or pulseless VT but remain comatose. The recommendations were reaffirmed in the 2010 AHA Guidelines for CPR and ECC.[132] However, even the AHA experts contributing to the 2010 AHA Guidelines for CPR and ECC recognize the shortcomings of many of the studies on which the most current guidelines regarding targeted temperature management are based.

Much of the interest in postresuscitation therapeutic hypothermia; that is, in targeted temperature management (to use current terminology), is driven by the results of a 2002 randomized control study demonstrating improved neurologic outcomes in comatose survivors after out-of-hospital VF or pulseless VT when hypothermia was induced and maintained.[133] The entire body must be cooled for improved neurologic recovery after resuscitation from cardiac arrest, not only the patient's head. Several hours are usually required for cooling to and rewarming from target core body temperatures (32° to 34° C). Current clinical practices use a combination of fluid-filled cooling blankets, ice packs, forced air blankets, cold IV fluids, and/or invasive devices or catheters for managing controlled cooling and rewarming of patients. Sepsis is more frequent when intravascular devices are used to induce hypothermia, making this approach unfavorable in most circumstances.[134]

Although enthusiastically received, the survival results in the therapeutic hypothermia study[133] remain sobering; a majority of patients in the hypothermia group either died before hospital discharge or suffered poor neurologic outcomes. However, those surviving to hospital discharge had better neurologic recovery when compared with the control patients. The exact mechanism responsible for improved neurologic outcomes after targeted temperature management is unknown.

In a retrospective study of the Finnish Intensive Care Consortium, investigators reviewed patients admitted to ICUs after resuscitation from out-of-hospital cardiac arrests in the "pre-hypothermia" era (2000 to 2002) and the "hypothermia" era (2003 to 2008), evaluating the impact of targeted temperature management on patient survival.[135] Patient characteristics were similar for age, sex, and initial Glasgow coma scores, except patients treated after 2003 had higher illness severity. Specific neurologic parameters were not evaluated. The authors reported that the implementation of targeted temperature management resulted in a significantly reduced risk for in-hospital death after out-of-hospital cardiac arrest (57.9% mortality decreased to 51.1% mortality). However, the survival rate has not changed since the widespread adoption of targeted temperature management in 2003, despite the increasing use of this therapy. The majority of patients experiencing out-of-hospital VF or pulseless VT cardiac arrests still die.

Targeted temperature management is beneficial most obviously with VF and pulseless VT cardiac arrests. Large registries have evaluated targeted temperature management for cardiac arrest scenarios other than VF and pulseless VT, finding no improved survival nor improved neurologic outcomes in these patients.[136] Coincident with the wide adoption of targeted temperature management after ROSC following cardiac arrest for any arrhythmia, BLS attention for uninterrupted chest compressions has improved. A large registry assessing the influence of uninterrupted chest compressions in cardiac arrest related to nonshockable cardiac arrhythmias has demonstrated improved resuscitation and neurologic outcomes.[137] The conduct of BLS in accordance with the 2010 AHA Guidelines for CPR and ECC may confound results from retrospective clinical observations, suggesting the benefit of targeted temperature management only to shockable cardiac arrhythmias. At this time, targeted temperature management is increasingly being considered for all survivors of nontraumatic cardiac arrest, particularly those with in-hospital cardiac arrests, although clinical evidence clearly demonstrates benefits for shockable arrhythmias.

The 2010 AHA Guidelines for CPR and ECC recommend that targeted temperature management be considered for any patient who is hemodynamically stable

and resuscitated from cardiac arrest but who remains unresponsive after ROSC. The optimal time for initiating targeted temperature management is not known, nor are data available on optimal rates of rewarming from induced hypothermia. In most circumstances, targeted temperature management is part of a postresuscitation "bundle" of care that coordinates induction and maintenance of hypothermia, followed by careful rewarming all provided by a team of health care providers familiar with induced hypothermia protocols.[138] Sedation, neuromuscular blockade, and mechanical ventilation are required for patient management during the period of inducing, maintaining, and rewarming from hypothermia.

Temperature management after ROSC following cardiac arrest has provided important observations. Patients with low body temperatures after resuscitation from nontraumatic cardiac arrest (median 34.5° C [interquartile range 33.7° to 35.9° C] versus 35.1° C [interquartile range 34.4° to 35.8° C]) had a higher rate of in-hospital mortality than those patients with higher body temperatures at admission.[139] This same study observed that in summer months, nonsurvivors after ROSC following cardiac arrest had higher body temperatures at admission than survivors. Together, these observations suggest impaired body temperature control is associated with poor survival after cardiac arrest. Hypothalamic dysfunction with impaired thermoregulatory control is proposed for both trauma-related and cardiac arrest–related body temperature observations.[139-141] The proposed hypothalamic dysfunction role in impaired temperature regulation after resuscitation from cardiac arrest might result from global cerebral ischemia affecting central thermoregulation and/or impairment of peripheral vasomotor pathways responsible for vasoconstriction and vasodilatation.[139,142]Although Benz-Woerner and associates[139] noted a lower body temperature in nonsurvivors at admission, the adjusted time to reach target hypothermic temperature was not different between groups. Finally, this study demonstrated that nonsurvivors after resuscitation from cardiac arrest required a longer time to rewarm, compared with survivors (600 ± 144 minutes in nonsurvivors versus 479 ± 120 minutes for survivors).[139] The management of impaired intrinsic body temperature appears to be an important predictor of survival after resuscitation from cardiac arrest.

During the time period of targeted temperature management, hemodynamic instability, arrhythmias, electrolyte abnormalities, seizures, bleeding, hyperglycemia, and infections are not uncommon. In a large prospective observational study of 754 patients resuscitated from out-of-hospital cardiac arrests, adverse events were studied evaluating their influence(s) on mortality.[134] Pneumonia occurred in nearly one-half of patients (with or without hypothermia therapy) but had no influence on mortality. Only seizures requiring anticonvulsant therapy and sustained hyperglycemia (>144 mg/dL) were associated with increased mortality. Seizures occurred in 182 of the 754 participants (24%) in this study group. Significantly longer delays between onset of cardiac arrest and the initiation of cardiopulmonary resuscitation and longer resuscitations before ROSC were unique to these patients, and the likelihood of asystole or PEA as initial cardiac rhythm were all unique to those experiencing seizures. Although an ominous sign, seizures did not imply uniformly poor survival; 31 patients with seizures requiring anticonvulsant therapy survived with good neurologic outcomes at 6 months. Sustained hyperglycemia is considered representative of a stress response related to increased endogenous and exogenous catecholamine loads, suggesting severe clinical insult. Currently, the ideal blood glucose level has not been established for survivors of cardiac arrest. Avoiding hypoglycemia in this period after cardiac arrest seems equally important as treating hyperglycemia; hypoglycemia was also associated with increased mortality as well.

Prognosis for neurologic recovery after targeted temperature management is a complex issue facing physicians caring for survivors of cardiac arrest. Benzodiazepines, neuromuscular blocking agents, IV sedatives, and narcotics are often used in the period during which hypothermia is induced after resuscitation from cardiac arrest. Hypothermia interferes with the pharmacokinetics and pharmacodynamics of these medications. The presence of medications with their effects on neurologic or neuromuscular function interferes with brainstem reflexes, electroencephalographs (EEGs), and somatosensory-evoked potentials (SSEPs), making interpretation of neurophysiologic findings difficult.[143]

Neurologists rely on a commonly used measure for predicting neurologic outcome after a neurologic injury, the Glasgow-Pittsburgh Cerebral Performance Category (GP-CPC) scale,[143] which is summarized in Box 108-5.

A neurologist's clinical evaluation assessing neurologic recovery after resuscitation from cardiac arrest includes pupillary light response, corneal reflexes, and motor responses to painful stimuli.[143] Current American Academy of Neurology (AAN) practice parameters for examinations 72 hours after resuscitation from a cardiac arrest submit that absent pupillary responses, absent corneal reflexes, or absent motor responses or extensor posturing predict a poor neurologic recovery with a high degree of certainty *in patients not exposed to induced hypothermia*.[144] In those patients treated with hypothermia, recovery of motor function within 24 hours of discontinuing sedation for induced hypothermia predicts good neurologic outcome with 100% specificity.[145] The EEG is useful even during hypothermia since the waveforms should not be significantly affected by hypothermia alone (also see Chapter 49). Sedatives and hypnotic drugs induce extremely low-voltage EEG patterns. The AHA 2010 Guidelines for CPR and ECC recommend a "spot" EEG as early as possible or continuous EEG monitoring

BOX 108-5 ***Glasgow-Pittsburgh Cerebral Performance Category Scale and Functional Outcomes***

CPC 5	Death

CPC, Cerebral performance category.

in patients being treated with hypothermia.[132] Seizures noted on EEG monitoring should be aggressively treated, but the effect that anticonvulsants have on neurologic outcomes is not known.

The AAN practice parameters do not address the influence that induced hypothermia after cardiac arrest resuscitation (and the pharmacologic interventions associated with this therapy) has on neurologic prognostication in this patient population. Traditional data used for determining poor neurologic recovery cannot be reliably used once the patient has undergone induced hypothermia. Neuroprognostication after targeted temperature management and resuscitation from cardiac arrest is an active topic of research and comment and will probably be addressed more thoroughly in the next version of the AHA resuscitation guidelines.

POSTRESUSCITATION OXYGEN THERAPY

Increased concern has been raised in the resuscitation community as to the optimal inspired oxygen concentration after restoration of circulation after cardiac arrest. Animal studies have demonstrated improved survival after hypoxic and ischemic episodes when low rather than high arterial oxygen concentrations accompanied restoration of blood flow.[146-149] Is an increased arterial oxygen concentration during ROSC harmful to ischemic cells, particularly neurons, and should lower inspired oxygen concentrations be provided during resuscitation efforts?

At the basic science level, when cells become hypoxic during normothermic hypoperfusion events (i.e., circulatory arrest), cellular energy (ATP) production converts from aerobic (oxidative phosphorylation) to anaerobic metabolism (glycolysis). Glycolysis is not sufficient for prolonged energy production in most cells, particularly neurons, during periods of low blood flow. If perfusion and oxygen delivery are restored to ischemic cells, then oxygen free radicals, particularly superoxide (O_2^-), are produced in the mitochondria and through nicotinamide adenine dinucleotide phosphate hydrogen (NADPH) oxidation. Superoxide dismutase is a cellular enzyme responsible for oxygen free radical detoxification but becomes overwhelmed as ischemia persists, as well as when large amounts of oxygen free radical species are generated during reperfusion. The negative consequences of reperfusion reported in animal studies are consistent with these oxygen free radical production theories.

Negative outcomes when high versus low concentrations of oxygen are provided during resuscitations from cardiac arrest have been shown in animal studies. However, human outcome studies addressing high versus normal arterial oxygen contents have not been nearly as convincing. Bellomo and associates, in a retrospective analysis of 12,108 patients resuscitated from nontraumatic cardiac arrest, reported that hyperoxia (arterial partial pressure of oxygen [PaO2] greater than 300 mm Hg) had no independent association with negative outcomes with respect to in-hospital mortality.[150] They also reported that hypoxia after cardiac arrest had the lowest hospital discharge rates.

At this time, no human studies have demonstrated clear evidence that hyperoxia must be avoided after resuscitation from cardiac arrest. Although hyperoxia probably offers no additional benefit to survivors of cardiac arrest, hypoxia is clearly harmful to these patients and must be avoided. Based on the available information, the 2010 AHA Guidelines for CPR and ECC recommend an approach for managing survivors of cardiac arrest that titrates oxygen therapies to attain oxygen saturations of 94% to 98% as soon as reliable continuous pulse oximetry is available.[132]

PEDIATRIC RESUSCITATION

Children are no more tolerant to cardiac arrest than adults, as demonstrated by the poor survival statistics in pediatric cardiac arrests. Overall, approximately 6% of pediatric patients survive out-of-hospital cardiac arrests.[151] Results for in-hospital pediatric cardiac arrest are better. The 2008 National Registry of Cardiopulmonary Resuscitation (NRCPR) reported an overall survival of 33% of pulseless cardiac arrests among in-hospital pediatric patients.[152] Survival from pediatric cardiac arrest requires prompt recognition and treatment, just as with adults (also see Chapter 93).

Pediatric resuscitation is an area of clinical expertise requiring unique understanding, clinical skills, and therapeutic considerations. Recognition of this perspective is evident in the 2010 AHA Guidelines for CPR and ECC. However, health care providers must realize resuscitation recommendations are intended for both adult and pediatric resuscitations; simplified and streamlined for retention and use in resuscitation efforts, regardless of the patient's age. As with adults, pediatric chest compressions, when performed by a single rescuer, should be delivered at a rate of 100 compressions per minute with 2 breaths interposed every 30 compressions.

Interruptions in chest compressions should be minimal and of short duration, even for airway management and defibrillation, just as with adult resuscitation. Minimally interrupted and effectively performed chest compressions, ventilation, and prompt defibrillation are associated with improved resuscitation from cardiac arrest in children rather than medication administration. In light of this information, ACLS training provides sufficient consistencies in treatment recommendations extending from the young to the very old to be effectively used in the treatment of any child or adult in cardiac arrest. AHA textbooks and handbooks are available for consultation regarding more specific details.

PEDIATRIC BASIC LIFE SUPPORT

Primarily for the convenience and uniformity of training, infants are considered to be 1 month to 1 year of age and children are 1 year of age to puberty (i.e., breast development in girls). Adults are considered those in or beyond puberty. Figure 108-20 depicts current recommendations for health care worker–provided Pediatric Basic Life Support (PALS) (see Fig. 108-20).[152]

When an unresponsive child is encountered, a brief attempt at confirming unresponsiveness is indicated. If the child is unresponsive, then a call for help, the retrieval

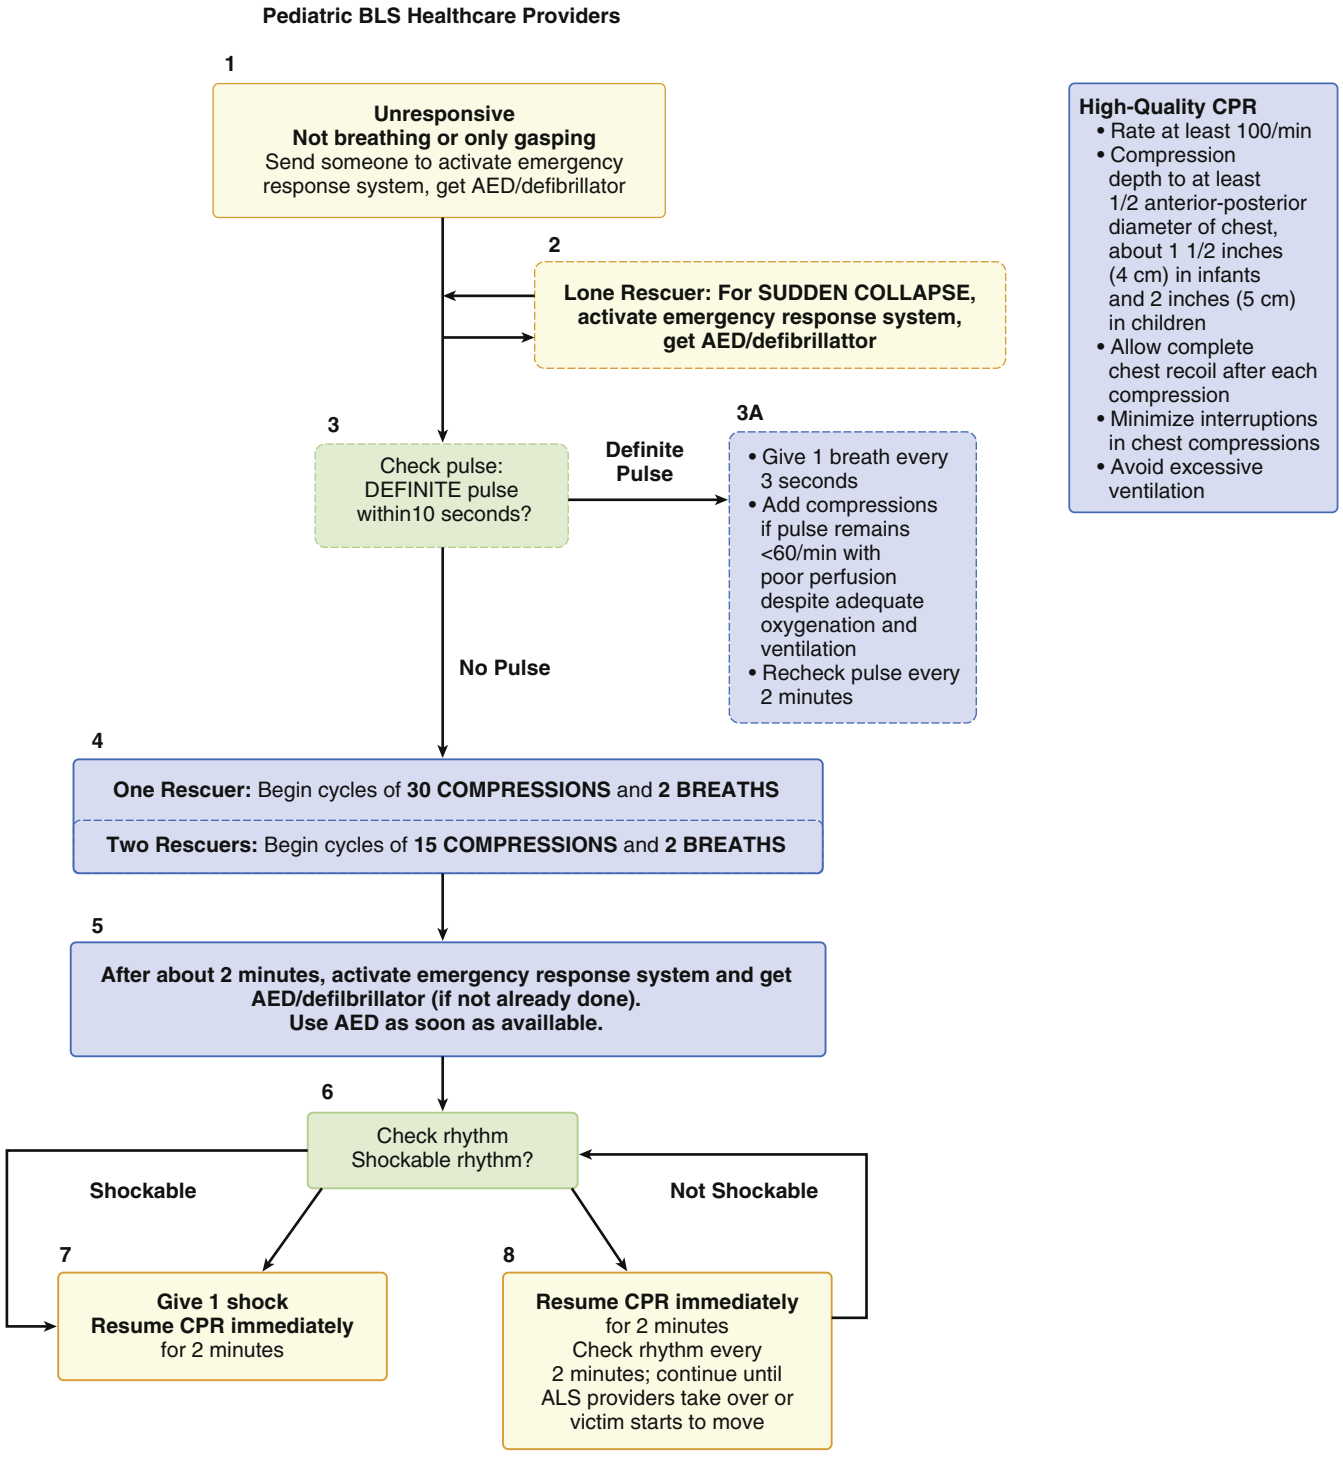

Figure 108-20. 2010 American Heart Association pediatric basic life support (BLS) for health care providers algorithm. *AED,* Automatic external defibrillator; *ALS,* advanced life support; *CPR,* cardiopulmonary resuscitation. *(From Berg MD, Schexnayder SM, Chameides M, et al: Part 13: pediatric basic life support: 2010 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care,* Circulation *122(18 Suppl 3):S866, 2010.)*

of resuscitation equipment, and the detection of the presence or absence of a pulse is indicated when more than one rescuer is available. The single rescuer should initiate an emergency response system and then check for a pulse. The detection of a femoral or brachial pulse is often difficult for both health care and lay rescuers.[153,154] The rescuer should spend no more than 10 seconds palpating for an obvious pulse. Chest compressions should be initiated if no obvious pulse is present or if a palpable pulse in an infant is less than 60 beats per minute.

As with adults, the initial pediatric basic life support resuscitation sequence now emphasizes chest compressions first, rather than airway management. Although asphyxia is a more common cause in pediatric cardiac arrest than VF, for simplicity in training, chest compressions rather than rescue breathing is recommended as the initial intervention for pediatric cardiac arrest resuscitation efforts. The cycle of 30 chest compressions before rescue breathing delays ventilation for only 15 to 20 seconds.

Chest compressions should be performed at a rate of 100 compressions per minute. In infants, the rescuer should place two fingers just below the inframammary line on the sternum and compress the sternum to one-third the anteroposterior depth of the chest (approximately 4 cm). In children, chest compressions should be performed by compressing the lower half of the sternum (avoiding the xiphoid process) with one or two hands to a depth one-third the anteroposterior depth of the chest (5 cm). Thirty compressions should be delivered, followed by two rescue breaths provided with minimal interruptions in chest compressions. Chest compressions and rescue breathing should be performed for 2 minutes before reassessing the presence of a pulse. Each compression should be followed by full recoil of the chest, which allows unimpeded venous return to the heart.

Lone rescuers should perform 30 chest compressions with two interposed breaths during resuscitation. If two rescuers are present, then a chest compression-to-ventilation pattern of 15:2 should be used with minimal interruption and pauses of chest compressions for rescue breath delivery. If an advanced airway is present, then rescue breathing can be provided at a rate of 8 to 10 breaths per minute without interruption of chest compressions.

Sudden witnessed collapse in a child is likely to be from VF. Application of an AED to an infant or child in cardiac arrest would ideally include a pediatric attenuator (limiting shock energy for the smaller body size) and pediatric defibrillation pads. With infant cardiac arrest, a manual defibrillator is recommended. Initial defibrillation energy in pediatric cardiac arrest is 2 J/kg and increased to 4 J/kg if a second shock is indicated. If no pediatric defibrillator is available, then an adult AED should be applied and used without hesitation. Defibrillation is critically important.

Foreign Body Airway Obstruction

More than 90% of childhood deaths from FBAO occur in children younger than 5 years old. Liquids are the most common source for infant choking. Small objects (e.g., balloons, food) are responsible for most childhood choking (also see Chapters 55 and 93). If a child is making sounds or is coughing, the adult should carefully monitor but not intervene. If the choking is severe—no coughing, no breathing—an intervention is necessary. Infant choking should be relieved with five back blows followed by five chest compressions until the obstruction is relieved. In the choking child, the Heimlich maneuver (abdominal thrusts) should be performed until the obstruction is relieved. In either circumstance, if the choking infant or child becomes unresponsive, CPR should be started with 30 chest compressions, followed by an airway examination to identify the presence of the foreign body. Two rescue breaths should be attempted. If the airway obstruction is not relieved, then CPR should be restarted and continued until the airway obstruction is relieved.

Drowning

When a drowning infant or child is encountered by a single rescuer, a CPR pattern of 2 minutes of 30:2 compression-to-ventilation should be provided before summoning help. If two or more rescuers are available, then help should be immediately summoned. Oxygen and ventilation should be provided at the earliest opportunity.

PEDIATRIC ADVANCED LIFE SUPPORT

Unlike adults, infants and children experience cardiorespiratory arrest secondarily, rarely as a result of a primary cardiac event. This observation is critical because ACLS interventions primarily directed toward the restoration of cardiac function may cause the physician to delay properly directed therapy (also see Chapter 95). As an example, progressive respiratory failure with worsening hypoxia and respiratory acidosis leads to bradycardia and hypotension that can further progress to cardiac arrest. The cardiac arrest is the result of hypoxia not a primary cardiac event. Treatment with atropine in a futile attempt to increase heart rate in a hypoxic, hypercarbic child would be an example of misdirected therapy.

VF and VT is the presenting rhythm in up to 15% of pediatric in-hospital and out-of-hospital cardiac arrests.[151] The incidence of lethal ventricular arrhythmias increases with age through childhood.[155] Increasing evidence supports a genetic abnormality that results in myocardial ion channelopathies as possible sources for lethal ventricular arrhythmias in children. This background provides evidence that primary cardiac events are possible causes for pediatric cardiac arrests. Distinguishing primary from secondary cardiac causes of pediatric cardiac arrest requires thoughtful consideration of relevant clinical data and a familiarity with multiple pediatric advanced life support resuscitation algorithms.

Airway Control and Ventilation

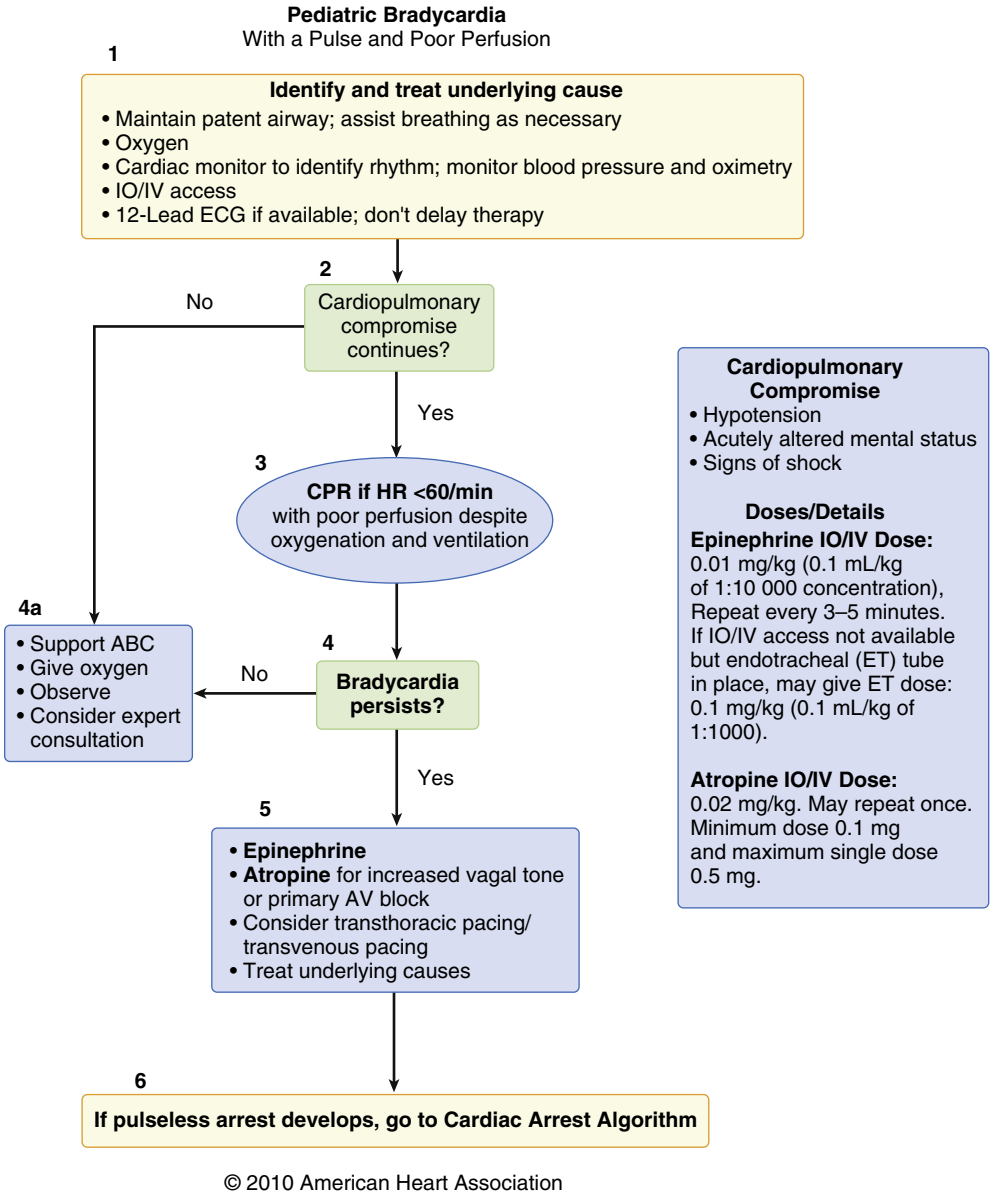
Considering the high incidence of respiratory rather than cardiac causes of pediatric cardiac arrests, anesthesiologists are fully aware of the need for effective basic and advanced airway management and the importance of oxygenation and ventilation. Airway management is of utmost importance in respiratory-related cardiac arrests. As with adult cardiac arrests, airway management should not cause prolonged interruption of chest compressions. If effective ventilation is provided with mask ventilation, then an endotracheal tube is not necessarily mandatory. Alternative airways (e.g., laryngeal mask airway) should be considered when endotracheal intubation proves difficult or when intubation would result in prolonged interruption of chest compressions. As with adults, the placement of an advanced airway warrants confirmation of placement using a carbon dioxide detector and bilateral breath sounds.

Venous Access

Vascular access can be challenging in the child who is critically ill. Intraosseous (IO) access is often pursued in

children who are critically ill without other IV access because of its ease of placement and the rapid entry of fluids and medications into the central circulation.

All resuscitation medications and blood products can be injected into IO catheters. Circulating medication levels are equivalent between IV and IO routes.[156] IO administration of medications is preferred to endotracheal administration. Because of the resistance to fluid flow from the IO catheter into the IO space, fluids must be pressurized to carry fluid into circulation.



Monitoring and Arrhythmia Recognition

ECG monitoring permits the immediate recognition of the arrest rhythm or, more likely in infants and children, the pre-arrest rhythm. Prompt intervention and correction in the latter event may prevent cardiac arrest that may be irreversible if induced by hypoxia manifested by progressive bradycardia. With this in mind, potentially life-threatening arrhythmias are discussed first, followed by cardiac arrest.

Supraventricular Bradyarrhythmia

The appearance and progression of a slowing of the heart rate in infants and children demand immediate assessment of the cause, beginning with hypoxia (Fig. 108-21). Bradycardia before cardiac arrest is most commonly sinus or junctional in origin. Second- or third-degree heart block may ensue if oxygen and other therapies are not provided. If hypoxia has been ruled out and the bradycardia is accompanied by clinical evidence of impaired perfusion, usually with systemic hypotension, then the patient should be treated with chest compressions and epinephrine. Chest compressions should be considered for infants and children with pulses less than 60 beats per minute.

Epinephrine is the drug of choice for treating bradycardia in infants and children. The recommended dose is 0.01 mg/kg of a 1:10,000 solution injected intravenously or intraosseously (IO doses are equivalent to IV doses). Epinephrine can be repeated as needed every 3 to 5

minutes. If the drug is injected into the tracheobronchial tree through an endotracheal tube, then 0.1 mg/kg of a 1:1,000 dilution is recommended.

If epinephrine does not increase the heart rate, then atropine can be used in a dose of 0.2 mg/kg and repeated once. TCP should also be considered for bradycardia refractory to epinephrine and atropine.

Supraventricular Tachyarrhythmias

In infants and children, SVT may represent ectopic atrial rhythms, atrial flutter or fibrillation, or paroxysmal reentrant tachycardia.[157] Standard pediatric cardiology texts should be consulted for specific diagnostic and therapeutic recommendations (Fig. 108-22). Although SVT is usually well tolerated in most infants and older children, immediate cardioversion may be necessary when heart rates in the range of 240 to 300 beats per minute are reached. Heart rates at these extremes may result in severe and rapid hemodynamic compromise. In the emergent setting where rapid SVT causes cardiovascular instability,[158] synchronized cardioversion is the treatment of choice. The initial energy dose is 0.5 J/kg to 1.0 J/kg

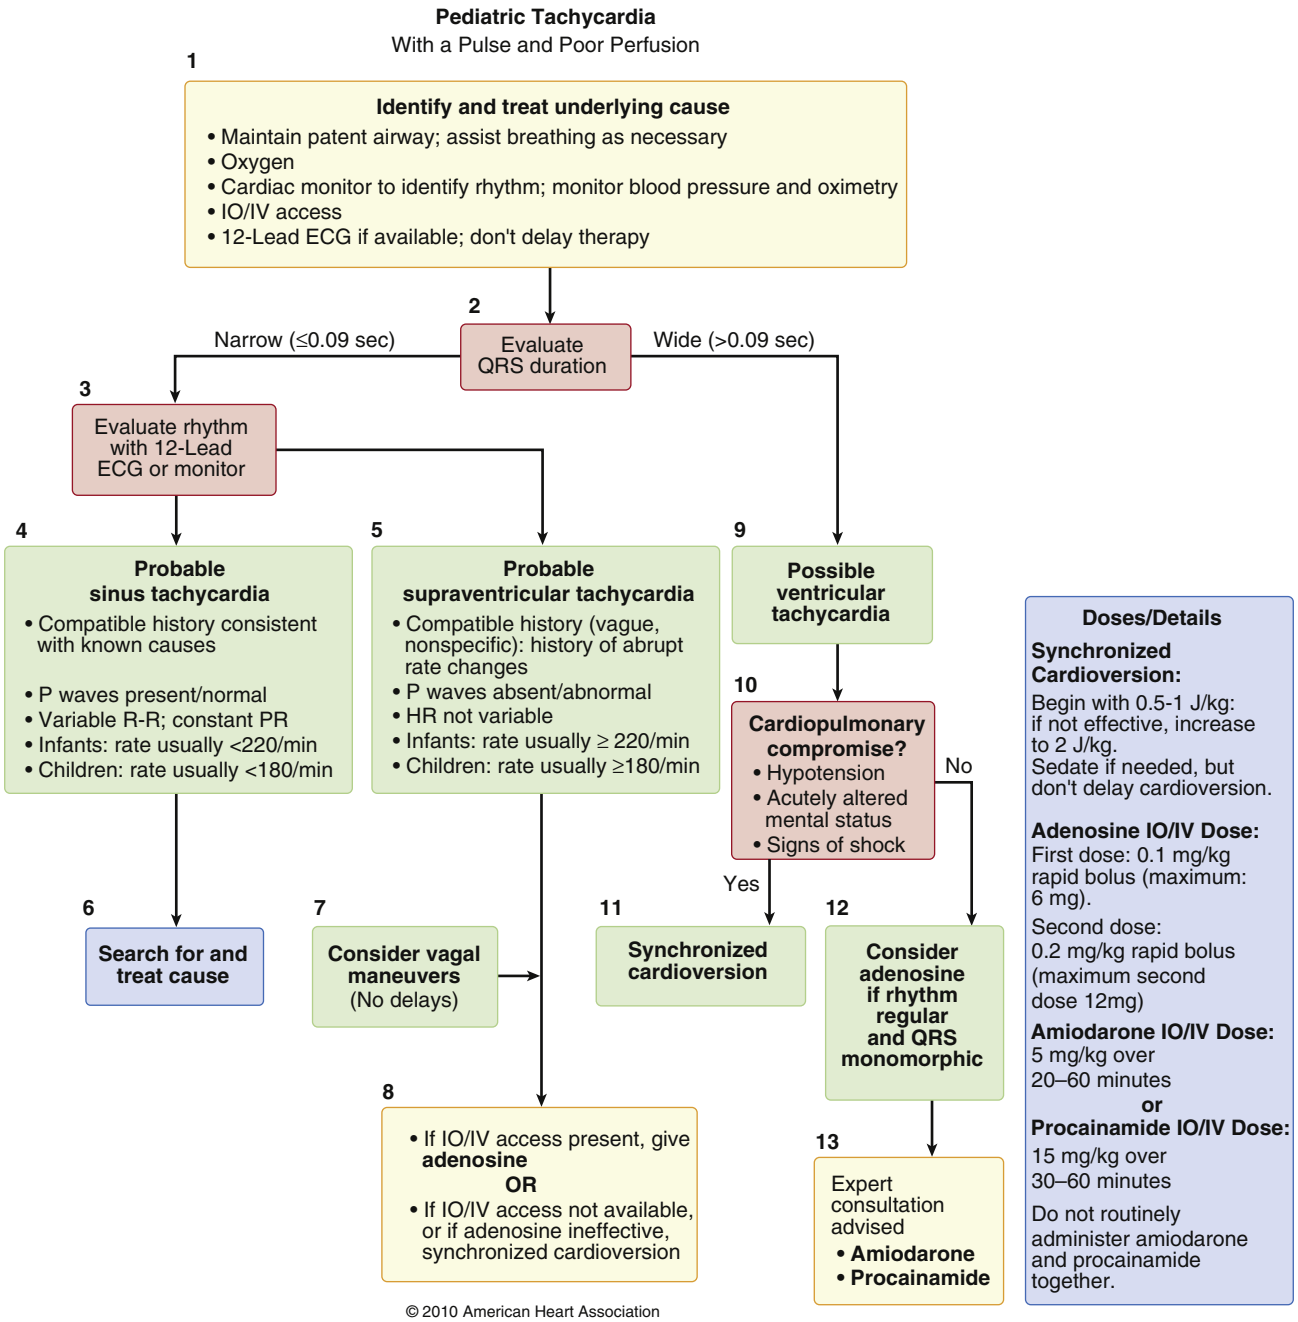

Figure 108-22. 2010 American Heart Association pediatric advanced life support (PALS) tachycardia algorithm. *ECG,* electrocardiogram; *HR,* heart rate; *IO,* intraosseous; *IV,* intravenous. *(From Kleinman ME, Chameides L, Schexnayder SM, et al: Part 14: pediatric advanced life support: 2010 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care,* Circulation *122(18 Suppl 3):S887, 2010.)*

body weight. If necessary, the energy dose is doubled.[159] If conversion to sinus rhythm remains unsuccessful, then the diagnosis of SVT should be reconsidered.

In children with SVT who are hemodynamically stable, vagal maneuvers are recommended before pharmacologic therapy. If vagal maneuvers are unsuccessful, then adenosine is the drug of choice and administered as a rapid bolus in an IV or IO dose of 0.1 mg/kg. If the SVT persists or recurs, then a second dose of an IV or IO dose of 0.2 mg/kg can be given in 1 to 2 minutes. The maximum single adenosine dose should not exceed 12 mg.

In circumstances during which adenosine has been unsuccessful in converting hemodynamically stable SVT, procainamide (15 mg/kg over a period of 30 to 60 minutes) and amiodarone (5 mg/kg over a period of 20 to 60 minutes) can be considered before cardioversion. Combining these therapies is not recommended.

Verapamil is not recommended for pediatric SVT in an emergency setting because it may induce hypotension and a state of depressed myocardial contractility. Specifically, verapamil is not recommended in this setting for infants younger than 1 year, children with congestive heart failure or myocardial depression, children receiving β-adrenergic blocking drugs, or children who may have an accessory pathway between the atria and ventricles.

Ventricular Bradycardia

As with supraventricular bradycardia, a slow idioventricular rhythm that has not yet produced pulselessness must be considered indicative of severe hypoxia, and treatment must be directed toward improving oxygenation and ventilation. Only after hypoxia has been addressed should rate-accelerating therapy be pursued, as discussed with supraventricular bradyarrhythmias.

Ventricular Tachyarrhythmia

Despite a common misconception, ventricular tachyarrhythmia is not always associated with severe hemodynamic compromise. Ventricular rates of 150 to 200 beats per minute may be tolerated and defined as a palpable pulse, but ventricular tachyarrhythmias should be converted to a normal rhythm. Emphasis is placed on an accurate diagnosis with 12-lead ECGs before treatment if the patient remains hemodynamically stable. In the setting of wide QRS complex tachycardia, synchronized cardioversion is the indicated treatment, beginning at 0.5 J/kg and increasing to progressively higher doses as needed and up to 2 J/kg using either monophasic or biphasic waveform shocks. If pharmacologic therapy is undertaken, amiodarone is the drug of choice and is delivered as described for the treatment of SVT. Intravenous procainamide (in doses identical for that of SVT) can also be considered. The two drugs should not be administered together. If the tachycardia is very rapid (greater than 300 beats per minute) and/or cardiovascular collapse and loss of pulses occurs, then this situation should be treated like VF with chest compressions and unsynchronized defibrillatory shocks.

Management of Cardiac Arrest

Once pulselessness occurs, therapy must be directed not only at correcting the underlying rhythm disorder but also at maintaining organ viability during the period of cardiopulmonary arrest. Meticulous attention must be paid to ensure proper chest compression rate and depth to avoid hyperventilation and chest compression interruptions, and to administer medication that supports perfusion pressures during resuscitation efforts. The Pediatric Advanced Life Support (PALS) Pulseless Arrest Algorithm is shown in Figure 108-23.

In the great majority of pediatric cardiac arrests, bradyasystole is the terminal cardiac electrical activity. Early dominance of the parasympathetic nervous system and α-adrenergic activity may, in part, explain this dominance of bradyasystolic mechanisms as the terminal event in infants. In addition, ventricular tachyarrhythmias (VF or VT) are most commonly seen in infants and children with congenital heart disease. Such children may have cardiac hypertrophy and increased ventricular mass sufficient to provide an anatomic substrate for reentrant wave fronts that initiate and sustain VF or VT.

Pulseless Electrical Activity and Asystole

Pediatric PEA, as in adults, includes disorders in which some form of cardiac electrical activity is present but without palpable pulses. In infants and children, this disorder is most commonly an idioventricular rhythm at a very slow and irregular rate (bradyasystole) and is the usual predecessor to ventricular asystole. When PEA is present, an immediate and aggressive effort should be made to identify treatable causes. As in adults, hypoxia, hypovolemia, tension pneumothorax, cardiac tamponade, and hypothermia or acidosis should be considered in light of the clinical setting in which PEA or asystole develops. Directing therapeutic efforts toward the most likely cause may avoid the administration of medications.

For both PEA and asystole, epinephrine is the drug of choice and is initially given in an IV or IO dose of 0.01 mg/kg (0.1 mL/kg of a 1:10,000 solution) (both routes result in equivalent blood levels) if potentially correctable sources of cardiac arrest have been pursued but ineffective in terminating the condition. Epinephrine can be repeated every 3 to 5 minutes via IV or IO routes as long as cardiac arrest persists. Defibrillation is not associated with benefit in PEA or asystole and should not be considered.

Pulseless Ventricular Tachycardia or Ventricular Fibrillation

VF occurs in 5% to 15% of all prehospital pediatric arrests,[160,161] and up to 20% of in-hospital pediatric cardiac arrests. VF and VT are relatively uncommon in infants and children, most likely with congenital heart disease. The increased cardiac muscle mass in congenital heart syndromes provides the anatomic electrophysiologic milieu for maintaining reentrant electrical wave fronts necessary for propagating VT and VF. As in adults, the treatment of choice for pulseless VT or VF in children is defibrillation, not medication therapy.

Defibrillation can be performed using adult defibrillator pads if the affected child weighs more than 10 kg. At least 3 cm should separate the defibrillation pads or paddles. Infant pads or paddles should be used for children younger than 1 year or weighing less than 10 kg. Energy doses for safe and effective defibrillation in infants are not known. The 2010 AHA Guidelines for CPR and

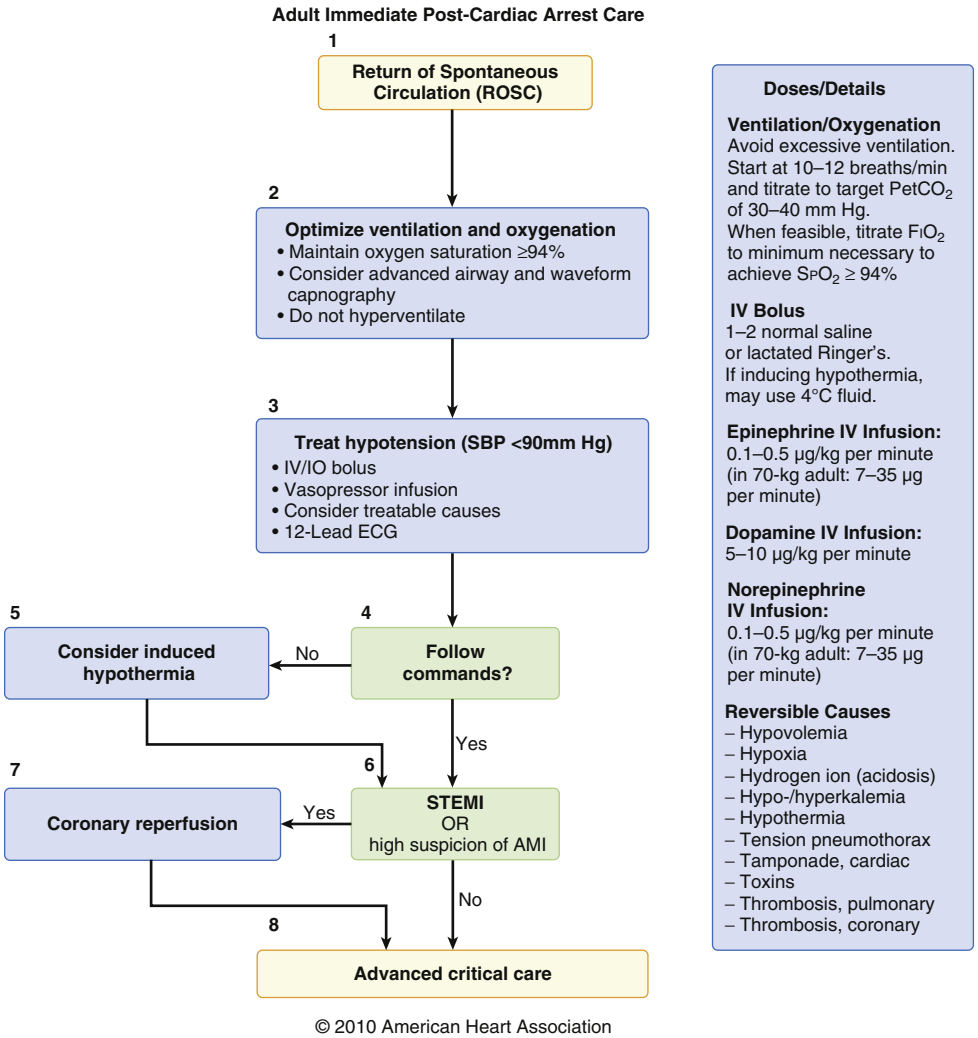
ECC recommend 2 J/kg for the first defibrillation attempt (monophasic or biphasic waveforms), progressing to 10 J/kg, or one adult defibrillation energy (depending on defibrillator manufacturer) if necessary for persistent ventricular arrhythmias.[158]

As long as the cardiac arrest persists, epinephrine is the drug of choice and is initially given in an IV or IO dose of 0.01 mg/kg (0.1 mL/kg of a 1:10,000 solution), as in PEA-related arrests. Evidence for using vasopressin in pediatric cardiac arrests is insufficient. IV or IO amiodarone, 5 mg/kg, can be considered for persistent VT or VF that is unresponsive to defibrillation. Amiodarone can be repeated two times as needed for persistent VT or VF.

Termination of Pediatric Resuscitation Attempts

No clear clinical signs or reliable predictors indicate whether efforts made in resuscitating infants and children will be successful. Witnessed cardiac arrest, prompt effective chest compressions and ventilation, and

rapid initiation of advanced resuscitative interventions improve the chances of successful outcomes but do not guarantee successful resuscitation. Prolonged resuscitations might be considered for infants and children with recurring or refractory VF or VT, particularly if cardiopulmonary support with extracorporeal membrane oxygenation (ECMO) is available[162] and the source for the cardiac arrest is believed reversible.



Sudden Unexplained Deaths

Unexpected and unexplained deaths in infants to young adults may be associated with genetic variations or mutations of ion channels in myocardial cells. Channelopathies allow abnormal electrolyte movement across myocardial cell membranes, predisposing the heart to irregular depolarizations and arrhythmias.[163-172] In 2% to 10% of infants or children[163-170] and 14% to 20% of young adults who experience sudden cardiac death, channelopathies are found on autopsy to have channelopathies.[171,172] This information should be discussed with families of young children who unexpectedly die. The AHA recommends an autopsy performed by pathologists with experience in cardiovascular disease and a genetic analysis of first- and second-degree relatives searching for evidence of undiagnosed channelopathies.

FUTURE OF RESUSCITATION SCIENCE AND CARE

At this time, resuscitation science is evolving into areas that could significantly improve the likelihood of survival after cardiac arrest. The 2010 AHA Guidelines for CPR and ECC emphasize uninterrupted chest compressions. Evidence clearly demonstrates the value of high-quality chest compressions in resuscitation efforts as improving the chances of ROSC for lethal ventricular arrhythmias and in patients experiencing asystole.

Several medications demonstrate improved rates of hospital admission after their use in cardiac arrest (e.g., epinephrine, amiodarone) yet failed in producing survivors to hospital discharge. As therapeutic hypothermia and targeted temperature management becomes increasingly used for comatose survivors of cardiac arrest, perhaps those surviving to hospital admission after cardiac arrest will eventually have higher chances for hospital discharge with good neurologic recovery resulting from this therapy. The key to targeted temperature management is a protocolized treatment regimen that provides reliable, timely, and consistent therapy for comatose survivors or through establishing centers of expertise in this therapy. The optimal time for initiating targeted

Available at:* http://circ.ahajournals.org/content/122/18_suppl_3/S768.full.*)*

temperature management has not yet been identified. Interfacility transfer should be considered if a survivor of cardiac arrest arrives at a hospital that does not have the capability of providing targeted temperature management since hours between resuscitation and the initiation of the therapy has been demonstrated to provide benefit.

EXTRACORPOREAL MEMBRANE OXYGENATION

Although not specifically addressed in the 2010 AHA Guidelines for CPR and ECC, a growing body of experience and clinical reports describing the use and benefits of ECMO for persistent cardiac arrest warrants mention in this chapter.

Extracorporeal life support (ECLS) can be considered for patients with severe biventricular failure after resuscitation from cardiac arrest, persistent VF or PEA after correcting an instigating coronary lesion in the coronary catheterization laboratory (where ventricular function recovery is anticipated), or in pediatric patients experiencing lethal arrhythmias as a result of myocarditis or the suspicion of myocardial channelopathies. Several institutions have reported their clinical experiences using ECLS that span many years.[173-175] In some reports, ECLS is being initiated in emergency departments by emergency physicians.[176] In nearly all reports, ECLS is considered very early in resuscitation efforts and is performed by experienced ECLS clinicians. Placement of large vascular catheters, one of which extends to the right atrium, during chest compressions to initiate ECLS therapy is technically challenging and time consuming. ECLS is only offered in tertiary centers with access to and experience with this technology. As a result, the theory of ECLS is far more hopeful than clinical evidence demonstrates at this time.

COORDINATED POSTRESUSCITATION CARE

Most deaths after cardiac arrest occur in the first 24 hours.[177,178] The AHA 2010 Guidelines for CPR and ECC emphasize the value of clinical experience with treating resuscitations from cardiac arrest, as well as access to cardiac catheterization laboratory interventions and intensive care management of cardiac arrest survivors. Figure 108-24 demonstrates a treatment algorithm for survivors of cardiac arrest. Although the best treatment algorithm for survivors of cardiac arrest is currently unknown, coordinated, consistent care provided by experienced health care professionals in a facility with multiple advanced interventions available and a review process for the care rendered to survivors of cardiac arrest all contribute to optimized care and will likely contribute to improved patient outcomes.[132]

Acknowledgment

The author cannot finish this chapter without expressing my profound thanks to Roger D. White, MD, for his thoughtful recommendations, professional guidance, and personal support that has been so freely offered throughout the writing of this edition. Working with such extraordinary talent is certainly a professional highlight in my career. Every physician should have a mentor of this caliber. Thank you, Dr. White.

Chapter 109

Electrical Safety in the Operating Room

LAWRENCE LITT

Key Points

Fire Safety Issues

- When setting up the anesthesia machine and drug cart before a surgical procedure, the anesthesiologist must know about the operation and the location of the emergency equipment. Questions to ask include the following:
- Where is the nearest fire extinguisher? There should be one in every operating room.
- Where are the oxygen shut-off valves, and how do I operate them to stop oxygen flow to the operating room?
- Where is the nearest fire alarm should it be impractical to call the hospital's equivalent of 9-1-1? Fire alarms are often recessed in the wall near fire hoses.
- Where is the nearest escape passage?
- Where is the nearest defibrillator and code cart?
- Electrical fires, particularly those that involve the electric panel, require a special approach. If possible, all electric power that feeds an electrical fire must be quickly cut, which then converts it into an ordinary fire. In fighting a fire, the proper type of fire extinguisher must be used. The most common type of fire extinguisher sprays water. However, water must never be thrown or sprayed on an electrical fire or onto burning flammable liquids. Electrical fires require a dry chemical extinguisher, but carbon dioxide (CO_2) extinguishers, which are optimal for controlling burning oils and liquids, may also be used.
- The use of high *blow-by* oxygen flow from an open facemask must be avoided if, after *blowing by* the patient, the flow ends up providing oxygen enrichment at a site of electrosurgery.

Macroshock Electrical Issues

- All electrical equipment used in the operating room should be grounded, although internally such equipment can contain ungrounded circuits. If the power cord for a piece of equipment has a plug with only two prongs (i.e., no grounding prong to go into the third hole in the outlet), then the equipment should not be in the operating room. When connecting or disconnecting plugs from outlets, the plug should not be yanked by the cord. Similarly, equipment whose power plugs have been damaged should not be used, and heavy equipment should not be allowed to crush power cords by rolling over them.
- Patients should not be directly connected to the operating room's electrical ground.
- When electrosurgery is in use, a grounding pad should be used that connects the patient to the ground connection provided on the electrosurgical machine. The grounding pad should be well gelled and placed in contact with the patient across a large area. The grounding pad should be inspected during lengthy procedures and gelled again or replaced, if necessary. The electrosurgical grounding pad should be placed as near to the operative site as reasonably possible and as far as possible from any pacemaker wires and electrocardiographic (ECG) wires. When grounding pads are removed, the underlying skin should be inspected for burns.

Key Points—cont'd

- If increasing current levels are required for electrosurgery, a search for a faulty connection of the electrosurgical grounding pad should be conducted. In the event of very *wet* operations, with or without increasing current levels for electrical surgery, the physician should beware of errant current paths that include the grounding pad and other electrical contacts (e.g., ECG electrodes). For example, saline and body fluids in an abdominal procedure can extend under the drapes beyond the operative site and potentially form an electrical connection to a grounding pad or ECG electrodes.
- If the line isolation monitor (LIM) sounds an alarm after someone activates a piece of equipment, then the offending equipment should be immediately unplugged. Plugging in that equipment has allowed the secondary side of the main isolation transformer to be coupled to the ground. It is also possible that too many items were simultaneously plugged, resulting in the secondary side of the main transformer to be coupled to the ground by their combined capacitance. Various combinations of unplugging one piece of equipment and plugging in another can be evaluated. However, if one piece of equipment is found to cause the LIM to sound an alarm under several combinations, then that piece of equipment should be removed from the operating room and examined for an unwanted connection to the ground contact.
- Experienced personnel, usually a clinical bioengineering group associated with the operating rooms, should periodically test all electrical equipment. Anesthesiologists should verify that the equipment has been properly maintained, that standards of performance have been met, and that the entire electrical environment also meets the National Fire Protection Association standards (NFPA) requirements.[1,2-7]

Microshock Electrical Issues With Pacemakers

- Patients with an automated implanted cardioverter-defibrillator (AICD) need to have the AICD turned off before surgery starts after first having established Zoll pad connections. Turning off the AICD feature is commonly done by magnet placement but can also be accomplished with reprogramming. It should be understood that magnets do not change the pacing program that is in an AICD. Thus preoperative cardiac electrophysiologic consultation is essential for establishing appropriate pacing.
- If possible, bipolar electrocautery units should be used instead of unipolar electrocautery.
- All programmable pacemakers should be preoperatively interrogated to ensure proper function.
- Patients who are dependent on a pacemaker need to have asynchronous pacing programmed, along with all rate-sensing features disabled. A conventional defibrillator should be available.
- Other pacemaker patients should have a pacing strategy established by preoperative cardiac electrophysiology consultation.
- A plan for pharmacologic treatment of complete heart block should be in place, particularly for patients who are dependent on a pacemaker, and isoproterenol should be readily available on the anesthesia drug cart.
- If electrophysiologic monitoring is being performed, then the anesthesiologist should review the locations of grounding pads that will be placed by the electrophysiologist.

Magnetic Resonance Imaging Issues

- When using a pulse oximeter to monitor the oxygen saturation of patients in an magnetic resonance imaging (MRI) scanner, the connection between the oximeter console and the patient must take place through a long fiberoptic cable that has no wires or conducting segments.

Key Points—cont'd

- Items with internal wires should not be present during an MRI examination, including pulmonary artery catheters that have a wire for determining temperature and certain epidural catheters with wires.
- Because of missile danger, ferromagnetic anesthesia equipment may not be brought into the magnet room.
- Essential anesthesia equipment that can be sucked into a magnet must be bolted to a wall and tested before entry of the patient into the scanner.
- Anesthesiologists who stay in the magnet room during examinations must wear ear plugs to avoid permanent hearing loss from high-decibel acoustic noise.

Common to All Issues

- If the cause of an electrical burn or incident is uncertain, then the relevant equipment or areas should be secured until experienced biomedical personnel mount a thorough investigation that may include simulation of patient conditions.

Despite technologic advances that have increased the sophistication of operating room electrical equipment, three types of danger persist from the days of flammable anesthetics: fire, electrical burns, and electrical shocks (e.g., macroshocks, microshocks). Improved alarm systems and safeguards have accompanied the technologic progress, but the size and number of electrical devices used per case has also increased. The result is the introduction of new ways to create unsafe electrical configurations that can lead to severe injury during surgery and anesthesia. Inattention to electrical safety can have serious consequences. Tragic events continue to be reported in the medical literature; in some cases, a moment of injury leads to a lifetime of patient suffering. Frequently, the culprit is unsafe surgical equipment or its unsafe use. However, disasters can also originate in damaged or misused anesthesia equipment, including physiologic monitoring devices.

From 1995 to 2000, a surge in the number of important articles concerning intraoperative fires were written,[8-13] with cause analyses being based on the *fire triangle* or the three requirements for a fire: oxygen, fuel, and ignition source.[13] Operating room fires fall into one of three basic categories: (1) the patient or something in the patient is on fire, (2) equipment has an electrical fire (i.e., one initiated and sustained by electric currents), or (3) the surgical drapes or other operating room items are on fire. Inadvertent ignition is often involved and easily identified, for example, when electronically generated sparks or a high temperature initiates the burning of the surgical drapes. However, ignition sources can also be complex and not immediately understood, as in the case of an exploding expiratory valve in an anesthetic breathing circuit.[14] In the operating room, anesthesiologists need to be aware of fire safety concerns, do all they can to keep ignition sources away from fuel sources, and safely use supplemental oxygen. Apart from fires, electrical equipment with inadequate grounding or other faults and induced currents from radiofrequency fields have caused severe burns. One report described a neonate with third-degree burns after the application of an external cardiac pacing device for a prolonged period[15] (see also Chapters 78 and 95). Another report described serious burns occurring from the electric direct current (DC) generated by a 9-volt battery in a small neuromuscular stimulator.[16] Fortunately, patient electrocution is now uncommon, although it was once a well-recognized hazard of surgery, of the operating room, and even of hospitalization in general.[17-20]

Although many types of modern equipment appear different from their ancestral counterparts, the injuries caused by electricity are similar or identical to those occurring generations ago. Electrical malfunctions in the operating room continue to cause fires and explosions, central and peripheral nerve stimulation and damage, muscle stimulation and contracture, tissue burns, pacemaker interference, and sudden loss of power to important equipment. Safety standards for medical equipment have been improving, and preventive maintenance of equipment, careful attention to the electrical contacts used on patients, and appropriate responses to alarm signals will avoid most complications. Understanding electrical safety is an especially important responsibility for anesthesiologists because perioperative electrical dangers can often be identified before they lead to the disruption of patient care or to injury.[21-25]

Having described the general situation, this chapter now turns to the essential details of electrical safety. The previous Key Points provide guidelines for safe clinical practice.

ELECTRICAL GROUND

What is an *electrical ground*? This question is important because discussions of electrical safety often center on whether circuits are grounded. To the clinician, an electrical ground is the wire connected to the third prong on plugs that are inserted into electrical wall outlets. With regard to circuits, an electrical ground is any object connected to a circuit that is capable of instantaneously supplying or receiving arbitrarily large amounts of electrical

charge. The National Electrical Code of the National Fire Protection Association* (NFPA) defines an electrical ground as a conducting connection, intentional or accidental, between an electrical circuit or equipment and the earth or as a connection to some conducting body that serves in place of the earth. Because the earth can be taken as an infinite reservoir of electrical charge with a limitless ability to give up or receive electrons, any charged object connected to the earth loses its charge and assumes the same potential as the earth.[21] Relative to the earth and to each other, the voltage between two grounded objects is zero.

When a circuit is intentionally grounded, the physical objects chosen to serve as the electrical ground can vary. In a remotely located mobile army surgical hospital unit or a recreational camping van, equipment may be grounded by connections to a spike that goes into the earth. In a large urban medical center, the ground may consist of a subterranean network of pipes. For a small, hand-held radio, a human being may serve as the connection to the ground.

In hospital settings, the clinician does not need to understand the details regarding the choice of the ground. However, clinicians must often know whether they, their patients, or their pieces of equipment are grounded. Living organisms tolerate only limited amounts of electric current. Unintended new contacts with electrical ground can sometimes be injurious when they enable small electric currents to reach the heart or neural tissue. However, they are always dangerous when they permit large electric currents to travel through the body. Fortunately, alarms for operating rooms and surgical equipment are designed to provide danger signals before errant currents are established by a sudden, new, unwanted ground connection. If the operating room has a *line isolation monitor* (LIM), explained later, hearing its loud warning sound means that a faulty ground connection is one step away from establishing a large current in the patient. Human protection from large currents can be ensured if connections to ground always occur through a sizable resistance. The danger of being grounded through an electrical resistance that is too small can be illustrated by an unrealistic but vivid hypothetic example. Imagine a person standing on top of a giant copper cylinder that extended down to the molten core of the earth. This low-resistance connection to the largest imaginable electrical ground would be quite unsafe because the person would essentially be a fuse, poised to suffer whatever large electric current is applied. The safety that would be achieved by inserting very large electrical resistance between the person and the copper cylinder—but not so large a resistance that it causes perfect insulation—explains a requirement that was established long ago when explosive anesthetic gases such as cyclopropane were used. Operating rooms were then required to have conductive floors made of specific resistive materials. Such substances had high carbon content, making them neither as conductive as metal nor as insulating as rubber. The high carbon content imparted a dark black color, one that can commonly be found in many of today's operating room tables and cushions made of resistive material.

In the United States, electrical plugs have three prongs with only two providing voltage or, equivalently, power. A special third prong serves only as a connection to a ground (i.e., to an object that makes an electrical connection with the earth or with a metal network such as iron pipes). Travelers to Europe and elsewhere may recall seeing electrical outlets for plugs that have only two prongs and no separate ground wire. A two-wire system becomes especially unsafe if three-pronged equipment is plugged into it with the third prong left unattached.

A ground fault current interrupter (GFCI) electrical outlet allows a person to test that the third connection in the outlet is connected to a functional ground. More significantly, GFCI outlets enhance electrical safety by serving as emergency circuit breakers that shut off power when one of the two power lines in the outlet is accidentally connected to a ground. Thus the GFCI is a *first fault* detector. GFCI outlets, found in hospitals and homes, have two buttons, *TEST* and *RESET*. Pushing TEST causes a special resistor to be connected across the power and ground terminals in the receptacle. If the ground connection (i.e., the third wire) is in place and connected to the system ground as it should be, then current flows through the resistor and causes a circuit breaker in the outlet to open. No electricity can then be delivered by the outlet. Pushing RESET resets the circuit breaker and restores electrical power. Pushing TEST would not cause the circuit breaker to open if, for example, a contractor accidentally forgot to install the ground wire or if an earthquake or other mishap caused a break in an installed ground wire. Protection against accidental grounding of one power line in an outlet is required by the NFPA for wet environments such as operating rooms. Installation of GFCI electrical outlets is one way to satisfy NFPA protection requirements. As discussed later in this chapter, a second (traditional but more expensive) way is to have power come from an isolation transformer equipped with an LIM.[26,27] In the operating room, if a power outlet is not part of an isolated system with an LIM, then it should be a GFCI outlet.

Electrical engineers commonly choose the ground as a reference location where the voltage is defined to be zero. Therefore the voltage at any point in a circuit is the difference between the voltage at that point and the voltage at the electrical ground. Because of this, ground connections in commercial circuits help professional personnel check for proper functioning. A technician connects one voltmeter probe to the electrical ground while touching different circuit elements with the other voltmeter probe. The manufacturer's table can be used to compare readings and, in this way, identify problems in the circuit. Specifying the location of the electrical ground helps people communicate standards for circuit performance.

ISOLATION OF ELECTRIC POWER FROM THE GROUND

Electrical contacts with the *ground* can cause injury if they occur in two different locations, completing a circuit and permitting a large flow of current through the ground.

*National Fire Protection Association, 1 Batterymarch Park, P.O. Box 9146, Quincy, MA 02269-9959. http://www.nfpa.org. Standards are available for download at http://webstore.ansi.org.

One strategy for ensuring safety is to isolate all electric power sources from the ground, thus making it impossible for the ground to be used as a path for injurious or damaging currents.

Traditionally, isolation transformers, which usually take the form of large wall panels that have outlets and meters, implement this strategy in the operating room. The term *isolation transformer* comes from the fact that power output is isolated from the electrical ground. Figure 109-1, *A*, shows a schematic diagram of an isolation transformer. A device built into the transformer constantly checks that all is well with this setup. It monitors the extent to which the output power lines are isolated from the ground and is called the LIM. The following text reviews how the LIM came into existence, why it can be important, and precisely what it is.

Electric power for an operating room comes from a primary hospital source that usually originates from a connection to an electric alternating current (AC) station of the local power company. (Sometimes in an emergency, a gasoline-powered electrical generator is the primary source.) In the traditional setup, after arriving in an operating room, the secondary coils of one or more large isolation transformers modulate, isolate, and dispense the electric power to electrical outlets in the room. Such transformers are very expensive, and the traditional setup is found less often in new hospitals. However, when there is a transformer, connections in three-hole power outlets in the operating rooms are somewhat different from the connections in standard outlets found elsewhere in the hospital.[25] In such operating rooms, connecting one of the two power contacts to the ground contact cannot complete a circuit.

The panel of each isolation transformer is required to have an LIM, which is an electric current meter that demonstrates isolation of the transformer's output power from the ground. Large isolation transformers were originally required by the NFPA in all operating rooms because of the use of inflammable anesthetics.[26] It is permissible for operating rooms to be built without them as long as basic safety is maintained by otherwise isolating electrical circuits from the ground. Such is now accomplished by a power transformer inside most electrical devices that isolates voltage applied to the device's circuits. Instead of one large isolation transformer for all equipment, each piece of electrical equipment has a small isolation transformer inside it. Such was not the case when large isolation transformers were initially required. Arguing for the total abolition of operating room isolation transformers and their LIMs is therefore possible. In support of such an argument is the observation that isolation transformers and LIMs have always been absent in intensive care units and postanesthesia care units, places where medical personnel use the same electrical instruments that are used in operating rooms. Should anesthesiologists advocate the elimination of future installations of isolation transformers and LIMs in operating rooms? The answer can be either yes or no,[26,27] depending on the type of electrical equipment that is used and the surgical situation. Surgery can involve having very wet patients covered or soaked with fluids that conduct electricity and find pathways to the ground. In these situations, currents can be established through the errant pathways from electrosurgical tools, such as through saline solutions to electrocardiographic (ECG) electrodes or the operating room table. New operating rooms in ambulatory surgery centers would seem to not need isolation transformers, although they are well suited for operating rooms for liver transplantation and other procedures involving a large amount of fluid.

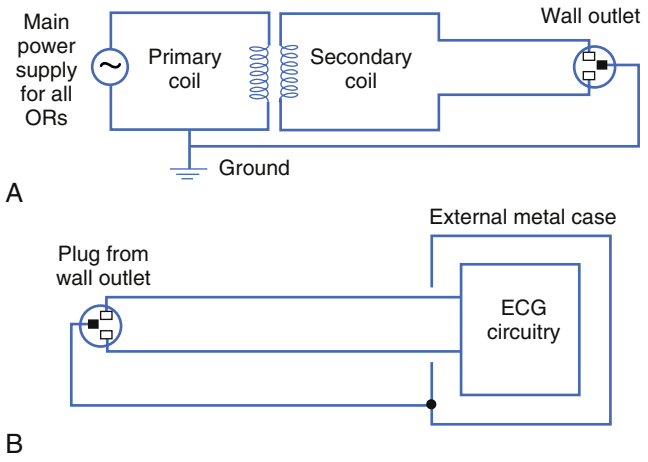

Figure 109-1. Schematic diagrams of an isolation transformer (**A**) and electric grounding (**B**) for an electrocardiographic (ECG) unit in the operating room (OR) (i.e., outlet to equipment).

The schematic diagram of an isolation transformer in Figure 109-1, *A*, shows what is presented by the power outlet to any power cord that gets plugged in. Each power outlet connects to two current-carrying wires that come from the secondary coil of the transformer. The third contact in the power outlet is connected to the standard hospital ground and not to the isolation transformer. The primary circuit of the transformer is attached to the ground, but the secondary circuit of the transformer is not.

When an ECG monitor is plugged into a power outlet in the operating room (Fig. 109-1, *B*), neither of the two current-carrying wires from the secondary coil of the transformer is connected to the ground by the ECG circuitry. This demonstrates the general principle that electrical circuits within an apparatus need not be grounded, although the metal case that houses the circuits is always grounded. For many circuits, proper functioning depends on good isolation. The statement "all operating room equipment must be grounded" means that the ground connection on a power cord that comes from equipment must always end up in contact with the ground provided by the transformer. In the example given in Figure 109-1, *B*, the ECG case is connected to the hospital's electrical ground, and the internal circuitry is connected to the output of the isolation transformer.

For reasons related to both safety and power conservation, three wires are in electrical circuits: (1) the *hot wire*, which is black in the United States and white in the United Kingdom and some other countries; (2) the *neutral wire*, which is white in the United States and black in the United Kingdom; and (3) the *ground wire*, which is commonly green. Electrical power boxes in hospitals, businesses, and homes generally receive 240-volt lines that are converted into 120-volt *main power line* circuits

(Figure 109-2, *A*). (The values *240* and *120* refer to root-mean-square voltage values for AC circuits. Peak voltages are larger by a factor of 1.41, the square-root of 2.) Although hot and neutral wires carry and return electrical currents to power outlets, the sample situation in Figure 109-2, *A*, illustrates why the neutral wire, which is connected to the ground from the center of the upstream transformer, is somewhat safer. For the situation shown in the figure, both 120-volt daughter circuits have equal current loads, and this results in the neutral wire's return current for one daughter circuit being equal and opposite to that of the other daughter circuit. The unequal widths of prongs in electrical plugs and outlets lets electrical equipment preserve the circuit asymmetry created by main power boxes that are designed to have hot wires and neutral wires. Additional background and details of such fundamentals have been recently reviewed.[1]

Figure 109-2, *B*, which illustrates the safety of one daughter circuit, is worthy of further discussion. If mechanical or electrical damage causes concern about the electrical safety of an ECG monitor, then could a failure occur inside the ECG monitor that would place the patient or anesthesiologist in contact with the internal circuitry? If so, then would electric current travel through the person from the ECG circuitry to the ground and cause injury or distress? If the ECG circuitry remains isolated from ground, then the answer is no.

The first part of the schematic in Figure 109-2, *B*, shows how isolation provides safety. A grounded person is touching the internal circuitry at point B. The isolation

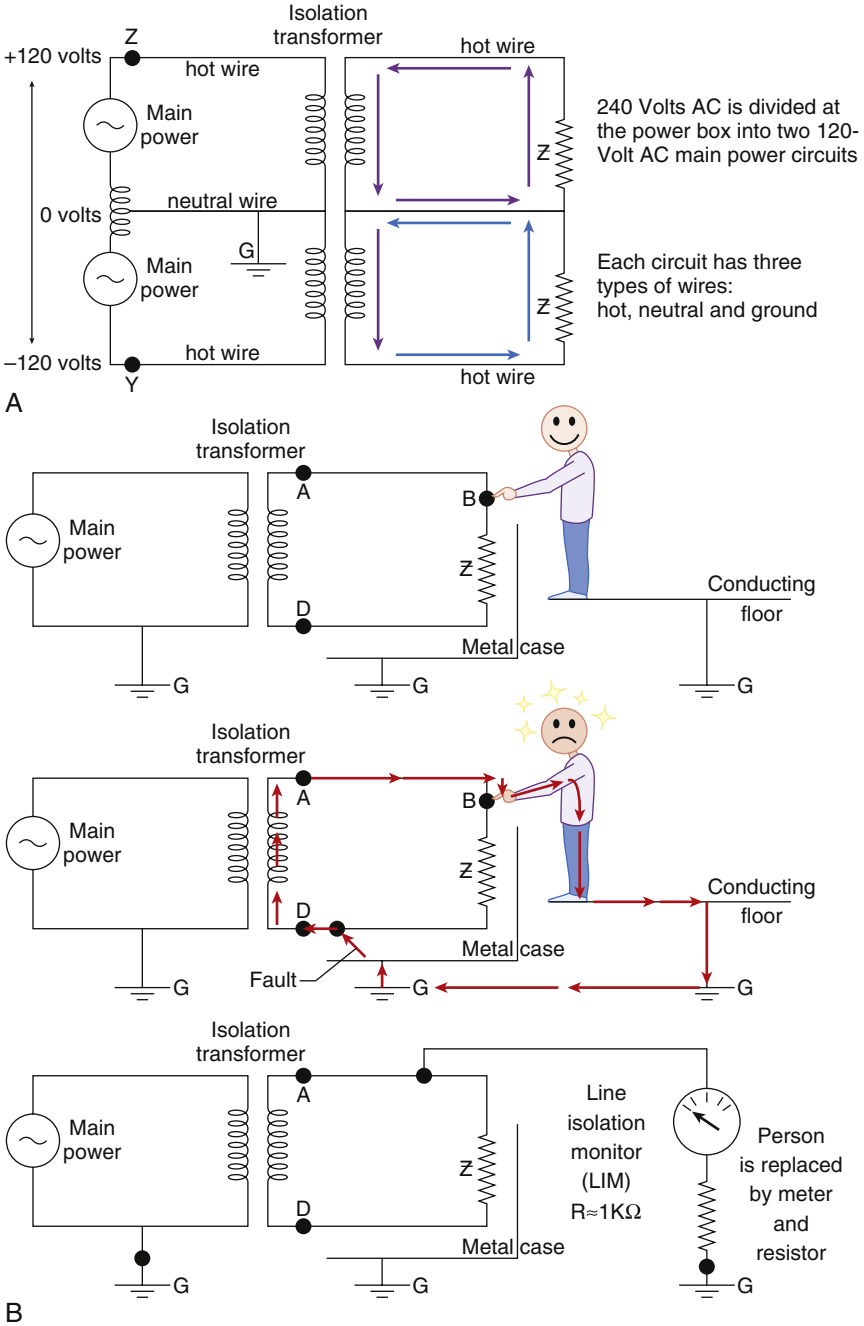

Figure 109-2. A, Schematic diagram shows the creation of two isolated 120-volt alternating current (AC) circuits in a power box that receives 240 volts of AC from an upstream source. The left side of the diagram represents the secondary coil in a transformer whose primary coil is not shown. The *neutral wire* connects the center of the 240-volt main power input on the left to the ground (G). The *isolation transformer* creates two isolated circuits of 120 volts, each loaded with a piece of equipment represented by the impedance Z. *Arrows* indicate simultaneous current directions. The central horizontal wire in the isolated circuit that is opposite to the *neutral wire* in the primary circuit is connected to the neutral wire contact in electrical outlets. **B**, When the transformer output is ungrounded, no electric shock occurs to the person at the right if an isolated power line is touched *(top)*. An electric shock does take place if the person touches the circuit after occurrence of the ground fault shown *(center)*. In the potentially injurious electricity path, shown in *red*, current comes up from the ground through the fault, circles around, and returns to the ground by traveling through the person's body. The person suffering the electric shock has been replaced by a current meter and a large resistance to ground. This is the basis for detection of the *first fault* by the line isolation monitor *(bottom portion)*. *R*, Resistance; *KΩ*, 1000 ohms.

transformer supplies current to pathways that connect the two hot leads in the outlet (points A and D). However, the only way for electric current to get from point A to D is through impedance Z. Because each of the hot points in the wall outlet are not grounded, the person in Figure 109-2, *B*, is safe from shock.

The second part of the schematic in Figure 109-2, *B*, however, shows that two inadvertent ground contacts could produce a dangerous situation, especially if one of those contacts is a human being. Suppose that a fault occurs near point D and causes the internal circuitry to come in contact with the external metal case. A dangerous shock would result from touching the circuit at point B. Because of the fault, current could complete a pathway through the person and ground (i.e., from point A to D). Isolating the power lines from the ground and knowing when isolation is compromised by a fault is useful.

Every isolation transformer has an LIM that monitors isolation of the transformer's two power output lines from the electrical ground. The third part of the schematic in Figure 109-2, *B*, shows how the LIM (an ammeter) replaces the smiling and frowning people (see Fig. 109-2, *B*). When very low amperage is indicated, the LIM verifies that the power output lines of the transformer are isolated from the electrical ground (see Fig. 109-2, *A*). The reality of the LIM connections is different because either of the hot wires could become accidentally grounded. The LIM is actually connected to both sides of the isolated power output (Fig. 109-3) and is set to sound an alarm when either side has an impedance to the ground that is less than 25,000 Ω or when the maximum current that a short circuit could cause exceeds 2 milliampere (mA). The LIM is insensitive to currents below 2 mA. As discussed later in this chapter, the LIM provides no protection against microamp currents and microshock.

Many events that commonly occur in operating rooms can produce a short circuit between the power and ground and result in the LIM sounding the alarm. For example, dripping or spilling saline, blood, or another conducting liquid into the receptacles of an electrical extension cord that is on the floor near the operating table can produce a short circuit. For this reason, rules from the NFPA and The Joint Commission (TJC) (formerly the Joint Commission on the Accreditation of Healthcare Organizations) have evolved to generally forbid the use of electrical extension cords in operating rooms and other clinical areas. Ideally, every piece of electrical equipment in the operating room is supposed to have a power cord that is safely routed to a wall outlet. In the rare circumstance when an exemption permits the use of an electrical extension cord, the cord must tolerate high current and have watertight covers that flip into place over unused outlets. If wet receptacles on an extension cord appear to set off an LIM, then the extension cord should be changed. If the LIM suddenly and unexpectedly or immediately rings after a new piece of equipment is plugged in, then that equipment should be immediately unplugged. If plugging in a piece of equipment repeatedly causes the LIM to sound an alarm, then the equipment should not be used until it is checked. Similarly, if the use of a particular power outlet repeatedly causes an alarm, then it should not be used until it has been checked. When an LIM alarm indicates a first fault (i.e., one power line is grounded), large, potentially damaging currents may subsequently occur through ground connections if a second ground fault is indicated. The path of damage may include the anesthesiologist, the patient, or an essential piece of equipment. An alarming LIM warns that someone in the operating room may receive an electrical shock or burn when touching connections to electrical equipment.

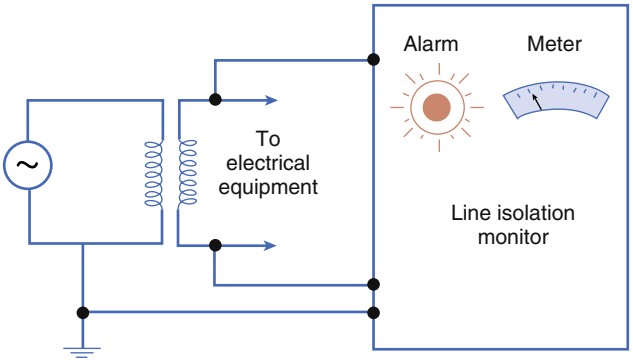

Figure 109-3. Schematic diagram shows the complete connections of the line isolation monitor (LIM). The alarm sounds a *first fault* if either isolated power line has less than 25,000 Ω of impedance, which corresponds to 2 milliampere (mA) or more being drawn through the LIM.

As noted earlier in this chapter, detection of a first fault in grounding is possible without the use of isolation transformers and LIMs. GFCI outlets provide protection against a first fault. However, they provide protection by suddenly shutting off all power from the outlet. An advantage of the LIM is that operating room personnel learn about a first fault without losing electric power. A disadvantage of the LIM is its susceptibility to newly developed artifactual causes of alarm. Certain devices used in operating rooms emit electrical radiation, intentionally or incidentally, that falsely cause LIMs to sound an alarm. Such devices include instruments that generate ultrasonic sound waves for the disintegration of a tumor and infrared and laser surgical navigation systems for stereotaxic surgery or anatomic localization, such as the computerized Stealth System and the Brainlab surgical guidance platform. These systems use electromagnetic waves to track fiducial markers attached to patients to enable locations on the patient to be linked to locations on three-dimensional MRI and computed tomographic scans. Noise can also be introduced into infrared pulse oximeter sensors that are connected to patients, when these are in an infrared navigation system's field of view. However, shielding the sensor with a cloth towel easily avoids such interference and misleading values of peripheral oxygen saturation (SpO_2).

CAPACITIVE COUPLING

The direct connection of two circuit elements by a wire or resistor is known as *resistive coupling* and is the easiest type of coupling for an anesthesiologist to recognize and understand. The connection is visible and the effects of the connection are apparent for circuits carrying DC

or AC at all frequencies. More subtle and abstract is the concept of *capacitive coupling*, which applies only to AC. This concept is relevant to anesthesiologists because it can account for electrical connections being present at high-current frequencies. If the alarm of an LIM goes off only when the electrosurgical electrode delivers high-frequency current to the patient, then capacitive coupling may be causing the dangerous pathway to the ground, and some power outlets that are safe for low-frequency currents but not for high-frequency currents may be present. Grounding pads, connections to electrical plugs, and equipment may need to be separated even farther from each other before the problem is remedied. The rationale directly follows the basic principles governing capacitive coupling.

The parallel-plate capacitor (Fig. 109-4), a circuit element that permits temporary storage of electrical charge, is very real to anesthesiologists when they use a defibrillator and announce "charging" just before delivering an electrical shock. More abstract is the concept that capacitors block the passage of DC while allowing the passage of AC. The total number of ohms that a capacitor has for obstructing AC or DC quantifies the *electrical impedance* of an object. This concept, which is a generalization of electrical resistance, permits the frequency-dependent assignment of ohms to all circuit elements: capacitors, inductors, and resistors. For capacitors, the ohmic calculation is performed with a simple formula. The impedance (Z, in ohms) of a pure parallel-plate capacitor is a function of the AC frequency (f):

$$Z = \frac{1}{2\pi fC}$$

In this instance, capacitance (C, in farads) is directly proportional to the area of the capacitor plates and inversely proportional to the space between the plates. As f increases, impedance to the flow of current decreases. For DC, f equals 0, and impedance becomes infinitely large.

At very high frequencies, capacitive coupling to the ground occurs through fewer ohms of impedance than at low frequencies. Because any two conducting objects in a room have surface area and an average distance of separation, they form a kind of capacitor. Any two objects have a capacitive coupling, which means that each of the two output lines of an isolation transformer is always coupled to the ground at AC frequencies.

Although such capacitive coupling is usually insignificant, it can sometimes be significant at frequencies

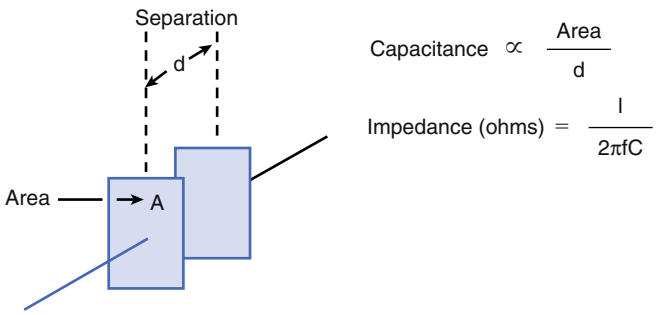

Figure 109-4. Schematic diagram of a parallel-plate capacitor. *C,* Capacitance in farads; *f,* frequency of alternating current.

of 60 cycles per second (i.e., 60 Hz). More commonly, capacitive coupling becomes a problem during electrosurgery performed at higher frequencies, typically hundreds to thousands of kilocycles per second. Capacitive coupling, which lets high-frequency currents easily pass, is commonly used by manufacturers in two connections: between the electrosurgical unit and the electrosurgical pencil (i.e., cutting or coagulation tip) and between the electrosurgical unit and the large-area *grounding pad* that attaches to the patient. The formal term for this large-area conducting pad is *dispersive electrode*. Capacitive coupling gives high-frequency electrosurgery currents a low-impedance path to and from the patient. At the same time, by presenting high-impedance paths at low frequencies, capacitive coupling prevents the electrosurgical pencil and the large-area conducting pad from participating in dangerous low-frequency grounding of the patient.

Capacitive coupling in an electrosurgical unit might have prevented a serious burn caused by the DC of a 9.5-volt battery within an anesthesiologist's damaged nerve stimulator.[16] An older electrosurgical unit was used in that case, and it was not capacitively coupled to the large-area grounding pad on the patient. The damaged nerve stimulator had a connection to the ground contact that permitted completion of a DC circuit (i.e., the patient through the faulty connection to the ground and then the ground through the large-area pad back to the patient). The DC persisted throughout the case, even when the stimulator was not pulsing. In laparoscopic and endoscopic surgery, avoiding unwanted capacitive coupling between the unipolar cautery tool and neighboring metal conductors such as trocar cannulas is important for surgeons. Stray currents from unwanted capacitive coupling can involve and injure organs such as the bile duct and bowel.[28,29] Anesthesiologists need to be aware of such potential surgical complications, particularly if they may be erroneously attributed to anesthesia.

Capacitive coupling can be responsible for severe burns from conventional pulse oximetry (with nonfiberoptic cable) in patients anesthetized for MRI.[30-32] However, the possibility of being burned by a faulty pulse oximeter probe exists independently of capacitive coupling or radiofrequency currents induced by the MRI environment.[33,34] In the setting for such a burn, the patient is external to a malfunctioning electrical circuit that causes the probe, which contains the photodiode and attaches to the patient, to overheat and burn tissue. Connecting the wrong kind of probe (e.g., one from another type of unit) to an oximeter console can cause such a catastrophe.

It has long been known that a perfectly safe conventional pulse oximeter (with nonfiberoptic cable) can be transformed into a dangerous, burn-causing device if attached to a patient being scanned in an MRI magnet. The problem arises from magnetic and electric fields that oscillate at megahertz frequencies (in radiofrequency coils) and at kilohertz frequencies (in gradient coils) during the acquisition of MRI data. Capacitive coupling can connect a patient to wires in a pulse oximeter cable and to metal in a pulse oximeter probe. In such a situation, the patient becomes part of a high-frequency loop circuit, with currents entering and exiting at the points of capacitive coupling, particularly at the site of probe

attachment.[35-38] Fortunately, anesthesiologists now know to use only pulse oximeter cables that have long, nonconducting fiberoptic connections between the photogenerating and photodetecting parts. Connections of the console to the cable are outside the magnet, distanced from pulsing MRI coils, and only nonconducting components are connected to the patient in the magnet. The absence of metal or conducting components of the cable or probe attachment eliminates the possibility of patient burns from induced currents during MRI.

Anesthesiologists monitoring patients with pulse oximetry in MRI magnets must use only units that are MRI safe and MRI compatible—those with a long fiberoptic cable as previously described. If, for some reason, the anesthesiologist decided to take a conventional pulse oximeter from an operating room to the MRI suite and attach it to a patient in an MRI magnet, then severe burns could occur.

ELECTRICAL SHOCK

MACROSHOCK

Macroshock refers to disturbances in neural or muscular function, or both, caused by the application of high voltage or current. Problems can arise if macroshocks occur near the heart, as in a fatal case when a patient's ECG leads were accidentally attached to a power cord.[17] However, macroshock can also cause injury if contact is made at locations remote from the heart.

If someone's hand or arm accidentally touches a voltage terminal, then the response to electric current flowing through the arm will depend on the amplitude and frequency of the current. Sensation of a 60-cycle current occurs at approximately 300 microamperes (μA), and pain occurs at approximately 1 mA. If the current exceeds a certain value, which is called the *let-go current*, then the person is unable to release the object.[39] The value of the let-go current varies with the frequency and among individuals. Figure 109-5 shows the range of average values as a function of AC frequency. The currents at 50- and 60-cycles per second have the lowest values and are therefore the most dangerous. The response of the cardiac muscle to electroshock also depends on frequency. Electric current is more important than voltage when issues of safety arise. Table 109-1 indicates the physiologic responses to increasing total-body current.

Continuous, total-body currents that reach 0.1 to 2.5 A (approximately 10 times the let-go value) can cause ventricular fibrillation. The electric current generated by one pulse of an implanted cardiac pacemaker ranges from 0.1 to 50 μA. Only a small part of the total-body current needs to pass through the heart to affect cardiac function. An electrosurgical unit generates so much power that it can induce microshock currents when it is used near implanted pacemaker wires. However, as a result of compliance with the safe grounding practices described earlier, the last convincing report of ventricular fibrillation induced by electrosurgery occurred in 1968.[40]

Defibrillation is often based on the same principle—the skin is a good electrical insulator that requires large electric fields at its surface for the production of small electric fields internally. A jolt of 360 watt-seconds (or joules) during closed-chest cardiopulmonary resuscitation delivers energy to the body comparable with that produced by a large-caliber handgun. (A 0.45-caliber bullet weighs 250 grains and has a muzzle velocity of 860 ft/sec when fired, which corresponds to energy of approximately 540 watt-seconds.) Only a very small portion of a defibrillator's energy dose is needed to depolarize the heart.

MICROSHOCK

The passage of even small amounts of electric current through the body can interfere with normal functioning of muscles and nerves. *Microshock* refers to the direct

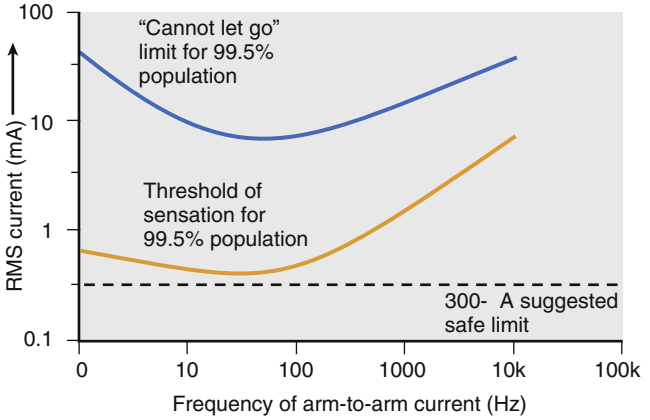

Figure 109-5. The response to electric current flowing through an arm when the hand accidentally touches a voltage terminal depends on the amplitude and the frequency of the current. Sensation of a 60-cycle current occurs at approximately 300 microamperes (μA), and pain occurs at approximately 1 milliampere (mA). If the current exceeds a certain value, called the *let-go current*, then the person is unable to release the object. The value of the let-go current varies with frequency and among individuals. *RMS,* Root mean square.

TABLE 109-1 AVERAGE EFFECTS ON HUMANS OF 60-HZ CURRENTS APPLIED AT BODY SURFACE AND PASSING THROUGH THE TRUNK

Current (mA) for 1-Second Contact	Effect
1	Is the threshold of perception.
5	Is accepted as the maximum harmless current intensity.
10-20	Let-go value is exceeded. Sustained muscle contraction is next.
50-100	Pain; possible fainting, exhaustion, mechanical injury; and heart and respiratory function continue.
100-2500	Ventricular fibrillation occurs. Respiratory center remains intact.
≥6000	Sustained myocardial contraction is followed by normal rhythm. Temporary respiratory paralysis occurs. Burns if the current density is high (usually if the current >100 mA/cm^2).

Modified from Bruner JMR: Hazards of electrical apparatus, Anesthesiology *28:396, 1967.*

application of very low voltage or current to the heart, often intentionally, by means of external or internal cardiac pacemaker electrodes. Inadvertent microshock, however, is dangerous because it can produce ventricular fibrillation. A faulty endoscope and faulty dialysis equipment have caused deaths from accidental microshock.[16,41] Before 1980, arterial and central venous pressure transducers were a potential source of microshock because they brought electrodes very close to heparinized saline in contact with the intravascular compartment.[42,43] However, in 1982, miniature disposable pressure transducers appeared that could be powered and operated with low-voltage telephone cables. These are now exclusively used, and their safety with respect to microshock has been demonstrated by years of frequent use without reported complications. Such systems, however, are vulnerable to more subtle dangers, as was reported when a faulty cable connection permitted precision pressure tracings but caused a substantially lower pressure reading.[44]

Electric current is the most appropriate variable to address when setting safety limits. Because investigators have reported that electric current passing through the human heart needs to be at least 50 µA before ventricular fibrillation occurs,[39,45,46] the American National Standards Institute (ANSI) on December 2, 1993, set 10 µA as the maximum leakage of current allowable through electrodes or catheters contacting the heart. This amount of current is considerably less than the peak electric current generated by an implanted pacemaker during a single pulse (0.1 to 10 µA). Because 2 mA is the LIM warning level, the LIM does not provide protection against microshock hazards.

ECG-monitoring electrodes are electrically isolated from power circuits in the monitor by an isolation transformer in the main unit, a second level of isolation (see also Chapters 44 and 47). However, an anesthesiologist who wishes to perform intravenous or intracardiac ECG monitoring, as occurs during P wave–guided brachial placement of a central venous pressure catheter, should have qualified personnel check the ECG monitor for current leaks. In some ECG and electroencephalographic (EEG) systems, electrode signals from the patient are translated into optical signals by a battery-powered amplifier with a photodiode output that is optically coupled to the main ECG or EEG unit, an even more thorough second level of isolation.

Endovascular procedures performed by interventional neuroradiologists include the placement of procoagulant coils inside certain types of intracranial aneurysms. The coils are directly placed in aneurysms with a considerable depth and a narrow neck. However, when the aneurysm has a wide entrance and a short depth, concern is high that a loose coil could get carried away and act as a thrombus wherever it lodged. Therefore in such cases, a detachable coil is generally used to completely occlude the unfilled region. After being convinced of the coil's location and stability, the angiographer sends a short electrical pulse through the coil, as though it were a unipolar surgical knife, which causes detachment at a known location. Although anesthesiologists should be aware of potential electrical hazards that come with new techniques,[47] they should be comfortable about electrical issues in detachable coils inasmuch as they do not cause macroshock or microshock.

ELECTROSURGERY

Most concerns with electrical safety in the operating room arise from the use of electrosurgical units because they are capable of causing electrical shock, burns, explosions, arrhythmias, and disturbances in pacemaker functioning.[48] Electrosurgical units operate at frequencies of approximately 300,000 to 2,000,000 cycles/sec (300 kHz to 2 MHz) to minimize the likelihood of ventricular fibrillation. During electrosurgery, high currents enter the patient through a small-area surface electrode at the tip of the cutting tool. The combination of high resistance (R), which is attributable to the small area, and high current (I) causes local tissue heating proportional to I^2R, which produces cutting or coagulation. The tip of the electrode is also designed to produce lower current densities (low I^2R) at points farther than a few millimeters from the electrode tip. Figure 109-6 shows fanning out of the electric current. Electrosurgery is therefore a form of highly controlled localized burning of tissue.

Concern about suffering an unwanted electrosurgical burn is a legitimate issue for patients with metal jewelry that pierces the body, such as umbilical rings, nipple rings, earrings, and tongue studs, among others. Obviously, the best solution is to remove all metal jewelry before surgery, and its removal is highly recommended. However, removal of metal jewelry can, at times, be cumbersome, burdensome, inconvenient, or simply unwanted by the patient. In such instances, leaving the jewelry in place is reasonable if the site of electrosurgery is far from the jewelry and if the jewelry is not directly within the path of the electrical current that travels from

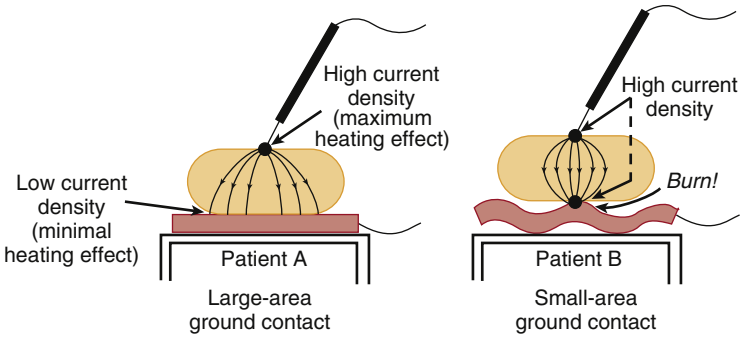

Figure 109-6. Schematic diagram shows the flow of electric current through the body when small- or large-area grounding pads are used.

the cutting electrode to the grounding pad. For example, a nipple ring should be removed if surgery is on the breast with the nipple; if a nipple ring is allowed to remain on the opposite breast, then the grounding pad should not also be on the patient's opposite side. As previously mentioned, in the case of no metal jewelry, electrical current rapidly fans out as it leaves the cutting electrode. The concern with metal jewelry is that it might re-concentrate electrical current that passes near it and thereby cause a burn. Thus metal jewelry that is left in contact with the skin should be held with tape in as large a contact area as possible. For example, a metal umbilical ring should be taped flat against the abdomen. If instead of a grounding pad a capacitive-coupled return electrode is used, then all metal jewelry should be removed. Because all metal objects have a surface area that can form capacitive coupling with a capacitive-coupled electrode, its use in certain circumstances can dangerously increase the risk of burns.

Because smoke often appears where there is fire, concern has been expressed regarding the safety of inhaling smoke from electrocautery. One group, assisted by the National Institute of Occupational Safety and Health, used the Ames test to examine the potential mutagenicity of electrocautery smoke collected during breast surgery.[49] Although the compounds collected were mutagenic, it is not known whether electrocautery smoke represents a serious health risk to operating room personnel. Nevertheless, the study recommended that surgeons minimize the production of electrocautery smoke and exposure of human beings to the smoke.

Because smoke is often present where there is fire, it is also important that nonflammable materials be used during electrosurgery. Fires have occurred in operating rooms because highly combustible surgical boundary drapes were placed close to electrosurgical units.[50] The smoke from such fires can contain toxic substances.

From the preceding discussion, finding that electrosurgical units are powerful enough to provide excess electric currents capable of causing extensive tissue burns is not surprising. Surgical patients who become wet with blood, saline, urine, or other conducting fluids can form electrical contacts with the operating table, the ground, or other conductors, including monitoring electrodes and surgical retractors. Such contacts can create potentially dangerous current pathways. For example, current from an electrosurgical unit may enter a patient through the grounding pad and return to the unit through one or more ECG electrodes. In this situation, the electrosurgical unit can provide current that burns the patient but never passes through the tip of the electrosurgical pencil used in the surgical procedure.

The dangers of electrosurgery in a wet environment, especially the possibility of establishing ground faults through wet connections, account for the presence of an isolation transformer (and LIM) in modern operating rooms. As noted earlier, GFCI outlets protect against ground faults by causing sudden deprivation of power, whereas isolation transformer setups turn on an LIM alarm instead and thereby permit less disruption. Loss of electric power during cardiac surgery can be a serious concern, which is one reason why anesthesiologists must know how to hand-crank cardiopulmonary bypass pumps.[51] Desflurane vaporizers require electricity for operation. The NFPA requires first ground fault detectors in operating rooms. However, anesthesiologists, surgical colleagues, and hospital administrators are free to choose GFCIs or isolation transformers with LIMs, whichever best suits local conditions and practices.[26,27]

UNIPOLAR ELECTROSURGERY

Understanding the difference between unipolar and bipolar electrosurgery is important. In both cases the surgeon applies electrodes directly to tissue to produce electric currents that burn and cut or burn and coagulate. In unipolar electrosurgery, the more common of the two, the electric current that enters the patient through one electrode travels throughout the body and is collected outside the surgical field by a large, wide-area, well-jelled grounding pad (i.e., the dispersive electrode). Skin burns can occur if the grounding pad is dry (i.e., most of the conducting gel is gone) or is otherwise in poor contact with the patient. In such situations, the electric current collected by the grounding pad is required to traverse small surface areas, and these inherently have high electrical resistance. Because I^2R can substantially increase at such small areas of grounding pad contact, increases in resistance can lead to electrical burns of the skin.[52] Electrical burns have also occurred at the site of ECG leads when the grounding pad was defective and the leads became an alternative path for returning high-frequency electrosurgery currents.[53,54]

A significantly more powerful unipolar electrosurgical tool, the argon beam coagulator (ABC), has become popular among surgeons who must cut or coagulate vascular tissue.[55] Operating room personnel unfamiliar with the design and use of the ABC can easily mistake it for an argon laser because a well-collimated, brightly colored beam of argon light glows at the tip of the electrosurgical pencil. The glow, which has the same color as light emitted from an argon laser, represents a continuous electrical discharge in a small, flowing column of argon gas having a density that supports electric current. The ABC was developed to solve a problem occurring with metal coagulation or cutting tips. In regions where a lot of blood is present, electrosurgical currents result in the adherence of sticky, burned tissue to the tip of the cutting electrode, thus electrically insulating it and making further use impossible until the tissue is scraped off. Surgery must stop while the tip is scraped clean. When large areas of vascular tissue must be traversed (e.g., in hepatic resection or repair of traumatic lacerations of the liver), conventional metal tips become difficult surgical tools. With the ABC, no metal surface is present to attract sticky, burned tissue. The tip of the cutting electrode is a cushion of argon gas that can transmit current as long as it touches tissue.

The anesthesiologist must understand that the use of the ABC means that significant electrosurgery is taking place and that safety measures are more important than ever. As in conventional electrosurgery, surgical cutting and coagulation with the ABC come from local I^2R heating losses at the point where the electrosurgical pencil

is applied—in this case, where the argon gas meets the tissue. ABC operation therefore resembles conventional arc welding. Because the ABC is perhaps the ultimate spark generator, its use illustrates the extent to which one safety concern that was prominent in the days of inflammable anesthetic gases has been abandoned.

Some body locations are never safe for unipolar electrosurgery. This situation is frequently encountered during neurosurgery and in patients with implanted cardiac pacemakers. The solution is bipolar electrosurgery (see the discussion that follows). Recently, during laparoscopic removal of a subphrenic mass in a patient with an intracardiac Swan-Ganz catheter, ventricular fibrillation occurred with unipolar electrosurgery, the most common type used in laparoscopic surgeries. One can ask whether the cause was stray current from the active electrode on its way to the grounding pad or capacitive coupling to the intracardiac catheter, issues related to things discussed so far. Both reasons might suggest it prudent to consider bipolar electrosurgery during laparoscopy when cautery is needed close to the heart.[2,56]

BIPOLAR ELECTROSURGERY

In bipolar electrosurgery, as in unipolar electrosurgery, current enters the patient through one electrode. However, instead of traversing the body to be collected by a dispersive electrode at a site remote from the surgery, injected current is collected millimeters away from the first electrode by a second electrode that appears identical to the first. Two pencil-point electrodes arranged at the tips of a forceps are used to perform bipolar surgery. Electric current flows through the patient's tissue only at the site of surgery, where it is confined to the few millimeters between the electrodes. Bipolar devices are required when electrosurgery is performed on an ovary or a fallopian tube. Several cases of fatal bowel injury have occurred after female sterilization with unipolar devices.[3,4]

Patients with an implanted pacemaker or an automatic implanted cardioverter-defibrillator (AICD) frequently come to the operating room for procedures requiring electrosurgery (see Chapter 48). For such patients, bipolar devices should be used whenever possible. Nevertheless, interference with the pacemaker can occur on rare occasions in such cases. Regardless of the type of electrosurgery being performed, an AICD should be turned off during surgery because an unexpected intraoperative delivery of its 3- to 20-J defibrillation shock could result in injury not only to the patient but also to the surgeon and others near or in contact with the patient. People in contact with the patient at the moment of an AICD's defibrillation shock can also receive a dangerous, painful electrical shock. Placement of a magnet over an AICD turns off its defibrillation feature and converts it to pacemaker mode alone. However, magnet placement does not affect the pacing program of a programmable pacemaker. (All AICDs have pacemaker circuitry.) Zoll pads connecting the patient to an external defibrillator/pacer should be fully operational when the AICD's defibrillator is turned off, with the obvious exception being situations involving *code* resuscitation, such as when an advanced cardiac life support (ACLS) team has defibrillator pads ready for use. If anesthesiologists on ACLS teams arrive at a situation during which cardiac arrest has occurred and find that the patient has an implanted pacing device, then they should immediately learn whether the device is an AICD to ensure that precautions such as magnet placement can be taken to avoid shocking the code blue team during resuscitation.

Because so many different types of pacemakers are now in use, the plan for avoiding intraoperative pacemaker interference must be based on the details of each particular case.[5,6] In general, the likelihood of interference depends not only on patient factors, such as the type of pacing electrodes (i.e., unipolar, bipolar) and how well the pacemaker circuitry is shielded, but it also depends on surgical factors, such as the proximity of the cutting electrode's discharge and the path of the electric current within the patient. In all such cases, grounding pads should be placed as far away as possible from the pacemaker and its wires. In addition, if possible, the path from the grounding pad to the surgeon's electrosurgical cutting electrode should not traverse the path from the pacemaker circuit to the heart. Because of capacitive coupling, electrosurgical noise can potentially affect either the heart directly or disrupt processing by the pacer's program in a programmable pacemaker. Such interference can result in complete heart block and no pacing or in severe tachycardia. Descriptions of incidents can be found in numerous recent reports.[7,57-60]

Although anesthesiologists should always be prepared to reset a pacemaker to the asynchronous mode (i.e., regular, uninhibited pacing), assuming that magnet placement always converts a pacemaker to asynchronous mode, which is the mode needed by patients dependent on a pacemaker, is no longer correct. Because of pacemaker diversity, preoperative consultation with an electrophysiology cardiologist is always appropriate and often essential, as is preoperative assurances that programmable pacemakers have recently been interrogated and found to have no faults and then properly reprogrammed. Although some precautions with programmable pacemakers can be easily understood, such as turning off rate-sensing features, consultation with someone with the proper expertise is often the only way to review the many essential details of the pacemaker.[6,54] Most hospitals have a cardiologist on call who can be reached for an immediate electrophysiology consultation.

Finally, the anesthesiologist should be familiar with the use of isoproterenol, a pharmacologic pacer, which should be available on the anesthesiologist's drug cart. Concentrations of 1 µg/mL are appropriate for small bolus injections.

SAFE PRACTICE

One approach to safe practice involves having complete, efficient checklists to consult for each concern, such as fire safety or safety for patients with pacemakers. The anesthesiologist should go through the checklists relevant to every case, just as the pilot and copilot of a commercial airplane do for air travel. Years ago the word *vigilance* was used more commonly to describe how the

anesthesiologist's eyes and mind are repeatedly and systematically scanning everything in the operating room. Vigilance is now used more appropriately to describe the virtues of sophisticated electronic monitors and alarms in the operating room. However, no electronic monitors can direct the anesthesiologist's attention to issues "outside the alarms," to issues related to organization and planning, such as having enough electric power outlets in the operating room to accommodate all the equipment while also avoiding circuit overloads. Limitations of checklists include the danger of "finding only what one looks for and recognizing only what one knows."[61] Although safe practice is boosted by checklists, anesthesiologists should also always be vigilant for new problems. Thus the guidelines that the Key Points present at the beginning of this chapter should be considered a minimal summary that directs safe electrical practice, with a natural assumption that many anesthesiologists will add refinements and elaborations.

Chapter 110

Environmental Safety and Chemical Dependency

THEODORA KATHERINE NICHOLAU • CHRISTOPHER G. CHOUKALAS

Key Points

- Escape of anesthetic vapors into the operating room atmosphere is unavoidable. In the United States, the limits of exposure to atmospheric waste gases are set by the National Institute for Occupational Safety and Health (NIOSH), which recommends a time-weighted average of 25 ppm for nitrous oxide and a ceiling of 2 ppm for volatile anesthetics.
- Based on high-quality data, trace concentrations of anesthetics in the ambient air of the operating room probably do not present a health hazard.
- Occupational exposure to radiation comes primarily from x-rays scattered by the patient and surrounding equipment. A distance of 3 feet from the patient is recommended to minimize physiologic damage from occupational exposure, and a distance of 6 feet from the patient provides the same protection as 2.5 mm of lead.
- Occupational exposure to human immunodeficiency virus (HIV) and hepatitis B and C is most often the result of a percutaneous injury. The risk of transmission is generally infrequent but is most often from hollow-bore needles, needles contaminated with visible blood, and exposure to a source patient with high viral titer.
- Postexposure prophylaxis is recommended after occupational exposure to HIV or hepatitis B virus. The U.S. Public Health Service–recommended guidelines for postexposure prophylaxis are available on the Centers for Disease Control and Prevention (CDC) website. The National Post-Exposure Prophylaxis Hotline is open 24 hours a day for expert advice (1-888-448-4911).
- To minimize occupational exposure to bloodborne pathogens, standard precautions should be practiced at all times. The appropriate barrier precautions for anticipated contact with blood or body fluids are published by the CDC. Whenever possible, needleless systems should be used.
- Sleep deprivation has an adverse effect on physician mood, cognitive function, reaction time, and vigilance. Although sleep deprivation and fatigue clearly adversely affect clinical performance, their full impact on patient outcome has been difficult to determine.
- Anesthesiologists are overrepresented in drug treatment centers. The preference for and access to potent opioids contribute to the prevalence of drug addiction among anesthesiologists.
- The rate of drug-related deaths is more than twice as frequent in anesthesiologists as in internists.
- Although many successfully treated anesthesiologists return to the practice of anesthesia, they have a significant relapse rate. The chance of relapse is most frequent in physicians who become addicted to potent narcotics early in their career. Successful recovery requires a lifelong commitment to treatment. In some cases, leaving anesthesia as their specialty is the only solution.

The practice of anesthesiology exposes its practitioners to a variety of risks unique among medical specialties. Some of these risks are tangible or physical, such as waste anesthetic gases and communicable disease, whereas others are more insidious and psychological, such as stress, fatigue, and the pitfalls of substance abuse. Each of these risks can be mitigated, but probably not eliminated. In the case of physical exposures such as anesthetic gases, radiation, and bloodborne pathogens, efficient gas scavenger systems, needleless systems, needle-shielded intravenous

(IV) lines, standard precautions, and postexposure prophylaxis (PEP) protocols are now commonplace in contemporary anesthesia practice. The less tangible risks are, not surprisingly, more difficult to reduce. Although instituting work hour restrictions with house staff may limit fatigue, doing so may not improve patient outcomes, particularly when the restriction does not apply to practicing physicians. Substance abuse remains a problem with a multifactorial etiology and few satisfactory solutions. This chapter examines the relative risk of each of these environmental and situational hazards and reviews the measures one can take to avoid them. Awareness is essential to safe anesthesia practice.

ANESTHESIA GASES

Trace amounts of waste gases enter the operating room atmosphere each time an inhaled anesthetic is delivered. The possible effects of occupational exposure include cognitive impairment and reproductive problems (e.g., spontaneous abortions and developmental defects in children).[1] Various agencies have imposed limits for occupational exposure, but these are generally derived arbitrarily and are outdated. Although many strategies exist to mitigate exposure, imposed limits are routinely exceeded in clinical practice.

EXPOSURE LIMITS

Concentrations of waste gases are reported on a volume-per-volume basis in parts per million (ppm). For example, 100% sevoflurane, such as in the saturated vapor above the liquid in a bottle or vaporizer, has a concentration of 1 million ppm. Similarly, 2% sevoflurane represents 20,000 ppm. The National Institute for Occupational Safety and Health (NIOSH) recommends a limit of 25 ppm for nitrous oxide (N_2O) and a ceiling of 2 ppm for volatile anesthetics in the ambient air of the operating room.[2] When used in combination with N_2O, the ceiling for volatile anesthetics is reduced to 0.5 ppm.[3] In 1989, the American Conference of Governmental Industrial Hygienists incorporated duration of exposure into their guidelines and suggested a limit of a time weighted average of 50 ppm N_2O over an 8-hour work day.[1] The Occupational Safety and Health Administration (OSHA) published a detailed summary of causes and effects of occupational exposure to anesthetic gases, but this has not been updated since the year 2000, and it mimics the exposure limits set by NIOSH 2 decades earlier.[1] In 2012, the National Institutes of Health Division of Occupational Health and Safety published updated occupational exposure limits for sevoflurane (2 ppm) and N_2O (50 ppm), as well as for older anesthetics no longer in routine use (Table 110-1).[4]

To put these figures into perspective, assuming that 1 mL of a volatile liquid anesthetic produces 200 mL of vapor, that volume of liquid spilled in a closed room measuring 20 × 20 × 9 feet results in a concentration of vapor of nearly 2 ppm. The maximal concentration of halothane recommended by NIOSH is severalfold lower than the lowest concentration that humans can recognize. Only 50% of volunteers were able to detect halothane at concentrations as low as 33 ppm. The threshold of perception ranges from less than 3 to more than 100 ppm.[5] If the anesthetic can be smelled, its concentration is well above the maximum recommended level.

The NIOSH exposure limits were developed in the late 1970s for N_2O and halothane and, unfortunately, have not been updated since, nor do they include newer volatile anesthetics. These levels were selected somewhat arbitrarily, based on the lowest level known at the time to cause side effects (50 ppm N_2O or 1 ppm of halothane caused cognitive impairment in dental students[6]), juxtaposed against the level that could be easily and practically achieved.[7] Subsequently, it was realized that the subjects were Mormon, a subgroup likely more sensitive to depressant drugs; the general population may not be susceptible to gases at these low levels.[8] More recent work in a general, albeit small, sample showed cognitive impairment at 50 ppm,[9] and in any case, levels are routinely found by researchers to be well above these NIOSH levels.[10,11]

Waste N_2O and volatile anesthetics in the absence of scavenging may approach concentrations as high as 3000 and 50 ppm, respectively.[5] Although the concentration of waste gases can be well controlled with proper scavenging, in practice, the levels recommended by NIOSH are not consistently met in the routine delivery of anesthesia. Induction of anesthesia through a mask with likely leaks, disconnection of circuits, the use of laryngeal mask airways, and uncuffed endotracheal tubes all contribute to operating room contamination. Although exposure to anesthetic gases is more common in pediatric anesthesia (see also Chapter 93), during which induction of anesthesia and uncuffed endotracheal tubes are common, the introduction of the laryngeal mask airway to anesthesia practice probably increases operating room exposure to waste gases in adult cases as well. One study of inhaled induction of anesthesia and maintenance with sevoflurane and N_2O in adults resulted in violations of NIOSH standards 50% of the time.[12]

The universal use of scavenging systems can lead to a false sense of security among operating room personnel. Kanmura and colleagues found abnormally high ambient concentrations of N_2O in 402 delivered anesthetics, of which 42% were the result of ventilation through a mask,

TABLE 110-1 PROPOSED LIMITS OF EXPOSURE TO INHALATIONAL ANESTHETIC AGENTS

Agent	NIOSH (ppm)*	NIH (ppm)†
Nitrous oxide	25	50
Halothane	2	50
Isoflurane	2	2
Sevoflurane	–	2

*Data from National Institute for Occupational Safety and Health: *Criteria for a recommended standard: occupational exposure to anesthetic gases and vapors*, DHEW (NIOSH) publication no. 77-140, Washington, DC, 1977, U.S. Department of Health, Education and Welfare.

†National Institutes of Health: *Waste anesthetic gas (WAG) surveillance program,* 2012. <http://www.ors.od.nih.gov/sr/dohs/Documents/Waste%20Anesthetic%20Gas%20%28WAG%29%20Surveillance%20Program.pdf/> (Accessed 06.12.13.)

19.2% originated from a disconnected scavenging system, 12.5% were the consequence of a leak around pediatric endotracheal tubes, and 11.5% were the result of equipment leakage.[13] Although dysfunction of the scavenging system was not the most common cause of ambient contamination, scavenging system disconnections led to higher contamination levels than levels resulting from inhaled induction of anesthesia. Furthermore, all the scavenging system disconnects in this study were due to human error rather than equipment failure.[13] Because most anesthesia machines are not equipped to recognize disconnected scavenging systems, failure of the system may not be readily apparent. Thorough understanding and diligent maintenance of anesthesia scavenging systems is essential to comply with NIOSH standards and, more importantly, to minimize operating room exposure.

Occupational exposure is not limited to operating room staff; patients continue to exhale trace amounts of N_2O for 5 to 8 hours after arrival in the postanesthesia care unit (PACU).[14] Sessler and Badgwell measured the concentrations of gases at the lapel level of recovery room nurses during the first hour of PACU care in patients who had received inhaled anesthetics.[15] In this study, breathing zone anesthetic concentrations were in excess of NIOSH recommendations in 37% of patients who received isoflurane, 87% of patients who received desflurane, and 53% of patients who received N_2O. A more recent but similar study reported a much lower average concentration (3.1 ppm) of N_2O in the breathing zone of recovering patients in a Canadian PACU.[14] These studies demonstrate the importance of proper ventilation in PACUs. Both groups reported PACU room air exchanges of 8 volumes per hour; however, much of the air in the Sessler and Badgwell study was recirculated.[15] N_2O levels can be reduced to undetectable levels with air exchanges of 20 per hour, with 25% of each exchange taken from fresh air.[16]

Although OSHA does not currently regulate exposure to N_2O and halogenated anesthetics, this agency does provide guidelines designed to minimize workplace exposure. These include the appropriate assembly and monitoring of scavenging systems, the detection and correction of machine leaks, and the installation of effective ventilation systems.[1] In the operating room, the recommended air exchange rate is a minimum of 15 air exchanges per hour with at least 3 air exchanges of outdoor air per hour. In the recovery room, at least 6 air changes are recommended with a minimum of 2 exchanges of outdoor air per hour. OSHA recommends that air sampling for anesthetic gases be performed on a biannual basis, to document the extent of worker exposure and the effectiveness of scavenging and ventilation systems. Further, OSHA recommends maintaining records of air sampling methods, locations, dates, and concentrations measured, as well as results of anesthesia machine leak tests for at least 20 years. Although OSHA is a government agency, these recommendations are not yet legally mandated.[17]

HEALTH EFFECTS

Anesthetics have been implicated as causes of cancer, abortions, and deficits in cognitive and psychomotor performance. Although early studies with older anesthetics administered to rodents through gavage were associated with carcinogenicity, the route and dose may not be relevant to current anesthetic practice.[17] Newer anesthetics, when tested by the inhaled route, did not show such an association, although the newest inhaled anesthetics, sevoflurane and desflurane, were not tested.[17]

The possibility that chronic exposure to anesthetic waste gases could result in adverse health effects was first appreciated in the late 1960s, when a report of potential harm appeared in the Russian literature. In 1967, Vaisman reported an increased incidence of abortions among female anesthetists. Specifically, this study noted 18 spontaneous abortions in 31 pregnancies.[18]

After this initial report, many retrospective studies followed. Of these, three large studies conducted during the mid-1970s in the United States and the United Kingdom all concluded that the prevalence of abortion was substantially higher in female anesthesiologists than in female physicians working outside the operating room. Studies in this era also concluded that the incidence of congenital anomalies in children of male and female anesthesiologists was higher than in the control groups of physicians. In addition to these reproductive effects, meta-analysis of six of these early studies linked the exposure to anesthetic gases to hepatic disease in male anesthesiologists[19] and cervical cancer, liver disease, and kidney disease in female anesthesiologists.[20]

Subsequently, many reports criticized these original studies, citing faulty methodology as a basis for erroneous conclusions that were disproved when the data were reanalyzed. Biases may have arisen for many reasons, including inadequate response rates, lack of control for confounding variables (e.g., age, nutrition, obstetric history, drinking, smoking, exposure to methylmethacrylate, and radiation), lack of quantification of the exposure to anesthetic vapors, losses to follow-up, inappropriate comparison groups, and lack of independent verification of the reported data.[19-22] Even the titles of some questionnaires, such as "Effects of Waste Anesthetics on Health" and "Anesthetic Practice and Pregnancy," may have introduced selection and recall bias by stimulating respondents who work with anesthetics to overreport their past experiences.[23,24] Nevertheless, as late as 1997 a meta-analysis of more than 19 studies completed between 1984 and 1992 reported a relative risk of abortion in female subjects exposed to anesthetic gases to be 1.48 (confidence interval [CI] 95%, 1.4 to 1.58).[25]

Given the persistence of this controversy, a Task Force on Trace Anesthetic Gases was convened by the American Society of Anesthesiologists (ASA) Committee on Occupational Health of Operating Room Personnel. The task force analyzed data from all of the available epidemiologic studies at the time and concluded that no proof of an association between occupational exposure to waste anesthetic gases and adverse health effects existed. In addition to the analysis of retrospective studies, their report, published in 1999 and not since updated, cited data from a prospective survey in the United Kingdom.[26] This study monitored 11,500 female physicians in the United Kingdom and documented occupation, work practices, lifestyle, and medical and obstetric history, as well as hours

of exposure and the use of scavenging equipment. This report showed the incidence of infertility, spontaneous abortion, and children with congenital abnormalities in female anesthesiologists to be the same as that in other physicians.[26] A more recent review described the scientific evidence for hazard from trace occupational exposure as weak,[20] and the stance of the ASA is that "There is no evidence that trace concentrations of waste anesthetic gases cause adverse health effects to personnel working in locations where scavenging of waste anesthetic gases is carried out."[17] However, most of the studies have significant limitations, and routine occupational exposure may exceed that considered safe.

COGNITIVE PERFORMANCE

The NIOSH recommendations arose from a study by Bruce and Bach in which healthy volunteers in the laboratory suffered a decrease in psychomotor performance when exposed to concentrations of N_2O as low as 50 ppm, alone or in combination with 1 ppm of halothane. The same study showed that 25 ppm of N_2O combined with 0.5 ppm of halothane had no effect.[2,27] Subsequently, three other groups of researchers studying volunteers in laboratories were unable to confirm the findings of Bruce and Bach. The lack of agreement among investigators has led some to conclude "that there is no convincing evidence that anesthetics in concentrations equal to those found in unscavenged operating theatres have any effect on the psychomotor performance of healthy subjects in the laboratory."[28] A study conducted in volunteers in an operating room during normal clinical activities in which trace concentrations of N_2O and halothane ranged from 0 to 2300 and 0 to 37 ppm, respectively, also failed to detect impairment in psychomotor performance.[29] These studies suggest no definitive cutoff above which psychomotor performance is depressed. Hence occupational limits vary among countries. The standards set by the regulating bodies in Canada, United Kingdom, and Western Europe are often less stringent than the standards set in the United States.[5]

RADIATION

The anesthesiologist is routinely exposed to both ionizing and nonionizing electromagnetic radiation. Ionizing radiation is primarily from x-rays and occasionally from radioactive isotopes that release gamma rays, and the nonionizing radiation is from lasers. Less common is contact with ionizing radiation from radioactive isotopes that release either alpha or beta particles. Ionizing radiation has enough energy to create both free radicals and ionized molecules in tissues by driving electrons completely out of their stable orbitals. If the radiation exposure is severe enough, tissues may be destroyed, or chromosomal changes may cause malignant growth. Nonionizing radiation may excite electrons to move from the ground state to higher orbitals in molecules, but the electrons remain in the molecule. In this case, damage to tissues may result from the heat produced by the absorbed radiation.

IONIZING RADIATION: X-RAYS

In the past, exposure to radiation occurred mostly in the operating room with the use of portable fluoroscopy and x-ray machines. Since 2000, however, in concert with the rise in the provision of anesthesia services for imaging and image-guided procedures, anesthesiologists are increasingly at risk for exposure to larger doses of radiation. The advancement of endovascular surgery has led to a marked increase in the numbers of procedures performed in the radiology suite, thus significantly increasing exposure of anesthesia personnel to ionizing radiation. Because this type of radiation is undetectable with our normal senses, a basic understanding of its features will permit one to keep personal exposure to a minimum. Film badges, although not protective, provide a means of monitoring exposure.

Exposure is commonly reported in units of rem (roentgen equivalents man). A rem is essentially a measure of the biologic damage from radiation adjusted to apply to all tissues.[30] Estimates of radiation exposure from natural sources vary, depending on geographic location. The average in the United States ranges from 80 to 200 millirems (mrem) per year. Natural radiation comes primarily from cosmic rays (≈40 mrem at sea level, with an increase of 10 mrem/1000 feet), as well as from radioactive compounds found in soil, brick, and concrete. For most physicians, the additional radiation from occupational exposure is no more than that from natural sources. Although the maximum yearly occupational exposure is mandated to be no more than 5 rem, radiology personnel rarely absorb more than 10% of this dose. Their largest source of exposure is fluoroscopy. During pregnancy, radiography personnel are advised to limit their exposure to a maximum of 500 mrem.[31]

Occupational exposure to radiation comes primarily from x-rays scattered by the patient and the surrounding equipment, rather than directly from the x-ray generator itself.[32] One chest radiograph results in approximately 25 mrem of exposure to the patient; procedures requiring multiple films occasionally involve more than 1 rem. The amount of radiation generated during fluoroscopy depends on how long the x-ray beam is on. Just as light is reflected from surfaces, x-rays are reflected from the surfaces on which they impinge. This scattering accounts for most occupational exposure. Because the intensity of scattered radiation is inversely proportional to the square of the distance from the source, the best protection is physical separation. A distance of at least 3 feet from the patient is recommended. Six feet of air will provide protection the equivalent of 9 inches of concrete or 2.5 mm of lead.[33] Although they are uncomfortable, aprons containing the equivalent of 0.25 to 0.5 mm of lead sheet are effective in blocking most scattered radiation, and such devices are recommended to be worn whenever an exposure risk is present.[34] Uncovered areas, such as the lens of the eye, still bear the risk of injury.[32] Intraoperative radiation measurements have shown that exposure is inversely related to the experience of the surgeon, and the amount of radiation received by the anesthesiologist during orthopedic procedures is unmeasurable.[35]

Radiation physicists recommend adhering to the ALARA program: radiation exposure should be kept as low as reasonably achievable. Staff members of departments of radiology have been extensively educated in the safety of occupational exposure. Attention to recommended methods of protection will limit exposure to minimal levels. Technologic innovation leading to advances in imaging technology and industrial design may further limit exposure.[36,37]

NONIONIZING RADIATION: LASERS

Laser is an acronym for light amplification by stimulated emission of radiation (see also Chapter 88). Lasers produce infrared, visible, or ultraviolet light. Although the radiation from lasers is nonionizing, it is potentially unsafe both because of its intensity and because of the matter released from tissues during treatment.

Lasers are used in many surgical specialties, including ophthalmology, plastic surgery, gynecology, neurosurgery, urology, head and neck surgery, and gastrointestinal surgery. A surgical laser produces intense, focused electromagnetic radiation to cut or destroy tissues. The radiation is usually infrared or visible light and is created in a "laser medium" that is stimulated by high-intensity energy to release photons of identical wavelength (coherent or monochromatic light) from a laser chamber. The material in the medium (e.g., carbon dioxide, argon) is responsible for the wavelength produced by the laser. Of those in common clinical use, carbon dioxide and neodymium:yttrium-aluminum-garnet (Nd:YAG) lasers emit light in the far-infrared and near-infrared wavelengths, respectively; argon and tunable dye lasers produce visible light.[38]

Eye injuries are the greatest risk to personnel working near lasers. Strict standards for protection have been developed on the basis of current understanding but are subject to periodic revision as more experience is gained with these instruments. Either direct exposure or reflected radiation may cause eye damage. Injuries include burns to the cornea and retina, destruction of the macula or optic nerve, and cataract formation. Protective eyewear is designed to filter out the radiation produced by a specific type of laser while still permitting vision. For example, clear plastic lenses block the far-infrared (10.6 μm) radiation from carbon dioxide lasers but provide no protection against the near-infrared (1060 nm) radiation emitted by Nd:YAG lasers. The type of protection provided by a given filter is marked on the frame of the goggles and should be checked before use. Filters that are scratched should not be used. Because certain filters block portions of the visible spectrum, it is prudent to confirm preoperatively that patient monitors can be seen and interpreted correctly with goggles in place. Protective eyewear is recommended for all personnel because reflected radiation can be as hazardous as direct radiation, and the intensity is not diminished significantly in the distances traveled in the average operating room.[38]

Until recently, the plume (i.e., the vapor and cellular debris produced during laser surgery) was not considered to be harmful. Now, concern exists that the plume may present a significant risk. The median size of particles in plume samples obtained intraoperatively is 0.31 μm in diameter (range, 0.1 to 0.8 μm). Most surgical masks do not trap such small particles.[39] Even after filtration of particles greater than 0.5 μm in diameter, exhaust smoke from tissues treated with a carbon dioxide laser causes pulmonary lesions in laboratory animals. If all particles larger than 0.1 μm are scavenged, no lung damage occurs, thus pointing out the importance of scrupulous removal of the plume.[40] Under experimental conditions, viable bacteria have been recovered from the plume emanating from laser irradiation.[41] Intact DNA from human papillomavirus (HPV) has been detected in the vapor from both laser-treated plantar warts and genital condylomata.[42,43] Human immunodeficiency virus (HIV) proviral DNA has been found in laser smoke produced by vaporizing cultures of HIV-positive cells. Although these experiments, which used tissue cultures, do not replicate the clinical situation, they stress the importance of strict attention to smoke removal.[44] With adequate evacuation and filtration using equipment specifically designed to scavenge such vapors, it is unlikely that operating room personnel will be contaminated by laser-dispersed HPV DNA.[42] However, one case report documented the appearance of laryngeal papillomas in a surgeon who had previously treated (with a laser and without the benefit of a laser smoke evacuator) several patients infected with anal condylomata. Tissue from the surgeon's laryngeal tumors contained HPV DNA types 6 and 11, the same viral types that are commonly harbored by anogenital condylomata. Although not conclusive, these findings suggest that the laryngeal papillomas may have been caused by inhaled virus particles.[45] Hence, all vaporized debris should be scavenged.

INFECTIONS

Hepatitis B virus (HBV), hepatitis C virus (HCV), and HIV are the most concerning bloodborne pathogens for which health care workers are at risk. Of 493 anesthesia personnel surveyed in a multicenter study, 32% reported having been stuck with a contaminated needle at least once in the preceding 12 months. Of those, only half sought treatment.[46] The risk of infection is more frequent with hollow-bore needles than with solid needles and is further increased with large-bore needles and deep intramuscular injection.[47] In a study evaluating percutaneous injuries (PCIs) in anesthesia personnel, nearly 90% of the injuries were from hollow-bore needles, were self-inflicted, most commonly involved the nondominant hand, and were deemed preventable. Most of the injuries occurred during disposal of contaminated needles.[48] *Mycobacterium tuberculosis* (the agent of tuberculosis [TB)], which is transmitted primarily by respiratory droplets, represents a significant source of occupational risk, and routine screening measures are frequently employed.

HEPATITIS B

In the 1980s, it was estimated that 200 to 300 health care workers would die annually from the effects of HBV. Fortunately, the introduction of an effective vaccine for

hepatitis B dramatically decreased the incidence, morbidity, and mortality of the disease.[49] Before this, the development of covert seropositivity for HBV during residency was common. In a multicenter study, the overall prevalence of serologic indicators for HBV in anesthesiology residents who had received neither hepatitis vaccine nor hepatitis B immune globulin (HBIG) was 17.8% in 267 tested. Most seropositive residents were unaware of having been exposed to HBV. No correlation was found between the incidence and geographic location, but the incidence of seropositivity increased in parallel with clinical experience. Thirty percent of residents with more than 11 total years of experience, including their current residency and previous work in other specialties, were seropositive for HBV.[50]

An estimated 800,000 to 1.4 million people in the United States have HBV infection, most of whom are unaware of their infected status.[51] Although the incidence of seroconversion after parenteral inoculation with HBV can be as high as 40%, the rate of conversion is proportional to the infectivity of the host and the magnitude of contact with the blood.[52] HBV is hardy; neither treatment at 60° C for 4 hours nor the use of disinfectants containing phenol or chlorine is sufficient to inactivate the HBV particle with certainty, and it remains viable on needles, environmental surfaces, and gloves for longer than 14 days.[53] Because gloves do not guarantee protection from accidental needlestick and because HBV is relatively resistant, accidental contact with live virus may occur in the course of patient management and also during cleaning of equipment. Active immunization of seronegative health care workers with hepatitis B vaccine is imperative for prophylaxis against infection. Since the late 1980s, the vaccine has been synthesized in yeast by the use of recombinant DNA, thus eliminating prior concerns about the potential infectivity of vaccines synthesized from the sera of hepatitis B surface antigen (HBsAg)–positive patients.[54] The current OSHA standard on bloodborne pathogens mandates that employers make vaccination against HBV available at no cost to all employees who have a reasonable chance of exposure to the virus.[55] Unvaccinated anesthesiologists who suspect HBV exposure with an HBsAg-positive source should be passively immunized with HBIG and begin a series of three injections of hepatitis B vaccine.[49] The combination of HBIG and HBV vaccine prophylaxis is believed to be 85% to 90% effective, whereas either treatment alone is 70% to 75% effective.[56]

HEPATITIS C

Like HBV, HCV is transmitted principally by infected blood. Fortunately, the incidence of HCV in stored bank blood has dramatically decreased (see Chapter 61). Using the anti-HCV assay, some investigators have reported only a 1% to 2% incidence of antibody to HCV in health care workers (similar to that seen in volunteer donors), a finding suggesting that HCV is not easily transmitted.[57,58] Reports based on the same assay indicate that transmission of HCV by contaminated needles occurs in less than 4% of these injuries.[59] At present, no effective postexposure treatment is available for HCV exposure. Instead, the recommendations for postexposure management are geared toward early recognition and intervention in chronic disease. Serum immune globulin prophylaxis is of little value because anti-HCV antibodies are not consistently found in production lots of immune globulin.[52] Health care workers who are exposed to HCV should undergo baseline testing for anti-HCV and alanine aminotransferase activity as soon as possible after the injury, with follow-up testing 3 and 6 months after exposure.[56]

HUMAN IMMUNODEFICIENCY VIRUS

HIV is a retrovirus that attaches to cells with $CD4^+$ surface antigen (predominantly helper T lymphocytes) and ultimately replicates by integrating virally produced DNA into the nucleus of the host cell.[47] Fortunately, HIV is a relatively fragile virus, and with proper attention to cleanliness and care in performing invasive procedures, the likelihood that the disease will develop in an anesthesiologist during the course of patient management is very low.

Initial infection with HIV follows within 2 to 10 weeks of inoculation. It is usually a self-limited, nonspecific, febrile viral syndrome lasting 1 or 2 weeks. An individual is considered to be both infected with HIV and infective if the results of both a serologic screening test, the enzyme-linked immunosorbent assay (ELISA), and a supplemental, more sensitive test, either Western blot or indirect fluorescent antibody, are positive. ELISA tests are relatively easy to perform in a clinical laboratory but may be subject to false-positive results. Supplemental tests are time consuming but necessary for confirmation. Results of the tests become positive within weeks of inoculation, but the median latency for the first opportunistic disease may be as long as 11 years.[47]

Although occupationally related infections have been reported, most cases have been attributed to nonvocational contact.[60] According to data published in 2001 by the CDC, 56 probable cases and 138 possible cases of occupationally acquired HIV infection had been reported in the United States.[56] Of these, 48 resulted from percutaneous exposure. Of 1746 reported cases of acquired immunodeficiency syndrome (AIDS) in physicians, only 6 were directly linked to occupational exposure. Injury from a needle is the most likely route of occupationally related HIV infection for anesthesiologists. Although the minimal dose of contaminated blood needed to infect humans is unknown, the likelihood of development of antibodies to HIV is related to the volume of the inoculum and the concentration of viral particles.[49] Consequently, most seroconversions have been associated with deep intramuscular injection of contaminated blood through large-bore needles. The theoretic risk for occupational infection in anesthesiologists over a 30-year exposure period has been calculated to be 0.049% for HIV and 0.45% for HCV, depending on the infectivity of the patient population.[61]

The risk of transmission of HIV from health care workers to patients, with the exception of errors in technique, is extremely small. No infections were identified in more than 19,000 patients who had been treated by 57 infected health care workers, including 29 dentists,

12 surgeons, and 16 physicians in nonsurgical specialties. The only documented infections have been in 6 of 1100 patients treated by a dentist in Florida.[62] With proper attention to routine methods of disinfection, sterilization, and housekeeping, HIV on instruments, surfaces, and laundry can be destroyed. The amount of HIV usually found on contaminated surgical instruments and equipment used in anesthetic management can be killed with "high-level disinfection." Such disinfection involves careful cleaning, followed by exposure either to one of the commercially available germicides or to a 1:10 to 1:100 dilution of sodium hypochlorite (household bleach). These methods annihilate bacteria and viruses but may not be effective against bacterial spores. If the instruments are to be sterilized, they should be thoroughly cleaned first. Contaminated hospital linen should not be washed or rinsed in the operating room or another patient care area; instead, it should be placed directly in sealed, water-impenetrable bags. It can safely be laundered by normal methods. Infective waste, including secretions, blood, and other body fluids, should be incinerated or autoclaved. Alternatively, large volumes of fluids may be discarded in a sanitary sewer.[63] Personal protection and protection of patients are afforded by standard precautions.

PREVENTION OF OCCUPATIONAL EXPOSURE TO BLOODBORNE INFECTIONS

In 1992, OSHA issued comprehensive, enforceable standards designed to minimize occupational exposure to bloodborne pathogens. These standards hold the employer responsible for the maintenance of an exposure control plan that protects all health care workers who have potential for contact with blood or blood products. Protective equipment, including gloves, gowns, and eye shields, must be supplied by the employer at no cost to the employee. The standard also provides for hand-washing facilities, proper receptacles for contaminated materials, methods for handling contaminated laundry, and management of waste, among many other things.[55]

Despite the adoption of standard precautions, contaminated needlestick injuries in health care workers persisted at an unacceptable rate. In 2000, the CDC estimated that more than 380,000 contaminated PCIs occur in hospital workers in the United States on an annual basis.[64] As a result, Congress revised the bloodborne pathogen standard to include the Needlestick Safety and Prevention Act (H.R. S178).[65] This act emphasizes the use of safety devices and needle-free systems, in addition to requiring that employers establish an exposure control plan with records documenting each incident. Since the act was signed into law in November 2000, as part of a comprehensive program to prevent the transmission of bloodborne pathogens in health care workers, NIOSH has called for the elimination of needle devices when "safe and effective alternatives are available." This recommendation was based on accumulating evidence in the 1990s showing that devices with safety features could reduce needlestick injuries.[66]

The risk of contaminated PCI correlates with medical specialty and clinical experience. The Duke Health and Safety Surveillance System tracked blood and body fluid exposures among 24,425 health care workers over a 4-year period ending in 2002. The investigators reported an average rate of 3.9 PCIs per 100 full-time equivalents (FTEs), with higher rates among persons employed for less than 4 years. Anesthesia house staff members reported among the highest rates, at 19.1 PCIs per 100 FTE.[67] Extended work hours were implicated as a major causative factor in a study of PCIs in interns. In this study, 498 PCIs were reported from a total of 17,003 monthly surveys. Whereas lapse in concentration (64%) and fatigue (34%) were the 2 most commonly reported contributing factors, PCIs were significantly more frequent during extended work hours and at night.[68]

Not all PCIs are associated with disease transmission. Rates of transmission of HCV and HIV are quite low (0.5%[69] and 0.3%, respectively),[69-71] but depend on the type of exposure (e.g., hollow-bore, vascular access needles, depth of penetration) and source factors (e.g., viral load). Rates of transmission of HBV are 30% in health care workers without adequate vaccination or PEP.[69] Because most occupational exposures do not result in HIV transmission, the guidelines for PEP weigh the relative risk of infection against the potential toxicity of treatment. The relative risk of infection depends on both the type and amount of blood exposure. The risk of transmission is increased by (1) percutaneous exposure, (2) devices contaminated with visible blood, (3) hollow-bore needles, and (4) high viral titer (i.e., a patient late in the course of the disease). In general, health care workers encountering needlestick injuries should be given HBIG, the hepatitis B vaccine, or both, unless they have already been vaccinated, and antiretrovirals for HIV should be considered in consultation with experienced clinicians. In the event of an exposure to blood or body fluid, health care workers should immediately contact their on-site occupational health department and the National Clinicians' Post-Exposure Prophylaxis Hotline (PEPline) at 1-888-448-4911 for expert advice. This hotline can be accessed 24 hours a day, and it offers advice on evaluating the risk of disease transmission and initiation of PEP. In addition, updated guidelines for the management of occupational exposures to bloodborne pathogens are available on the CDC website at http://www.cdc.gov/mmwr/preview/mmwrhtml/rr5011a1.htm.[56]

Evaluation for PEP and baseline HIV testing should be completed within hours of exposure. Prophylaxis should begin as soon as possible because animal studies show that prophylaxis is less effective if begun more than 24 to 36 hours after exposure. Because the time to no benefit in humans is unclear, the U.S. Public Health Service advises beginning prophylaxis up to 1 week after exposure. Four weeks of treatment is recommended if tolerated. Regardless of whether PEP is initiated, follow-up should include counseling and HIV antibody testing at 6 and 12 weeks and again at 6 months after exposure.[72]

Data on the efficacy of PEP in health care workers are insufficient, primarily because seroconversion from occupational exposure in health care workers is rare. A single retrospective study of HIV PEP with zidovudine in health care professionals after PCI showed a risk reduction of 81% (95% CI, 45% to 94%).[73]

TUBERCULOSIS

TB, the leading cause of death in the early twentieth century, appeared to be steadily decreasing in incidence with the advent of streptomycin in 1946, isoniazid in 1952, and rifampin in 1970. However, in 1985, the incidence in the United States began to increase significantly. Between then and 1990, reported cases increased by 16%, with a 10% increase in 1990 alone. This increase was the largest since national reporting began in 1953.[74] Most cases were from reactivation of old infection in immigrants or in patients whose immune system had been compromised, and many cases involved multidrug-resistant strains of *M. tuberculosis*. Epidemic transmission between hospitalized patients and from patients to health care workers also occurred.[75,76] Common to most of these cases was a low index of suspicion for TB, which was occasionally not confirmed before postmortem examination.[77]

In response to the resurgence of TB in the United States in the mid-1980s, the CDC published new guidelines for the prevention of transmission of TB in 1990. These guidelines were revised throughout the decade, first in 1992 and again in 1994. The 1992 guidelines targeted the prevention of TB transmission in the hospital setting, and the 1994 guidelines added recommendations for the management of multidrug-resistant TB. The guidelines, most recently updated in 2005, include a comprehensive program for the prevention of multidrug-resistant TB in health care facilities.[78] The program places the responsibility for managing prevention of TB on individual health care facilities, rather than requiring identical standards for all hospitals. Paramount are the following: identification and treatment of patients with TB; development of engineering controls, including isolation rooms, filters, and ventilation; use of personal protective equipment; and implementation of educational programs for health care workers.

Since the implementation of CDC guidelines in the 1990s, the number of new cases of TB has steadily declined such that the number of cases now being reported is the lowest since 1953, the first year of reporting in the United States.

In 2010, the overall incidence of TB in the United States was 4 cases per 100,000 population.[79] This was less than the 8 per 100,000 reported in 1996. Despite this general decline, a marked geographic variation in incidence remained. In 2011, the highest incidence was found in Alaska (9.3 per 100,000), followed by California (6 per 100,000), and New York (4.7 per 100,000).[80] The lowest rate of infection was documented in Wyoming (0.7 per 100,000). The risk to health care workers probably correlates with the region in which they practice.

The goal of the CDC was to decrease the rate of TB infection in the United States to less than 1 per million by 2010.[78] To this end, the scope of the current recommendations were significantly broadened to include health care "settings." The term health care settings in this document encompasses all facilities in which health care is delivered, including clinics, correctional facilities, and so on.[78]

TB spreads by small (1- to 5-μm), airborne droplets released when a person with pulmonary or laryngeal TB speaks, coughs, sneezes, or sings. The probability of transmission is directly related to the concentration of infectious droplets (up to 600,000 droplets may be expelled with each cough) and the duration of exposure. Droplets can travel up to 3 feet from the source and remain viable and airborne for several days.[74] Not surprisingly, endotracheal intubation is second only to bronchoscopy as a risk for skin test conversion in health care workers. In healthy persons who have inhaled contaminated droplets, the resulting systemic infection is usually limited by the immune system within 2 to 10 weeks. In these individuals, the lifetime risk of developing active TB after infection is approximately 10%. The likelihood is more frequent in patients with HIV, who have a 7% to 10% risk of converting per year.[78]

The commonly used tuberculin skin test (purified protein derivative) provides a qualitative measure of TB infection. A newer quantitative test for TB is now available, but it requires a blood sample. This test can identify infection with atypical organisms.[78] All health care workers at high risk for exposure to TB should be skin tested at the time of employment. Those whose test results are negative should be retested annually. A positive test in a person who has not tested positive in the past suggests a new infection. A two-step test is recommended in anyone who tests negative more than a year after TB exposure or previous tuberculin testing. This is because latent infection can produce false-negative results from waning over time of the delayed-type hypersensitivity response. The first test will "boost" the response, leading to a positive result. The second test, performed 1 to 3 weeks after the first, increases the negative predictive value of the test.

A newly positive skin test requires exclusion of active disease by chest radiograph and clinical evaluation. If TB is diagnosed, treatment according to recommended guidelines should begin immediately. Disease reporting laws generally require notification of local or state health departments within 24 hours. If active disease is excluded, drug therapy for latent TB infection should be considered, in consultation with occupational health and infectious disease physicians, given the documented liver toxicity of common drug regimens.

Asymptomatic conversion does not preclude the anesthesiologist from working.

OSHA standards to prevent airborne contamination include both environmental controls and respiratory protection. Environmental controls include engineering measures to manage exhaust ventilation and general ventilation. Examples are air exchange rates, high-efficiency particulate air (HEPA) filtration, and ultraviolet germicidal irradiation (UVGI; irradiation of the air in the upper portion of a room, or within ducts and recirculating units). Respiratory protection requires masks with the ability to filter particles smaller than 1 μm with a filter efficiency of 95%, at inspiratory flow rates up to 50 L/minute. If these masks are worn properly, even with strenuous activity in the work setting, less than 5% of infectious particles will escape filtration. These masks are typically referred to as N95 masks. Essential to proper mask function are tight mask fit, so as not to allow entrained air with inspiration, and a clean filter. To this end, the NIOSH requires the annual oversight of mask fit and maintenance by the employer.

NOVEL INFECTIOUS AGENTS

Occasionally, novel infectious agents come to the fore and create anxiety among populations and health care workers. Examples include the prion disease Creutzfeldt-Jakob disease (CJD), coronavirus infections such as severe acute respiratory syndrome (SARS-CoV) and a potential new Middle East SARS (MERS-CoV), and the H1N1 influenza outbreak of 2009. In the presence of such outbreaks, medical centers must have plans and procedures in place to contain infectious agents and protect workers from infection.

In the context of occupational exposure, perhaps the least infectious of these novel agents are prions. Transmission of prion disease such as CJD is thought to occur as a result of eating meat from animals that suffered from prion disease, or of receiving contaminated implants such as corneal or dural tissue, or from exposure to cadaveric pituitary hormone supplementation, all of which are highly unlikely in the occupational setting. It is controversial whether prions can be transmitted in the donor blood pool, but no such transmission has ever been reported, even though anesthesiologists are frequent handlers of donor blood products. Similarly, the CDC reported in 2007 that no reports of casual or occupational transmissions through airborne or droplet routes had been submitted,[81] and standard precautions are recommended for the care of patients with prion diseases.

Patients with respiratory viruses present a significant risk of occupational exposure to the anesthesiologist.

The SARS-CoV epidemic of 2003 is a great example of the potential impact of programs directed at containment and occupational safety. In Toronto, 77% of the patients in the first phase of the outbreak were infected in the hospital setting, and half of all SARS cases in Toronto were in health care workers.[82] The large number of health care workers who contracted SARS-CoV demonstrates the importance of early detection and infection control in halting the spread of disease. Although SARS-CoV has not been diagnosed since 2004, concerns generated by the outbreak apply to other infectious respiratory illnesses such as seasonal and nonseasonal (H1N1 epidemic of 2009) influenza, and a more recently discovered SARS-CoV–like virus.[83,84] For example, MERS-CoV was documented to have been transmitted from patients to health care workers,[85] and it has an overall case fatality rate of more than 50%.

Although it is too soon to determine how severe an epidemic MERS-CoV may become, and even though advisory groups such as the CDC have yet to issue recommendations, other respiratory viral epidemics may likely occur in the future, and lessons learned from previous epidemics may serve us well in the containment of these agents (Table 110-2).

FATIGUE

The impact of fatigue on patient safety has come to the forefront in recent decades (see also Chapter 7). Well-defined periods of vulnerability to sleep have been identified in humans. The major peak occurs between 2 AM and 7 AM, and a smaller peak occurs in the midafternoon.[86] These peaks appear to be enhanced by irregular work schedules and sleep disruption, and they may also contribute to diurnal variation in the frequency of mishaps (e.g., single-occupant motor vehicle accidents and catastrophic industrial accidents; the nuclear reactor accidents at Three Mile Island, Chernobyl, and two other sites in the United States all began between 1 AM and 5 AM). In 1990, an anonymous survey of anesthesia providers revealed that many respondents participated in clinical work for hours beyond their perceived limitations. Most respondents reported making errors in patient care that they attributed to fatigue.[87]

Last updated in 1988, the Committee on Catastrophes, Sleep, and Public Policy of the Association of Professional Sleep Societies made the following recommendations:

1. Management should be made aware that performance errors are more common between 1 AM and 8 AM.
2. Programs should be developed to identify signs of sleep-related error.
3. Because inadequate sleep or irregular sleep patterns enhance the tendency for error, work hours should be limited to permit adequate sleep.[88]

Although it is difficult to single out fatigue as a cause of increased patient morbidity and mortality, increased rates of anesthetic complications for cases started late in the day and during "off-hours" have been reported.[88-90] In one study,[90] most of these complications were related to postoperative nausea and lapses in effective pain management. More compelling data from a Veterans Affairs (VA) study of nonemergency surgical procedures did, however, show an impact on mortality for cases starting after 4 PM.[91] Being on call every third or fourth night has a negative impact on the cognitive function of university house staff on standardized tests.[92] However, when patient simulation was used to study the effects of sleep deprivation on the psychomotor and clinical performance of anesthesia residents, psychomotor performance and mood were found to suffer, whereas clinical performance did not,[93] a finding that has also been published in the surgical literature[94,95] (see also Chapter 8).

Fatigue does affect clinical outcome. For instance, resident physicians made fewer medication errors after their work hours were adjusted to minimize sleep deprivation and fatigue. This study, in a university-affiliated VA, also demonstrated a decrease in the length of patient stay and the number of laboratory tests ordered.[96] In another survey of 225 physicians, 48.8% blamed tiredness and 19.5% blamed the pressure of overwork to be a significant cause of clinical mistakes and suboptimal patient care.[97]

To reduce the presumed effect of fatigue on medical care provided by trainees, the Accreditation Council for Graduate Medical Education in 2011 updated standards for house staff duty hours, as summarized in Box 110-1.[98]

The validity of resident work hour restrictions would be difficult to overcome, even in the presence of conflicting data. Residents' hours of sleep and cognitive performance generally improve with restricted work hours. In contrast, consistently improved patient outcomes remain elusive, and the effect on attending physicians' working conditions and professional satisfaction are generally detrimental.[99] In favor of work hour restrictions, companion papers in the *New England Journal of Medicine* documented both fewer attentional failures (when intern work hours were reduced from 80 to 60 hours per week) and medical errors (when interns' shifts were reduced to, at most, 16 hours).[100,101] However, both studies were small in scope, and duty hour changes were limited to interns, whereas more senior residents continued to work longer shifts.[99] In an effort to determine the effect of work hour regulations on clinical outcome, two large-scale nationwide multicenter studies measured patient mortality within 30 days of hospital admission both 2 years before and after the rules went into effect in July of 2003.[102,103] These investigators compared death rates between hospitals with a large number of residents (thought to be most affected by the rule change) and those hospital with few residents. Although no differences in mortality were identified after the regulations went into effect among millions of Medicare recipients in both more and less teaching-intensive hospitals, a smaller scale VA study did suggest an improvement in patient outcome in a subset of medical patients. Perhaps the effect of fatigue could be mitigated without changes in work hours; a study in surgical residents showed improvements in memory, planning, impulsiveness, and attention, but not psychomotor performance, when fatigued residents were given modafinil, a central nervous system stimulant, compared with placebo. How pharmacologic augmentation of resident performance would be viewed by educators, policy makers, patients, and residents themselves remains to be seen.

It is likely that a fatigued physician who knows a patient well and a rested physician who knows the patient only through a hand-off both have the potential to commit errors; it remains unstudied which will err more. Patient outcomes depend on a delicate balance between discontinuity of care and the effects of fatigue on medical judgment.[104-106]

Stress in the workplace continues beyond the residency years. In a study conducted in the United Kingdom, the most significant source of stress for those beyond their training years was lack of control of circumstances at work.[107] Specific causes included professional relationships (especially with surgeons), work overload, threats of litigation, peer review, and increasing administrative responsibilities. A subsequent survey of retired members of the ASA identified similar stressors. Difficult anesthetic cases, the threat of professional liability, and the stress of night call were all considered significant causes of stress.[107]

Perhaps more than any other medical specialty, the practice of anesthesia requires uninterrupted vigilance with immediate reaction to life-threatening situations. An inappropriate response can prove to be acutely fatal to an otherwise healthy patient. Does the day-to-day practice of anesthesia produce episodes of significant physiologic stress in the practitioner? Evidence for this hypothesis is lacking. In an investigation of 38 anesthesiologists over the course of 203 anesthetic courses, clinically significant changes in physiologic stress did not occur, as measured by changes in heart rate, blood pressure, and cortisol levels.[108] Although management of stress is rarely addressed in medical school or in continuing medical education seminars for anesthesiologists, it should be. Stress is a universal phenomenon to which no one is immune. Vital to our interactions with others is the ability to recognize stressed behavior, not only in other people but also in ourselves. Healthy means of coping with stress include an ability to communicate, appropriate assertiveness, interactive management of conflicts, adequate time with family, and time for recreational pastimes totally unrelated to professional activities.[109]

BOX 110-1 ***Summary of Resident Work Hour Restrictions***

- Residents at all levels are permitted to work no more than 80 hours per week, averaged over 4 weeks.
- PGY1 residents are permitted to work no more than 16 consecutive hours in house.
- Residents beyond PGY1 are permitted to work no more than 24 consecutive hours in house, with an allowance of 4 hours for care hand-off or, in rare circumstances, for continued duty in the service of a single patient, provided doing so fulfills a unique educational or humanistic role.
- Moonlighting is not allowed by PGY1 residents, and, for more senior residents, hours spent moonlighting count toward the 80-hour week.
- Residents should have 10 hours (and *must* have 8 hours) between assigned shifts. If post call, there must be 14 hours between assigned shifts.
- Residents must have 1 day in seven completely free of clinical duties, including home call, averaged over 4 weeks.

PGY1, Postgraduate year 1.

SUBSTANCE ABUSE

The abuse potential of the psychotropic drugs used in the practice of anesthesia is well documented. Potent psychoactive drugs are readily available and familiar to anesthesiologists in the course of their daily practice. Even inhaled drugs pose an abuse potential to health care workers with easy access to these agents; Zacny and Galinkin reported a case of an Air Force pharmacist court-marshaled during the 1991 Gulf War for abusing

isoflurane,[110] and a fatality from sevoflurane abuse has been reported.[111] No doubt, familiarity and availability contribute to the increase in propofol abuse by anesthesia residents since 2000.[112,113]

Scientific evidence increasingly indicates that addiction is a chronic, relapsing disease resulting from the long-term effects of drugs on the brain.[114] Acceptance of this fact is crucial for those dealing with chemically dependent physicians. This section provides information about chemical dependence in anesthesiologists and the steps required to help a colleague or yourself.

EPIDEMIOLOGY

The prevalence of substance abuse among graduated physicians,[115,116] interns and residents,[117-119] and medical students[120] has been studied. A national survey published in 1992 reported a 2.1% annual and a 7.9% lifetime prevalence of substance abuse among physicians. This rate was substantially lower than the corresponding rate of 16% reported for the general population These results cast suspicion on the myth that physicians are more likely to become substance addicted than the population in general.[118] A more recent review suggested that the actual prevalence may be unknown because of variances in case reporting habits and that prevalence may be at least as high as in the general public.[121] Although physicians are less likely to use cigarettes and illicit substances such as marijuana, cocaine, and heroin, they are five times as likely to take sedatives and minor tranquilizers without medical supervision.[122] This tendency to self-prescribe begins in medical school with tranquilizers and continues in residency with benzodiazepines and prescription opioids. Alcohol abuse is of particular concern in physicians, and although heavy alcohol use is lower in young physicians than in matched controls, the incidence increases with age in the physician population and decreases with age in the general population. By the age of 50 to 55 years, extensive use of alcohol in physicians surpasses that of the general population.[123]

A commonly repeated perception is that anesthesiologists are more likely than other physicians to engage in substance abuse. Three retrospective surveys suggest that the prevalence of drug abuse in anesthesiologists ranges from 1% to 2%.[124-126] These published percentages rely on the recall of directors of U.S. anesthesiology programs and the honesty of individual anesthesiologists responding to questionnaires. Nevertheless, the estimates from these surveys are remarkably similar. Furthermore, the prevalence is similar to that seen in published studies of anesthesia trainees in Australia and New Zealand,[127] as well as in newer estimates from the United States.[128] In 1993, approximately 2% of U.S. anesthesia residents became addicted to a substance during their residency.[129]

When comparing the published incidence of substance abuse in physicians as a whole with that of anesthesiologists, both graduated and resident anesthesiologists are consistently overrepresented in drug treatment centers.[130] Although anesthesiologists account for 12% to 14% of physicians treated in three well-known treatment programs, they constitute only 4% of physicians in the United States.[129,131,132] This threefold overrepresentation of anesthesiologists in drug treatment centers is relatively consistent across state lines and over time. For example, data from the California Physicians Diversion Program have anesthesiologists accounting for 17% of physicians in treatment and 5% of physicians in practice.[133] Although these statistics imply that the incidence of chemical dependence is significantly higher among anesthesiologists, these data may instead be a reflection of the potency of the drugs abused, the ability of anesthesiologists to recognize the disease in their colleagues, and the diligence within the specialty to refer colleagues for treatment.

Reports from state-run impaired physician treatment programs that began in the 1980s[132-135] suggested that although all the anesthesiologists were chemically dependent, at least 10% of the other physicians had other forms of impairment, such as depression.[131,133,136] Nearly 50% of anesthesiologists were less than 35 years old, and one third were residents. Half used both drugs and alcohol, 40% used drugs alone, and a minority used only alcohol. Fentanyl was the most commonly abused narcotic, followed by sufentanil, meperidine, morphine, and oral drugs.

Sadly, loss of life may be the first indication that a physician is abusing drugs. These deaths could alter the frequency numbers when comparing younger and older physicians. For example, young physicians who die will obviously not become older drug abusers. Numerous studies have examined the mortality risk of physicians in general,[137,138] and of anesthesiologists specifically,[139-141] as opposed to the mortality risk of the general population. The death rate from all causes is lower among physicians than the public in general. This difference is attributed to lifestyle awareness among physicians that results in decreased rates of destructive behavior such as smoking. The higher socioeconomic status of physicians and greater access to health care may also contribute to this advantage. Although the mortality risk for anesthesiologists is no higher than that for other medical specialties, anesthesiologists' risk of drug-related death and suicide is alarmingly high. Studies have shown a twofold increase in suicide among U.S. white male anesthesiologists[140] and British (mostly female) anesthetists when compared with appropriate population controls.[138] A more recent study in the United States reported the relative risk of suicide in anesthesiologists to be 1.45 when compared with internists. The relative risk of a drug-related death was even higher, at 2.79.[141] All these studies identify drug-related death as a significant occupational hazard in the practice of anesthesia.

ETIOLOGY

Occupational stressors first surface in residency, during which long hours preclude much time for relaxation, and certain patients may evoke negative emotions. The death of a patient under one's care may cause a sense of professional inadequacy to surface for the first time.[135] Without doubt, the practice of medicine can be stressful, but is that stress a major cause of drug addiction among physicians? Contrary to common belief, stress is not necessarily the precipitating factor in a physician's addiction

to drugs. Preexisting personality traits, a family history of substance abuse, and previous recreational drug use have been associated with substance abuse among physicians.[123,142]

Availability

Patterns of abuse differ by specialty and are influenced by familiarity and availability. Psychiatrists most frequently abuse oral benzodiazepines, whereas anesthesiologists preferentially abuse potent opioids. Anesthesiologists are unique among physicians in that they administer drugs directly rather than order their administration by others. Drugs are immediately available, and this may be the most important cause of addiction in the specialty. One report indicated that 85% of anesthesiology residents who were treated for substance abuse in one large program stated that the ready availability of drugs influenced their choice of specialty.[136] Since the late 1990s, anesthesia departments have introduced measures to monitor the use of controlled substances by staff and resident physicians closely.

Nonetheless, an increased level of accountability of controlled substances in U.S. residency programs has thus far not correlated with a decreased incidence of drug dependence.[143] Although one program published their experience with random mandatory drug testing as a proof of concept, more work is required to demonstrate the effectiveness of prevention.[144] In a 2002 survey of 123 academic anesthesia departments, measures were introduced to regulate the use of controlled substances including changes in drug dispensing, disposing, and accountability. The study covered a span of 7 years, during which time drug dispensing was shifted from nurses to satellite pharmacies (42%) or dispensing machines (31%). Opened, but unused drugs were either returned to the pharmacy (52%) or were wasted in front of a witness (41%), and the amount of drug administered was compared with the amount dispensed (80%). Despite these changes in drug dispensing and accountability, the incidence of drug abuse did not decrease.[128]

In the future, the direct monitoring of atypical drug transactions from automated dispensing systems may more accurately identify drug diversion.[145,146] In addition, the linkage of anesthesia information management systems with medication dispensing systems has been proposed as a means to detect medication discrepancies accurately, but these systems have yet to be fully realized.[147]

Drug Potency

Abuse of drugs by physicians is much more common than addiction. Casual abuse of alcohol probably does not always lead to addiction, and although exceedingly risky, neither does abuse of less potent opioids such as morphine, meperidine, or codeine.[116] In contrast, the addictive potential of fentanyl and other potent opioids is so great that anyone who experiments with these drugs is at enormous risk of becoming chemically dependent.[136] The time until detection of abuse is inversely proportional to the potency of the drug abused. For example, abuse of sufentanil is typically detected within the first 1 to 6 months, whereas the abuse of fentanyl is not detected until 6 to 12 months. In contrast, alcohol abuse may not be detected for more than 20 years.[134] Rapidly developing tolerance stimulates the ever-increasing doses needed to attain the desired sensation. The use of 50 to 100 mL of fentanyl or 10 to 20 mL of sufentanil per day is common in an addicted physician. These doses are easily reached within a few months for fentanyl and a few weeks for sufentanil. The potency of these drugs is reflected in associated fatality statistics. Between 1990 and 1997, 18% of identified substance abusers in academic departments either died or required resuscitation before substance abuse was suspected.[127] Fentanyl was most often the drug of choice.

Other Factors

Chemical dependence is a complex disease influenced by multiple factors. A history of experimental use of drugs is known to increase the risk of future addiction,[116] and a genetic predisposition may contribute to the progression from abuse to addiction. To identify availability and potency as the only significant factors in chemical dependence in anesthesiologists risks overlooking other significant factors such as previous use of drugs and a family history of drug abuse.

MANAGEMENT

Management of physicians who are chemically dependent includes identification, intervention, referral for treatment, and help with reentry. Each department should have an established mechanism in place to deal with impaired physicians. Identification of a chemically dependent physician does not usually occur until the disease is in its late phases, when performance at work becomes significantly impaired. The ASA Task Force on Chemical Dependence, last updated in 2002,[148] identified certain characteristics of addicted anesthesiologists (Box 110-2).

Although none of the signs and symptoms of chemical dependency or addiction are diagnostic, an awareness of the usual sequence of events may help identify an ill colleague in the earlier stages of the disease (Table 110-3).

Normally, withdrawal from outside interests is the first sign. Examples include giving up athletics, community activities, church, and activities with friends. Next comes increased turmoil at home. Domestic arguments, sexual problems, and lack of interest in family matters are common. Third is the appearance of frequent unexplained

BOX 110-2 ***Summary of Identified Characteristics of Addicted Anesthesiologists***

- 50% are <35 years old
- Residents are overrepresented
- Many are members of the American Osteopathic Association
- 76% to 90% abuse opioids as their drugs of choice
- 33% to 50% are polydrug abusers
- 33% have a family history of addictive disease
- 65% are associated with academic departments

Modified from Arnold W, et al: *Chemical dependence in anesthesiologists: what you need to know when you need to know it,* 2002. <http://anestit.unipa.it/mirror/asa2/ProfInfo/chemical.html> (Accessed 30.04.14.)

illnesses, personality changes, multiple jobs, and frequent moves between cities. This progression, which may take years to become apparent, is common with addictions that develop slowly.

The last activity to be affected is usually job performance. Page operators and nurses may be the first to recognize behavioral changes. Record keeping may become sloppy. Excessive use of certain drugs becomes apparent, perhaps accompanied by an unusual compulsion to explain the need for these drugs in patient management. Colleagues may note similar changes. Direct observation of self-administration confirms the diagnosis, but it is not common.[149]

Impaired physicians disclaim their illness by using superficially logical reasons to explain their bizarre patterns of behavior. Colleagues, too, use denial. Typically, they would rather accept these explanations than consider that a friend is a drug addict. For these reasons, the diagnosis is not usually made until its manifestations are clear.

TABLE 110-3 NOTABLE BEHAVIORS COMMON TO THOSE ABUSING SUBSTANCES

At Work	At Home
Unusual changes in behavior (e.g., wide mood swings, depression, anger, euphoria)	Withdrawal from family, friends, and leisure activities
Gossip by others	Changes in behavior (e.g., wide mood swings)
Progressive increase in apparent narcotic use for anesthetic management	Fights and arguments at home
Careless charting	Frequent unexplained illness (common in alcoholism)
Preference for working alone	Gambling
Frequent requests for bathroom breaks	Extramarital affairs
Unusual willingness to provide relief for others	Legal problems (e.g., arrests for driving while intoxicated)
Inappropriate willingness to take calls	Decrease in sexual drive
Frequent appearances in the hospital when not on call	Finding of drugs and syringes in the home
Frequent unexplained absences	Seclusive behavior at home
Difficulty finding the person when on call	Odor of alcohol on breath
Excessive postoperative pain in patients cared for by an individual	Weight loss
Common wearing of long-sleeved gowns (to prevent chills often seen in early withdrawal and to hide needle tracks)	Pinpoint pupils (in persons addicted to opioids)
Pinpoint pupils	Symptoms of withdrawal (e.g., diaphoresis, tremulousness)
Weight loss	Denial of drug or alcohol use if confronted
Finding the person comatose	
Finding the person dead	
Witnessed self-administration (the only pathognomonic sign)	

TREATMENT

The appropriate initial response to the discovery of chemical dependence in a colleague is to seek help. A call to a person experienced in managing chemically dependent physicians initiates the next steps.[133] Most state medical societies in the United States have committees on impaired physicians to act as advocates for sick physicians. Advocacy continues as long as the physician cooperates with the committee's recommendations. These committees serve as a buffer between the physician and the medical board or licensing agency. They also provide advisers to aid in confirmation of the diagnosis and to intervene and refer impaired physicians to appropriate treatment centers. Although laws vary, the committees are usually required to notify the board of a physician's recalcitrance at any stage of treatment. In many states, the board does not censure impaired physicians who comply with the committee's recommendations.

Intervention is the process of demonstrating to chemically dependent persons that they are ill and need treatment.[150] Interventions should never be attempted with fewer than two concerned persons and ideally should be directed by a person with previous experience. Before meeting, the group must collect documentation of drug usage including pharmacy records, anesthetic records, and other pertinent testimony. It is important to rehearse with members of the group (e.g., colleagues, psychiatrists, family members) before meeting with the patient. Many experts suggest that each participant prepare written notes to be used for reference during the intervention. The objectives are to present irrefutable proof of the addict's symptoms in a compassionate manner and to begin an appropriate treatment regimen. A recovering physician at the intervention can be a valuable role model for the patient. Arrangements for inpatient treatment and travel, if anticipated, should be made before the intervention.[150]

When all is in order, the patient is invited into a room in which the other participants are already seated. Each, in turn, should express concern for the colleague's well-being and, without passing judgment, should describe the aberrant behavior that has been seen personally. If necessary, the documents at hand can be shown. The basics of the disease and its treatment should be explained, and the patient should be urged to accept the proposed plan. If the patient refuses, as many do initially for fear of losing control, the patient should be told that the ultimate decision regarding therapy will not be made until after a thorough evaluation by a group of specialists at the facility. If the evaluation does not confirm the diagnosis, the patient will be discharged. Otherwise, formal treatment, perhaps lasting several months, will start. If still reluctant, the individual should be advised that the interveners must, by law, report that person to both the medical board and the controlled substance authorities. Although it does not provide legal

immunity, acceptance of treatment is looked on favorably by many courts.

After the intervention, the patient should be accompanied continuously, not only to prevent the possibility of self-inflicted injury or elopement, but also to provide the social support necessary to begin recovery. With adequate preparation, most interventions are successful.

Treatment consists of an in-depth evaluation, which is usually followed by both inpatient and outpatient therapy. Formal therapy may last as long as several months,[131] but on the basis of the initial workup, some programs permit a recovering physician to continue practicing medicine during what may be several years of outpatient care.[133] Although this approach is debated by some, physicians often fare better if they are treated at a facility experienced in managing physicians. Philosophies of treatment vary among programs, but the common goal is to provide a recovering physician with the ability to remain sober. The physician is assisted in developing a strong relationship with peer support groups such as Alcoholics Anonymous and Narcotics Anonymous.

PROGNOSIS AND REENTRY INTO THE WORKPLACE

Return from treatment is a difficult process for a recovering physician. The comprehensive treatment program has provided a structured environment that is much different from the workplace. For this reason, reentry is greatly facilitated by understanding, compassionate peers who are willing to provide emotional support to the recovering physician. Gradual return to work, perhaps with others initially managing narcotic administration, is important. Without this support, the likelihood of relapse may be much greater.

In many states, the committee on impaired physicians plays a vital role in recovery. At discharge from formal treatment, the committee prepares an "aftercare contract" with the physician, who agrees to be bound by the committee's recommendations. The contract usually stipulates the number and the type of meetings that the physician must attend, the name of a "monitoring physician," the requirement for random urine samples on demand, and the procedures to be used in the event of a relapse.[131,151,152] Many recovery programs insist on the use of naltrexone or disulfiram, or both, for 6 months or more after the physician returns to work. Novel treatments for alcohol dependence include investigational drugs such as acamprosate, bromocriptine, selective serotonin reuptake inhibitors, buspirone, and dexmedetomidine.[153-155] As long as physicians adhere to the contract, the committee continues to serve as their advocate.

Federal law in the United States (the Americans with Disabilities Act [ADA]) provides limited protection against employment discrimination for recovering individuals.[156] Although persons who are currently using drugs are not protected by this law, those who have been successfully treated and are otherwise capable of working are considered to be "qualified individuals with a disability." The ADA defines a history of chemical dependence as a disability. Although it does not require an employer to provide for treatment, the ADA may require that "reasonable accommodation" be made for a qualified individual who wants to return to practice. For a recovering physician, such accommodation could include a modified work schedule, such as no call for several months and assistance with administration of narcotics. An employer is not required to make accommodation if "undue hardship" for the employer would result. For example, it could be argued in court that the accommodations needed to permit a recovering physician to return could have a negative impact on other employees or could result in prohibitive costs for the employer. Whether the ADA can be used also depends on the type of employer-employee relationship between an individual and a hospital or group practice. Clearly, any person who seeks the support of the ADA needs competent legal guidance.

As indicated by reports from treatment programs, most recovering physicians are able to return to a productive professional life.[157] Successful outcomes depend on lifelong participation in aftercare programs, total abstinence from drugs and alcohol, and continual acknowledgment of one's disease. Some now believe that the prognosis for long-term sobriety in anesthesiologists depends on the age and the status of the physician at the time of identification. Residents who have been dependent on fentanyl appear to have a significant rate of relapse.[126] Although each case must be handled separately, strong consideration should be given to a change in specialty for junior residents who become addicted to potent opioids. A survey of anesthesiologists in recovery who underwent subsequent anesthetic procedures showed that although most respondents informed their anesthesia provider about their history of dependency, less than half of the respondents asked to avoid the use of previously abused agents, and at least two patients experienced relapse.[158] A regression analysis identified several risk factors that predict relapse, including a history of mental health problems, the use of a "major" opioid (e.g., injecting fentanyl, as opposed to oral oxycodone), and previous relapse.[159] It is unknown whether physicians using prescription opiates for chronic pain are at a higher risk of relapse.

The American Board of Anesthesiology (ABA) permits a physician recovering from alcoholism or other drug dependence, who is otherwise qualified, to take both the written and oral examinations. After a candidate with this history has satisfied the requirements for certification, "the [board] will determine whether it should defer awarding its certification to the candidate for a period of time in order to avoid certification of a candidate who poses a direct threat to the health and safety of others."[160] If the ABA deems that such deferral is appropriate, "the [board] will determine the length of time the candidate's certification is deferred following an individual assessment of the specific circumstances of the candidate's history of alcoholism or illegal use of drugs." This practice is in keeping with the intent of the ADA.[160]

Chapter 111

Statistical Methods in Anesthesia

STANLEY H. ROSENBAUM

Key Points

- Data should always be plotted. Significant trends should be visible to the eye.
- The statistics program should be known well enough to ensure that it is calculating what is wanted.
- Interval data should not be treated like categorical data—the mathematics is different.
- Many statistical methods assume that the data are distributed "normally," that is, in a symmetric bell-shaped curve; these methods can be misleading if the data are not normally distributed.
- Standard deviation (SD) is used to describe the spread of data, and standard error of the mean (SEM) is used to compare data sets.
- Multivariate regression, which relates the outcome variable to more than one other factor, requires more data but will probably pick up correlations that may be missed if only univariate regression is used.
- When using multivariate regression, if two variables closely correlate with each other, then the statistical package may miss reporting one as correlating with the outcome.
- In hypothesis testing, a negative result may indicate no real difference or may just mean that the study was underpowered to pick up a true but small difference.
- A *P* value is the probability that the observed result will occur, assuming no true difference between the tested hypotheses, which is not the same as the probability of the difference being true.
- A Bayesian approach to diagnostic testing recognizes the fact that the value of a test depends on the patient population; if the test is almost always truly positive in the population, then false-negative results will outnumber true-negative results and make the test less useful. This situation is also true if the test is almost always truly negative, in which case false-positive results cause the confusion.
- Selection biases make many real-life clinical studies difficult to interpret. Randomized clinical trials are the best way to minimize this problem.
- Beware of the error of *data dredging.* Applying too many tests to insufficient data will probably find something that, misleadingly, seems significant.

The advance of scientific knowledge in the past half millennium has been closely related to the linkage between experimental results and mathematical assessment of empirical observations. The role of the branch of mathematics, termed *statistics*, is to describe the results of experiments and to analyze, as best as can be mathematically done, the causes and effects behind the experiments.

A serious problem for a clinician or clinical scientist who wishes to use statistical methodology is that it is a modern branch of mathematics, much of which has been developed in the past century. Its mathematical sophistication is often considerably beyond that of the university-level calculus that is the upper limit of conventional medical training. Furthermore, many statistical methods involve extremely long and tedious calculations that require computerized techniques to be practical. This drawback leads clinicians to the quandary that although statistical methods are useful and often essential to the understanding of medical science, they may be subtle to comprehend and difficult to use.

It cannot be the role of a chapter in a book such as this to derive or even genuinely explain the mathematics behind statistical methods. Many accessible introductory texts give some of the reasoning and rough cookbook approaches to practical usage (see the bibliography). In real life, almost no one ever performs any sort of statistical calculations beyond the most simple with paper and pencil. Application programs for statistical calculations are widely available for personal computers. Many of them are reasonably well documented and simple enough to use without much preparation.

The problem with these statistical programs for personal computers is that the assumptions behind the statistics remain obscure. It is extremely easy to use the wrong method or approach and still have the program generate an output that, although appearing to be correct, is simply wrong. The old computer adage of "garbage in (statistically misleading), garbage out" is very easy to achieve with a computer package and a data file.

The goal of this chapter is to provide some of the correct language for describing statistics and to suggest the proper methodology for the use of statistics in some standard situations. Some of the classic errors common in medical statistics are indicated. Of course, readers must be familiar with whatever program they actually use.

STATISTICAL APPROACHES

Within the broad rubric of statistics, several distinct and valuable areas can be separately viewed. *Descriptive statistics* is the use of mathematical methods to describe or categorize a collection of data that results from a set of empirical observations. *Statistical testing* is the broad approach to the determination of conclusions from a set of observations. Within each of these categories are many separate techniques.

TYPES OF DATA

It must be remembered that behind every statistical methodology are formal mathematical definitions and proofs. Although it may sometimes seem that a simple intuitive approach is sufficient to understand what is happening, mathematical statistics can be misleading and unforgiving. The mathematical proofs and calculations that are behind statistical tables and computation programs make strict distinctions among the several types of data (Table 111-1).

One grouping of data, termed *interval* data, is simple *continuous* numerical measurements (e.g., 1.2, 33.4). Often, *discrete* numerical measurements, such as counts or integral quantities in the same categorization, are described. This approach is occasionally misleading; the claim that a "typical family has 2.3 children" is meaningful in a crude way, although the quantification of children is obviously not a continuous numerical fraction. In practical use, both continuous and discrete data can be handled by techniques similar to those used for interval data.

The other major grouping of data is *categorical* data. One type of categorical data is *ordinal* data, which refers to the ordering or ranking of subjects (e.g., 1st, 3rd, 10th). Taking care to resist the temptation to regard the number of the ranking as an interval number, that is, to confuse *first* with the number *1*, and so on, is important. Such a grouping does not usually have much numerical meaning and is false to the mathematics if an attempt is then made to manipulate the number as though it were an interval value. The arithmetic manipulation of arbitrary numerical assignments may easily produce misleading results.

TABLE 111-1 TYPES OF DATA

Data Type	Examples
Interval	1.1, 22
Ordinal	1st, 3rd
Categorical—binary	Male or female, alive or dead
Categorical—multiple	Red, green, blue

Binary data (e.g., up versus down, greater versus lesser) is another similar category. The most general grouping is the simple *category* (e.g., red, green, blue; cancer, diabetes, ulcer). When using simple or binary categories, attaching numbers to the groups and trying to get numerical results is incorrect—the mathematics are not appropriate, and the results are not likely to mean much. Specific statistical techniques for categorical data are necessary.

DESCRIPTIVE STATISTICS

The most general statistical goal is to describe the data set. The simplest method is to simply present all the crude data. For small data sets, the actual measurements can be presented. For larger amounts of data, a graph or statistical plot of the data can be helpful. Frequently, trends and groupings in a picture can be extremely difficult to describe numerically. It is often suggested that before any mathematical method is applied to data analysis, a graphic plot should be produced. If the data do not look *right* to the naked eye, then the statistical analyst should be extremely careful to avoid erroneous results. The choice of the correct format for the statistical plot can be an art form, and special data manipulation computer programs can be useful to search for visual clues in a data set.

NORMAL DISTRIBUTION

Perhaps the most powerful numerical concept of mathematical statistics is the *normal distribution,* often called the *bell-shaped curve*. The idea of a most likely central value with other values scattered evenly to both sides is a classic statistical concept with deep mathematical roots. It fits in nicely with an intuitive idea of a *true* value with measurements randomly distributed around the true value in such a way that more values are close to the center than are distant.

Many typical data sets follow a normal distribution around a center point. This distribution, also sometimes called a *Gaussian distribution*, is derived from the assumption that a center, a *true* value, exists and that deviations from the center are random and diminish in likelihood the farther the values get from the center (Figure 111-1).

The strict use of normal distribution implies very large amounts of continuous interval data. When, as is usual, a data set does not meet this criterion, approximations are needed. Fortunately, most computerized statistical programs can deal with this problem with good effect.

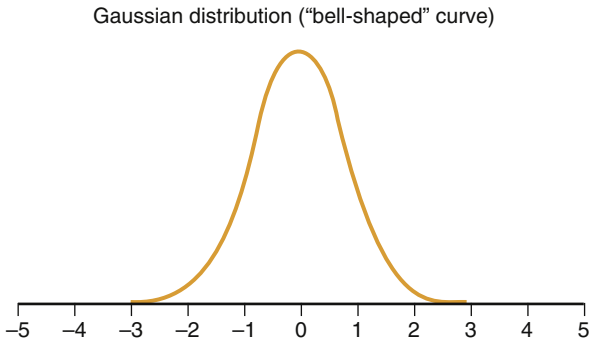

Figure 111-1. Gaussian distribution in a bell-shaped curve. The *x*-axis is in units of standard deviation.

In general, the mathematical description of the placement of the values is termed the *distribution.* There are many, mostly uncommon, distributions other than normal distribution. They yield different curves and have specific mathematical properties. Not all data sets, even if they look like a bell-shaped curve, are normal distributions. If the curve is too wide (i.e., many distant outlying points) or too narrow or uneven, then the mathematics derived for normal distributions will not work well.

When data follow a normal distribution or, more generally, any specific mathematical distribution, the methods of *parametric statistics* can be used. The term *parametric* refers to the ability to describe the distribution with a specific set of values. Frequently, such is not possible, and *nonparametric* statistical methods are necessary. These methods make fewer mathematical assumptions about the distribution of the data, but they are more difficult and can be less robust in finding statistical distinctions. Conversely, if parametric statistical methods are applied to data that are not normally distributed, then false or misleading results can be calculated. This type of error is common and can be prevented by using appropriate tests or checking the data for normality before applying tests that assume it.

In practical use, data are often treated as though they follow a normal distribution. However, wise investigators will use the tests in their computer statistics packages to test for normality and recognize that if the data do not follow a normal distribution, then other methods will be needed.

Measures of Central Tendency

In describing data, the first task is to give some indication of the approximate value, range, or size of what is being described. How this is done depends on the type of data involved (Box 111-1). For categorical or binary data, all that may be possible is to give the counts in each group. For categorical data with many groups, the most populous groups may be named and listed in order. For ordinal data, summary description may be difficult; often, first place or last place will be the most interesting.

The *median* is the center or middle data point if the data can be ordered from smallest to largest. This value would apply to both interval data and to ordinal types of categorical data. For interval data, many mathematical techniques can be applied. The simplest is the *mean,* or the simple average value of the numerical data, with each data point counted equally. In a *weighted mean,* the individual points may be added unequally, with some getting more credit (i.e., *weight*) than others.

BOX 111-1 *Measures of Central Tendency*

Mean ± standard deviation
Mode
Median
Percentiles

For interval data that can be mathematically analyzed, the data may be fitted to a curve, which means that a mathematical formula is computed that closely fits the measured data points, often by using a computer and sophisticated calculations. The relationship can be as simple as a straight line or a complicated mathematical formula with exponentials, polynomials, or other functions included as may be needed. The various computed values in these formulas would be the *parameters* of the curves. The data would thus be described by the parameters of the formula approximated to the observed data. For the simple case of a straight-line approximation to data, the parameters would be the slope and intercept of the line. For complex equations fitted to data, the parameters would be the various computed numbers that make up the equations.

The *mode* is the most common value in a set of data points. This concept can be misleading if the data are truly continuous because every data point would then be probably different (if only infinitesimally so) from every other point. Hence, to describe the mode of continuous data, grouping the values into brief intervals makes the most sense. In this case, the interval with the most points within it is the modal interval. The mode may also be a very misleading description of the central tendency of a data set because no reason may exist for the most common value to be anywhere near the middle.

Numerical data can be described by categorizing the values into *percentiles* or similar groups. The meaning here is that for the 10th percentile, 10% of the data points are at or below that value. The 50th percentile corresponds to the median of the data set, and the 99th percentile is the value at or above 99% of the data points. Similarly, quartiles, quintiles, or other groups can be computed. With any method used to describe data, the choice of the description may subtly bias investigators in how they think about the result. In the simple data set (2, 2, 3, 7, 14), the mode = 2, the median = 3, and the mean = 5.6. Which, if any, of these representations is more accurate? The answer depends on how the data are used because no one representation is perfect.

Measures of Dispersion

Often, analysts want to describe not only the values of the data but also how the data are spread out. For data that follow a normal distribution, the classic approach is to compute the *standard deviation* (SD) of the data. With this value, approximately 68% of the data fall within 1 SD of the mean, and approximately 95% fall within 2 SD of the mean value. The larger the SD, the wider the bell-shaped curve; the smaller the SD, the narrower the curve.

Another way of examining this concept is to consider that if analysts were making measurements of an unknown value and their values were scattered in a random normal distribution around that value, then approximately 68% of the data points would most likely be within 1 SD of the true value. Of course, this result is only the most probable outcome; in any real set of randomly distributed data, an analyst could be unlucky and have very atypical points.

For data that do not follow a normal distribution, describing the dispersion of the data set in a standard fashion can be difficult. Often, simply the *range* of the data, from the lowest to the highest, is given. Occasionally, the data may be so scattered, with very distant extremes, that the range is not as useful as reporting the 25th to 75th percentiles of the data.

Caution

Because using a computer package to calculate the SD is so easy, particular caution would be taken when using it. Frequently, data do not nicely fit into the normal distribution with a symmetric bell shape and unbounded tails out in both directions. As an example, consider a data set of subjects with widely dispersed ages including many children. Getting a value of 10 for the mean age would be easy, with an SD of 15. Clearly, no values lie at the lower end of the distribution with ages of –5. In such situations, the SD has some merit in describing the spread of the data but is, by strict mathematics, being misapplied.

Standard Error of the Mean

Just as random numerical data can often be described by the SD, the means computed from multiple grouped determinations of the data set can be described by making a computation very similar to the SD but applied not to the measured data but to the computed means. This computed quantity is termed the *standard error of the mean* (SEM). As more data sets are gathered, with each data point being a measurement of what is a *true* but unknown value, the means of the data sets will probably get closer and closer to that true value. Hence, as more and more data are gathered, the SEM gets smaller and smaller. This concept is intuitively very reasonable—as more and more measurements of a value are made, a mean value should be getting closer and closer to the *true* value, even if the data points, themselves, remain scattered.

The difference between SD and SEM is important. SD is used to describe the data, and SEM is used for computations about the certainty of the mean of the data. Because computer packages can as easily provide either of these values and SEM is a smaller value, one is tempted to describe the data by the SEM. Although this is not dishonest if clearly labeled, it can certainly be misleading. A very large number of data points will have a very small SEM, but widely dispersed data will have a large SD, no matter how many points are measured.

Graphing the Data. All experienced statisticians will stress that before statistical calculations are applied to a new data set, the data must be plotted in some graphic format. If the data are widely scattered, appear asymmetric, or have a specific pattern, then that information is useful in determining the statistical tools to be applied. Furthermore, noting the presence of extreme outlying points may be a clue to mathematical or experimental errors.

Regression Analysis. Data may often fit a mathematical formula, which may be a straight line (e.g., a linear relationship) or just about any sort of continuous mathematical formula. In *regression analysis,* the power of the computer program is used to determine the mathematical formula that best fits the data. To do this, the program with the type of curve to use (e.g., straight line, quadratic equation, exponential curve) must be provided. The program will then provide the parameters within the selected equation that best fit the data points.

The art of regression is complex. The first problem is to pick the appropriate mathematical relationship to fit the data. Graphing the data is obviously very useful for this. There are also some mathematical subtleties in how to best fit the data to the curve, but by far, the most common method is a *least-squares* approach, which minimizes the square of the distance of each data point from the proposed curve. Although this methodology is approximately two centuries old, it clearly benefits from the use of modern computerized calculations, without which it would be practically unusable.

The computer program for regression analysis will provide the parameters of the fitted equation, such as the slope and y intercept for a straight line, as well as some information about how well these parameters fit the data. The user has to be cautious in using the fitted equation if the agreement is poor because almost any jumble of data can be fitted to some equation, albeit with terrible agreement. It is fair to stress that the human eye has real power to judge trends; therefore, if a graph of the data does not look like it fits the curve, then the wise user will be very skeptical of the result.

Univariate versus Multivariate Regression. In fitting data in a regression analysis, the first step is to choose the variables that will be used as independent variables. In *univariate* analysis, only one variable is used for the data fit and the data are plotted and the computations are performed by using that one variable to describe the data. As an example, the weights of a group of subjects may be compared with their heights. However, in the real world, many possible variables can almost always be used to determine an outcome. In *multivariate* analysis, more than one variable is used to describe the observed results. In the weight example, the subjects' weights might be analyzed by using heights, ages, and gender. Note that in this multivariate example, the outcome is a continuous interval variable but is determined by a collection of interval variables (age, height) and a categorical variable (gender). The precise mathematical techniques that are used for multivariate analysis will depend on the nature of the variable used; in general, a mixed group of variables makes the most sense with real-world data.

On first approaching analysis of a data set, a simple univariate analysis may help in understanding the relationships involved. However, the data analyst must be cautioned that subtle relationships can be missed with

only univariate analysis if the relevant variable is not used. As an example, heart rate may correlate with the dose of pain medicine in an injured patient, but the causal relationship for both is likely to depend on the degree of pain.

With multivariate regression analysis, many potential pitfalls can be readily encountered with computerized calculations. One critical category of problems derives from the relationships that the various variables may have with one another, which is often described by indicating how *independent* these variables are in relation to one another. For an independent variable, the values of one variable do not tell what the values of the other would be. In the example of weight versus age and height, age and height would be expected to be independent in adults. Mathematically, it would be determined that age and height are *uncorrelated*. However, in children, age and height are correlated; therefore, weight could be expressed as a function of weight versus age or weight versus height. In this last case, a multivariate analysis that focused on independent variables might simply produce the result that weight is a function of height and throw out the relationship between weight and age. Hence, when many variables are involved, caution must be applied so that experimentally important relationships are not missed because they do not mathematically add up to the results. Sophisticated statistical computer packages will look for these sorts of problems. Identifying a significant correlation among the different variables would suggest that some information may be lost if only independent variables are reported. If a simpler statistical program is used, then performing multivariate analyses with some of the variables left out would be wise to determine whether other possible relevant relationships appear.

Another type of problem that can be misleading with multivariable relationships occurs in the situation in which the computer program produces a variable that only weakly correlates with the data but does so with high reliability. This situation would be expressed in linear analysis as a result with a small correlation coefficient but a very good *P* value (more about *P* later). The fact that the correlation is likely real (i.e., not a statistical chance occurrence) does not offer much to the experimental analysis if the correlation is small—the data are not well explained by the relationship. Here, the confusion comes from the fact that although the correlation is weak and does not explain much, the calculation shows very high confidence in the presence of this weak correlation.

Hypothesis Testing. A very common use of statistical techniques is to test a question, called the *hypothesis*. Also often termed *significance testing,* this approach yields the valuable concept of the *P* value. It is the *P* value that is often used to summarize the statistical strength of the data analysis in supporting or rejecting the hypothesis. If groups were to be compared, then the test is often described as a comparison of the *null hypothesis,* which states that no difference exists between two groups of data, and the *alternative hypothesis,* which states that a difference does exist. If a single grouping of data were analyzed and two descriptions of the data were compared, such as determining whether the mean value of the group as calculated from the data is different from 0, then the two hypotheses would be *mean = 0* versus *mean = measured value ≠ 0*.

The *P* value is computed from the observed data as the probability of obtaining this data set if, in reality, the null hypothesis were true. It is important to note that this calculation assumes the null hypothesis and is not the same as saying that *P* is the probability that the alternative hypothesis is true. If, in reality, the null hypothesis is true, then it would be unlikely that something else would be observed in the data. In actual experimental situations, all data have some randomness; therefore, one can never be certain that observation is not simply chance and bad luck.

In hypothesis testing, a *level of significance,* termed the *alpha* value, is chosen; if *P* is less than alpha, then the result can be declared statistically significant and accepted as true. If *P* is not less than alpha, then the hypothesis is rejected (equivalent to accepting the null hypothesis). Remember the logical sequence: alpha is chosen in advance, and then *P* is computed from the data. If *P* is less than alpha, then the hypothesis is accepted and the null hypothesis is rejected. The *P* value is the chance that the null hypothesis was true but, through bad luck, the data came out as observed anyhow. Typically, alpha is set equal to .05, and *P* is less than that. For that *P* value, it would mean that the chance of the data coming out this way was less than a probability of 5% ($P = .05$) if the null hypothesis were, in fact, true.

Choosing the level of significance is an arbitrary decision. Investigators might want to be very sure that they did not erroneously reject the null hypothesis and set alpha at .01. It is common in biomedical studies to pick an alpha value of .05. In addition, a very small *P* value may lead the analyst to reject the null hypothesis but may not give much information about the exact nature of the alternative. As an example, tossing a coin and getting six heads in a row might lead analysts to reject the null hypothesis that the coin is a fair coin, but it is not enough information to suggest that the coin always comes up heads. The *P* value is calculated from the data assuming the null hypothesis, and the use of a small value of *P* allows the rejection of the null hypothesis, yet that does not fully characterize the alternative hypothesis.

Power. It should seem intuitively obvious that the ability of a statistical test to make a valid determination depends on the amount of data available. With only a few observations or data points, investigators cannot be as certain about a conclusion as if they had large amounts of data. If the goal were to determine the fairness of a coin, then tossing it twice would not be convincing of much; tossing it a thousand times, however, would present a good idea about the nature of the coin. In statistical hypothesis testing, the *power* of a study is a description of the ability of the study to detect a true difference. A statistical hypothesis test may fail to achieve significance (fail to get $P <$ alpha) if either the data truly do not reflect a difference or if there are so few data points that the mathematics yields a poor *P* value. A *beta error* is defined as the probability of falsely accepting the null hypothesis (calculated by assuming that the alternative hypothesis is true), and the *power* = 1 – beta. For the power to be good,

that is, for the beta value to be small, the study must have enough data points to ensure that if a difference is observed between the null and alternative hypotheses, then it can be accepted with reliability.

A sample size calculation is often performed before an experiment is undertaken to determine how much data would be necessary to have a reasonable chance of observing what is guessed to be the observed result. Standard computer programs are available that will compute the number of data points necessary when the alpha and power values are provided and some estimate is made of the likely observed effect. Being cautious about any study that is interpreted as *negative* (i.e., no significant difference between the study groups is reported) is important. It may be that no difference truly exists, but it may also be that the sample size is too small to determine a difference with statistical significance.

Confidence Intervals. Using *confidence intervals* as a description of the statistical determination is becoming more common in reporting statistical measurements. A range of values may be given such that it is determined with some likelihood (often at 95%) that the true values lay within that range. For expressing simple results, the confidence interval is equivalent to providing a mean ± SD. This method becomes particularly useful for describing results when describing "no difference" in the correct statistical fashion. Here, the proper description would be that the true difference lies in an interval less than *x* with the given statistical confidence.

To summarize, the following is wanted for hypothesis testing:

- Null hypothesis (e.g., mean = 0)
- Alternative hypothesis (e.g., mean = m)
- Alpha value (chosen in advance; e.g., alpha = .05)
- Power (chosen in advance in conjunction with a sample size calculation to ensure enough data points; e.g., power = 0.8)
- P value—computed for data

The difference between the null and the alternative hypotheses could be significant if *P* is less than alpha. If a value is being described, then a difference could be considered a confidence interval; and if there is *"no difference,"* then the difference (if any) in the interval could be described as less than some computed value.

STUDY DESIGN

The essence of scientific study is generally some numerical determination of a result. This numerical analysis is approached with statistical calculations. However, without a careful design of the study in the way that the numerical data are generated, formal statistical analysis of the numbers will yield scant benefits and may even be misleading. In the typical study, analysts are usually attempting to either characterize some variable (e.g., mean or trend) or make a choice to accept or reject among various hypotheses. No matter what the question, analysts must always be careful that the results genuinely answer the question and that they are not misleading themselves with inappropriate conclusions.

Scientific studies may be *observational studies* during which data are gathered without performing any specific intervention affecting the assignment of groups or effects on group members. Because investigators in an observational study have to take what they find as data, they are always subject to other unrecognized factors that may distort their interpretation or limit their ability to ask questions about the data.

In an *interventional* study, investigators pick the group members, determine what is being done to them, and attempt to look out for and eliminate potential confusion before the data are collected. A *clinical trial* is a typical interventional study in which different therapies are compared.

In the design of a scientific study, one major fear is a statistical *bias,* which is a systematic effect in the study that produces an error in the interpretation of the results. When considering the various possible study designs, analysts need to beware of the potential biases that may creep in. A *selection bias* occurs when groups are compared with respect to some variable but analysts do not realize that the groups are different in other (but important) ways. Because groups of subjects may differ in multiple ways, the assignment of subjects into groups may result, either from misdirected choice or random bad luck, in groups that are not fairly comparable. Consequently, although the results are thought to be determined by the variable under study, it may actually be that some other factor results in a misleading conclusion. As an example, consider a study that is comparing surgical and medical treatment of some illness and ends up with a grouping in which a higher proportion of men than women are undergoing surgical therapy. Any conclusion from this study about surgery versus medical therapy is biased and might be truly reflecting simply the difference in the results of therapy on men versus women.

A *confounding bias* occurs when multiple variables are intimately intertwined so that although the variable under study is assumed to be important, the truth is that the confounding variable is more important. As an example, consider a study attempting to determine the effects of obesity on longevity. Because diabetes mellitus is closely correlated to obesity, a result that purported to be about obesity might easily be more accurate about diabetes. When variables do not correlate with each other so that changes in one variable do not go along with changes in the other, they are called (in a rough nonmathematical sense) *independent variables*. Variables that are correlated with each other are not independent.

A *measurement* bias occurs if the methods used for making measurements when comparing different groups have different scales or sensitivities. As an example, consider attempting to get a history of chest pain in groups of patients with and without known coronary artery disease. Patients who know that they have heart disease might be imagined to remember brief pain more thoroughly than healthy patients, or perhaps they might deny pain more in their wish to believe that they are healthy. Here, the art of the experimenter is to predict and avoid such biases.

In a *blinded* study (more properly called a *masked* study), measurement bias may be avoided if the person performing the measurement does not know which group is being measured, thereby avoiding subtle measurement bias in approaching or determining the data. As an example, consider an active drug being compared with an inactive placebo. A researcher who knows which patient is taking the active drug might be more diligent in pursuing benefits or side effects. In a *double-blind* clinical study, neither the patients nor the experimenters obtaining the data should know which participants are in which group to avoid subtle measurement bias.

Observational studies may be categorized as case, case-control, or cohort studies. In a simple *case study,* an individual case or group of cases is reported. Such reports may demonstrate the existence of some observation or effect, provide the presumably typical character of the observation, and suggest a therapy or natural history. These types of studies do not have the nature of a proof because it is always a possibility that some other hidden effect is producing the observation or that the observed characteristics are atypical in some fashion. Nevertheless, often "seeing is believing"; so much of what is reported in medicine is in the form of case observations.

The distinction between cohort and case-control studies is important but often misinterpreted. In both categories, groups of subjects are compared, usually in regard to the effects of some intervention. In a *case-control* study, the factor separating the groups is determined *after* the intervention. Typically, a comparison is made of some outcome in one group, the case group, versus a similar group that does not have the outcome and functions as the control group. Because the groups are separated after the intervention, selection biases or unappreciated confounding variables can mislead the investigators. As an example, consider a study investigating the effects of hypertension on surgical mortality. If the groups are divided into patients with and without perioperative cardiac events, one group may be different from the other. However, such a result may be misleading; perhaps it is the renal disease associated with the hypertension that is significant (a confounding bias). Alternatively, perhaps patients with hypertension are sent to surgery by their physicians only when they have worse surgical problems; therefore, the groups are not fairly compared (a selection bias).

In a cohort study, the study group is monitored before the intervention occurs. The group is assembled to be as similar as possible and then monitored forward in time. Such studies are useful for describing the natural history of disease and may be helpful in suggesting causes. However, as with the other observational studies, selection and confounding bias may occur and lead to misleading results.

A case-control study is sometimes termed a *retrospective* study because the analysis can only be done after the participants complete the study to determine to which group they belong. In this sense, a cohort study is a *prospective* study inasmuch as the data must be gathered before the intervention. Unfortunately, these terms may be misused because, obviously, a case-control study can be planned in advance (*prospectively*). In addition, no matter how truly prospective a study is, once the data are gathered, the analyses are performed after the fact (*retrospectively*). These terms are best avoided.

After considering the nature of observational trials, the strength of the interventional clinical trial is recognized, in which the investigators determine the membership of the groups to be compared in advance and attempt to make the groups as similar as possible. In a *randomized clinical trial,* the participants are assigned by chance to the groups; consequently, if some fluctuations in the participants or some subtle selection bias is present, then the effect will be the same in each group (and presumably cancel out in the result). Such a study is necessarily prospective in nature.

Randomized clinical trials are the idealized standard in medical research because they offer the best chance to minimize biases. However, the effort and expense in setting up a clinical trial may be considerable. Such a trial requires patients to be enrolled before the medical intervention is performed. Patients give up the choice of the therapy that they receive and allow their therapy to be randomly selected among various options. Such trials (even if they involve standard therapies) require full ethical board clearance and explicit patient consent.

Even with the best clinical trial methodology, potential difficulties include dealing with subtle selection biases regarding who is entered into the trial. Studies that are actively watched by investigators and their highly motivated associates may result in atypical practices that cannot be generalized into standard clinical practice. The patients in clinical trials are themselves mostly motivated by the search for personal benefit and cannot be depended on to follow protocols strictly or to stay with a program that does not appear to be successful.

DATA DREDGING AND THE PROBLEM OF MULTIPLE COMPARISONS

In all statistical interpretations regarding the acceptance of data-determined conclusions, the random chance of a highly unlikely statistical result being misinterpreted as the typical true conclusion is always recognized as a possibility. A coin tossed six times and coming up all heads might lead to the conclusion that the coin was not fairly balanced, yet that will happen every $2^6 = 64$ times that it is attempted even with an entirely fair coin. When an alpha value of .05 is picked, investigators are saying that approximately 5% of the time they will accept misleading random errors as though they were true. This is roughly equivalent to recognizing that for every 20 experiments, perhaps 1 will be wrongly accepted as true based solely on bad luck and random chance. If a large set of data is analyzed in many ways, then some random results may appear statistically significant, simply based on this sort of chance. This is the error of *data dredging* and typically occurs when too many variables are examined for correlations within a single data set—by random chance something will be found that appears significant.

In a similar manner, if a very large number of independent comparisons are made between two groups of subjects and an error rate of 5% is accepted, then a false but statistically "significant" result may occur approximately

once for every 20 comparisons made. This is the error of *multiple comparisons*. Mathematical methods are available to correct for these errors—what is most relevant for the consumer of the statistical analysis is to recognize the presence of the error and look for the correction.

CHOICE OF TESTS

Nonparametric Statistics

When calculating the random distribution of some variable, visualizing the values as clustered around some center value in the well-known bell-shaped (termed *normal*) distribution is easy. However, as noted earlier, not all data have such a nice distribution. Data that are not in interval format, such as nominal data (e.g., red, black; male, female) or ordinal data (first, third), cannot be described by mathematical distributions with parameters such as the mean or SD. Such a situation calls for nonparametric statistics. Nonparametric statistical methods are typically used for the analysis of nominal or ordinal data. Data that are distributed in a very atypical skewed fashion (a *nonnormal* distribution) will not be properly handled by analyses that have the mathematical assumptions of normality; such data will need nonparametric analysis.

The first step in considering the choice of a statistical test is to decide whether statistical methods that assume a normal distribution are appropriate or whether nonparametric methods are needed (Table 111-2). A test for normality is included in typical statistical computer packages. Often simple inspection of frequencies in tabular or graphic form will convey much information.

Contingency Tables

A very common nonparametric statistical problem is the analysis of a table of data in which each cell in the table is a count in a particular category. The question is to determine whether the groups are statistically different from one another. As an example, consider the question of men versus women and their political affiliation, Republican versus Democrat, in which a 2 × 2 table is generated. If additional political groups are added, for example, Green and Undeclared, then a 2 × 4 table is generated. If these data are to be analyzed to determine whether men and women differ in political affiliation or whether Democrats versus Greens differ in gender distribution, then nonparametric statistical methods appropriate to a contingency table would be applied.

Paired versus Unpaired Data

If statistical methods are applied to analyze data from multiple groups and each individual data point comes from a separate and distinct source, then the mathematics behind the statistics assumes an independence and randomness that would not be the same if the sources are highly related. As an example, consider a study of blood pressure in two groups of patients, one treated with medication and the other untreated. Because blood pressure measurements can be widely scattered in distribution, depending on the patients' previous medical conditions, a small drug effect might be difficult to notice. However, if the same individuals were studied before and after therapy, then the wide initial variations might cancel out and small effects would be noticed. In this latter study, the data points can be paired, one in each group, to detect these small effects. A study in which the data can be paired can be very sensitive in picking out small changes. Conversely, the erroneous use of paired statistics might suggest a statistically significant result when one does not exist.

Two-Group versus Multiple-Group Analysis

In a simple statistical analysis, one group of data may be characterized or a comparison may be made of that group with a standard value. Comparing two groups is slightly more intricate when the goal is to characterize each group and determine whether the groups are statistically different. Significantly more concern must be applied to the situation with three or more groups. In the case of multiple groups, two distinct types of questions can be asked. First, knowing whether the groups are significantly different or whether they are all the same (with any numerical differences attributed solely to random fluctuations) might be necessary. Second, if the conclusion is that the groups are not all statistically the same, then knowing which groups are different from one another might be desirable—that is, are they all distinct or are just one or a few different, whereas the rest are similar to each other?

In summary, three questions should be asked when choosing between tests (see Table 111-2):

1. One group, two groups, or many groups?
2. Paired or unpaired groups?
3. Parametric (interval data after a normal distribution) or nonparametric methods?

TABLE 111-2 **CHOICE OF TESTS**

Comparison Goal	Normally Distributed (Parametric) Interval Data	Nonparametric Interval Data	Categorical Data
Describe group	Mean ± SD	Median, mode, percentile	Counts and proportions
Compare group with value	t-Test	Wilcoxon	Chi-square
Compare two groups	Unpaired t-test	Mann-Whitney	Chi-square, Fisher
Two paired groups	Paired t-test	Wilcoxon	McNemar
Three or more groups	ANOVA	Kruskal-Wallis	Chi-square
Multiple matched groups	Repeated-measures ANOVA	Friedman	—
Regression	Linear regression	Nonparametric regression	Logistic regression

ANOVA, Analysis of variance; *SD*, standard deviation.

Bayesian Approach to Probability

The commonsense meaning of the term *probability* can readily become confusing within the mathematical morass of formal statistics. In practice, two definitions for probability are commonly used and interchanged. In the *frequentist* approach, the probability of an occurrence is viewed as the fraction of occasions that a selected event would occur if the trial were repeated many times. In other words, the probability of a fair coin coming up heads is .5 because if it is tossed many times, then approximately 50% of the tosses would come up heads.

However, in many real-life situations, repeating the trials many times to get a frequency of occurrence for an event cannot happen. In the *subjectivist* approach, a probability is assigned to an event, based on a best guess or opinion. Such subjective assessments are very similar to what is done in medicine when an interpretation is made on the basis of opinion and experience. This approach is often termed *Bayesian* statistics because of a mathematical formula, Bayes' equation, which is used to manipulate subjective probabilities.

The powerful practical insight that comes from Bayesian statistics lies in the requirement that statistical calculations is begun with an initial probability of an event. This very much matches the real-life situation in which any test or prediction depends on the patient under study. It is generally medically unwise to consider a diagnosis for a patient unless the patient's own characteristics are taken into account. It is obvious to any clinician that an abnormal cardiogram suggesting myocardial ischemia would not mean the same thing in a healthy 30 year old as it would in his obese hypertensive grandfather. In a similar argument, a negative exercise stress test does not give great confidence that a very high–risk patient is free of cardiac disease (because the chance of disease is so high and stress tests are notorious for missing disease in some patients).

In medical situations, Bayesian statistics are mostly used for the interpretation of diagnostic or predictive data. The term *Bayesian* is often an indication that the patient or population's *a priori* chances of disease should be considered when applying a predictive test.

When using diagnostic or predictive tests, the concepts of sensitivity and specificity are very useful because they are not dependent on the population. *Sensitivity* is, approximately, the ability of the test to detect the disease when truly present, and *specificity* indicates the ability of the test to avoid a false indication of the disease when truly absent. To use these terms, four possible situations are defined:

True positive (TP): The patient has disease, and the test is positive.
False positive (FP): The patient does not have disease, and the test is positive.
True negative (TN): The patient does not have disease, and the test is negative.
False negative (FN): The patient has disease, and the test is negative.

By definition,

$$\text{Sensitivity} = \text{TP}/(\text{TP} + \text{FN})$$

$$\text{Specificity} = \text{TN}/(\text{TN} + \text{FP})$$

The ideal test has a sensitivity of 1, which indicates that the test picks up all patients with the disease, and a specificity of 1, which indicates that the test never falsely claims that a healthy patient is diseased.

In addition, defining the following is also useful:

$$\text{Positive predictive value (PPV)} = \text{TP}/(\text{TP} + \text{FP})$$

$$\text{Negative predictive value (NPV)} = \text{TN}/(\text{TN} + \text{FN})$$

Although the sensitivity and specificity of a test do not depend on the characteristics of the population, it must be remembered that they certainly do depend on the quality of the test. However, PPV and NPV are dependent on the tested population—this situation is where the authors' comment about *Bayesian* is relevant. (Although it is not the goal of this chapter to prove these claims, the reader may be convinced by considering what happens to sensitivity, specificity, PPV, and NPV in situations during which the test is applied to a population in whom the disease is absent—only TN and FP are nonzero. PPV is vanishingly small and NPV approaches 1; similarly, for a population with almost all patients having disease, PPV goes to 1 and NPV vanishes.)

The Bayesian insight can now be stated that diagnostic or predictive tests are only applied to populations of patients who are somewhat likely to test positive but not "excessively" so. If patients who are very likely to test positive are tested, then a positive test is confirmatory and a negative result may be more likely a FN than a TN result. Similarly, if the tested population is very unlikely to have the specified disease, then a negative test is only confirmatory and a positive test is more likely a FP rather than a TP result.

Meta-Analysis

The statistical strength of a clinical investigation is generally related to the size of the patient population. Unfortunately, because of the expense, difficulty, and poor patient availability, many clinical studies involve small study groups with conclusions that may have poor statistical power. The technique of meta-analysis can be used to join relatively similar groups to achieve a total population size where the outcome can have computed statistical validity. This may either combine the evidence to support a conclusion or show variability between study groups that may reduce the believability of the conclusion. Of course, such combining of different research projects makes the possibly tenuous assumption that all the groups are similar in both participants and interventions. The combination of several studies of the same question may correct for a systematic error at one local site but is also vulnerable to bias because the combination will be weighted to favor groups with larger numbers of participants.

Propensity Scoring

This popular correction scheme has been used to compare different groups of subjects in a clinical trial when the groups are not necessarily identical. By computing correction factors for various initial risks, the groups can

be made to appear similar enough to be matched; therefore, the outcome of a study comparing the groups can be regarded as comparing genuinely similar groups. These correction factors are termed *propensity scores* because they balance out the propensity of the differing groups to respond to the studied intervention and, hence, can provide an unbiased estimation of a treatment effect. Although the scoring methods can be mathematically validated by making multiple comparisons within the groups or using other groupings, the technique seems open to question about subtle bias.

EVIDENCE-BASED MEDICINE

Making judgments in science is an intricate process. Medical decision making is formed by theoretical reasoning, extrapolation from empirical data, traditional conventions, and, often, local authorities. Most modern philosophers of science recognize that the old view of the scientific method as a totally unbiased approach to the interpretation of raw data is naive. All the data collected in any experiment are created, selected, and interpreted within the context of a theory-based view of the world. Science is the derivation of a set of generalized laws, consistent with each other, based on empirical data, and able to predict or explain further data. Often, more than one theoretical explanation can be generally given for any one set of data. The choice of a scientific explanation, similar to the choice of a statistical test, is always based on a prior understanding of the data and experimental situation.

All this being the case, it must still be stressed that modern medicine has passed from the era when *practice* and *art* were sufficient justification for medical decision making. *Evidence-based medicine* is the fashionable term for the approach to medical decision making in which careful use is made of the applicable experimental scientific data. Controlled clinical trials and large-scale observational studies are important methods for this approach. A *meta-analysis* is a report of data that combines results from multiple similar studies to create a statistically more powerful study with many more data points and a better opportunity to come to a statistically significant conclusion.

The practicing clinician has many sources that analyze empirical evidence and provide guidance for medical decisions. Governmental groups and private medical organizations have produced many guidelines and clinical practice documents that assess the quality of available evidence and make suggestions. To give further guidance, these suggestions may also be ranked by confidence. The most reliable data backed by well-established theories would give recommendations with the greatest weight. Reports that are backed by weaker data, such as uncontrolled studies, give recommendations with less confidence in the evidence.

SUMMARY

Clinicians use statistical methodology to both analyze their own data and assess the value of others' scientific reports. Because data analysis is generally the application of one of a number of commercial computer packages, each with its own menus, formatting, and subtle caveats, the most valuable suggestion to the budding statistician is to know the program, read the manual, and plot the data. The human visual system is well adapted to recognize groups and trends—if the conclusions do not appear like they fit the data, then caution and skepticism are prudent.

When assessing the value of a scientific report, a careful clinician reads the methods section and asks the questions suggested earlier: Are the subjects selected to minimize bias? Are the statistical methods appropriate? Is the study large enough to be statistically powerful? Are the conclusions warranted by the evidence? Can the conclusions from this study be extended to cover more general cases, or do they apply only to the limited situation under study?

Finally, despite the best statistical approaches and the most careful experimental procedures, a wise clinician recognizes that even some apparently well-done experiments can yield erroneous conclusions. A study that produces an important clinical conclusion, especially one that seems to change tradition or violate previous theoretical understanding, bears confirmation by another group using different patients in a different setting. Healthy skepticism is the basis of good statistics and good science.

Bibliography

STANDARD STATISTICAL COMPUTER PACKAGES

Instat, GraphPad Software, San Diego, California.
A simple, very user-friendly program with good built-in help.

JMP, SAS Institute, Cary, North Carolina.
The SAS group's simple stand-alone program. Although relatively simple when compared with the full SAS program, its completeness leads to some complexity for the beginner.

SPSS, SPSS Inc., Chicago, Illinois.
A full-featured, expensive, and very powerful program that is accessible to the nonprofessional statistics user. The help files are usable and exhaustive.

SAS, SAS Institute, Cary, North Carolina.
Expensive, very complex, very powerful. This standard package of programs is the one most commonly used by professional biomedical statisticians. Not for the amateur.

(*Note*: Many simple and midlevel statistical programs are available, all of which require careful reading of the manual to be reliable!!)

SELECTED INTRODUCTORY STATISTICS TEXTS

Altman D: *Practical statistics for medical research*, Boca Raton, Fla, 1990, CRC Press.
Well organized and complete. A good course textbook.

Dawson B, Trapp RG: *Basic & clinical biostatistics*, New York, 2004, McGraw-Hill.
Suitable for self-study, fairly complete.

Feinstein A: *Clinical epidemiology*, Philadelphia, 1985, Saunders.
Enormously insightful about the structure and problems of clinical research. A classic worth looking at.

Glantz S: *Primer of biostatistics*, New York, 2011, McGraw-Hill.
Very clear, very popular; also has a very simple-to-use statistics program that may be purchased with the book.

Chapter 112

Evaluation and Classification of Evidence for the ASA Clinical Practice Guidelines

RICHARD T. CONNIS • DAVID G. NICKINOVICH • ROBERT A. CAPLAN • JEFFREY L. APFELBAUM

The proliferation of practice guidelines in medicine is accelerating as physicians and professional organizations seek to improve patient safety and reduce preventable causes of illness and death. Numerous practice guidelines are developed and published by medical specialty groups each year, and they constitute a major resource for clinical practice.[1-3] Although these documents have certain features in common (e.g., literature review, consensus formation), the *process* by which guidelines are developed has not been uniform.[4-6] Guidelines that use a consistent and transparent methodology for combining multiple diverse evidentiary sources are more likely to be understood and implemented in everyday practice.

Since 1991, the American Society of Anesthesiologists (ASA) has employed a methodology that entails a thorough evaluation of evidence to formulate guidelines and practice parameters for its 48,000 members and other health care providers. The underlying principle of this process is that evidence from diverse sources (not just the scientific literature) can be rigorously collected, sorted, assessed, and usefully synthesized (Fig. 112-1). The key steps in this process are (1) collection and organization of literature, (2) literature evaluation and mitigation of bias, (3) aggregation and classification of literature-based evidence, (4) evaluation of opinion-based evidence, and (5) a protocol for organizing and integrating the aggregated evidence. In the following sections, we describe the major features of these five key steps.

COLLECTION AND ORGANIZATION OF LITERATURE

The collection and assessment of scientific information begin with the identification of a specific clinical problem or issue. The selected issue is subsequently defined in terms of patient and clinical characteristics, practice settings, treatment or administrative providers, the intended users of the guideline, and an explicit set of inclusionary and exclusionary criteria. Next, statements that formally describe measurable relationships or "evidence linkages" between interventions and outcomes are specified.[7] Each treatment or intervention in an evidence linkage includes an indication of how, under specified conditions, it is expected to be associated with an outcome. Third, the evaluation and reporting of literature findings must be succinct, clear, and transparent, so that potential biases originating from the design, implementation, or reporting of a study can be identified.[8,9] When the clinical problem or issue has been sufficiently defined and the evidence linkages delineated, a comprehensive and systematic literature search can then be initiated.

As an initial screening tactic, articles are vetted by the working group or "task force" of 8 to 12 individuals from relevant diverse backgrounds (e.g., generalists, subspecialists, private or academic practitioners, methodologists) and different geographic regions so as complete an array of articles germane to the focus of the guideline as possible is targeted and selected. A *comprehensive* literature search attempts to capture all relevant articles identified through both electronic and manual searches. The search is *systematic* to the extent that it is guided by the defined boundaries of the search protocol and the expected outcomes associated with the identified clinical interventions. Use of a methodology that properly incorporates a comprehensive and systematic literature search protocol can reduce potential biases that may not otherwise be recognized during a less rigorous search.[10]

Once the initial literature search is complete, the review, evaluation, and data extraction process can begin. Organizing and summarizing data from a large number of articles are facilitated by using a "data extraction" spreadsheet or table in which patient outcome data associated with each intervention are recorded and categorized (Tables 112-1 to 112-3). This tabular method of organizing outcome data, arranged by intervention, allows for the recording of critical analytic features (e.g., sample size, study design, and statistical parameters) of each study. This tabulation facilitates the narrative reporting of findings, as well as the recording of data that can subsequently be used for formal statistical analyses (i.e., meta-analysis). Moreover, the presentation of outcomes in this format is useful for detecting whether different patterns of outcomes are associated with an intervention and can also highlight the occurrence of rare or unique outcomes.

LITERATURE EVALUATION AND MITIGATION OF BIAS

Because a guideline focuses on a specific clinical problem or issue, relevant literature is identified based on

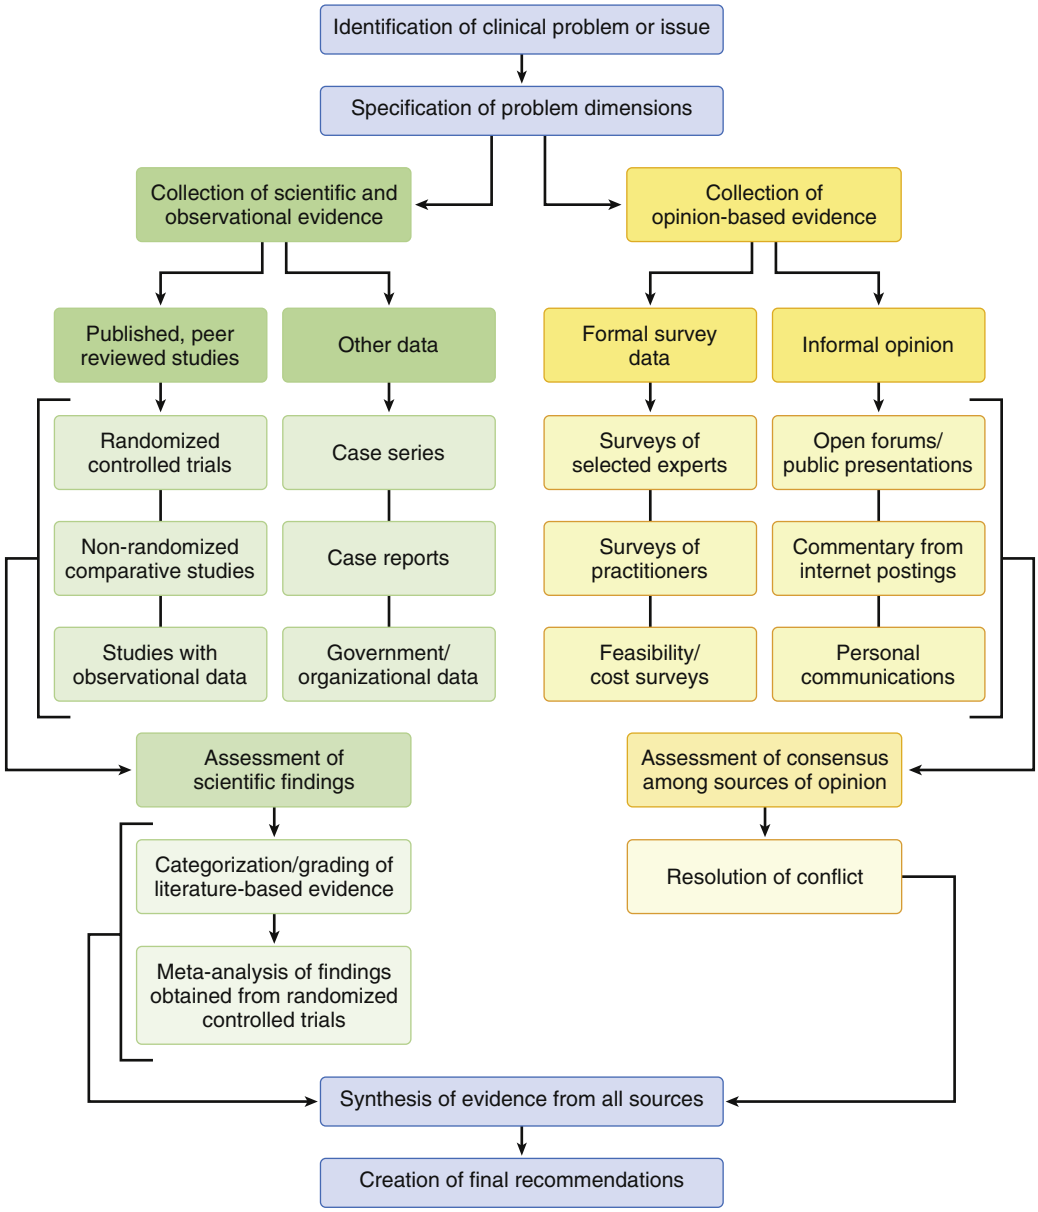

Figure 112-1. Evidence process flowchart.

the appropriateness of the patient sample and the relevance of the treatments or interventions identified in the various studies under review. In addition to a detailed recording of the clinical outcomes reported in each reviewed study, studies are also evaluated on the basis of research design, sample size, scale of measurement, power, and other traditional statistical parameters. The outcome findings reported in these studies are aggregated only if the patients in the different studies received essentially the same type of treatment and if similar types of patients (e.g., adult or pediatric patients, emergency or elective case patients) are represented in the studies. Each of these safeguards is predicated on an underlying concern with the identification and management of bias.

Identifying and managing bias are critical to the effective collection and synthesis of evidence. In general, bias associated with scientific literature–based evidence can arise from five major sources: (1) the article selection protocol, (2) the review process, (3) the reporting of findings from a predetermined type of article, (4) the evaluation of study design and statistical techniques, and (5) the grading or weighting of study quality. As an integral part of the ASA methodology, procedures are followed to mitigate the impact of these sources of bias. Practical countermeasures instituted for each type of bias are described in the following subsections.

ARTICLE SELECTION BIAS

One form of article selection bias occurs when studies are preferentially selected in the interest of promoting a viewpoint favored by the developers of a guideline. When individuals charged with reviewing and evaluating literature believe that a selected intervention is safe and effective, they may discount or exclude studies that

report contrary findings.[11] To safeguard against this type of bias, the literature used in the development of ASA guidelines is compiled from as large a collection of published articles as possible. The extensiveness of the ASA search protocol is immensely aided by the diverse clinical backgrounds and experiences of the task force participants, as noted earlier. This diversity helps ensure that the set of articles selected by the task force is as comprehensive as possible.

Article selection bias can also arise when editorials, letters, and position papers are used as sources of scientific evidence. These types of articles are often written to promote a particular point of view regarding an intervention or outcome of concern. Although some editorials and letters are informative and well documented, they likely have not been subjected to the same level of peer review as original research papers. The authors of these articles may or may not be experts, may rely on a narrowly selected subset of the literature, or may have intentionally written the article to be "controversial." Although these articles may be useful in highlighting certain clinical concerns or problems, they are not recognized as valid sources of literature-based evidence.

REVIEWER BIAS

Reviewer bias may occur when only one reviewer or type of professional (e.g., a biostatistician) extracts data and interprets study findings. Such a reviewer may not be fully cognizant of the constraints of the data or the proper context for analyzing and interpreting the reported findings (e.g., whether to combine data from studies that use different types of drugs, dosage levels, or routes of administration). Ideally, several individuals, including at least one clinician from each relevant subspecialty, should independently review all the literature. However, when several hundred studies must be reviewed, time and cost constraints prohibit such scrutiny. The ASA addresses this problem by conducting a "reliability check" during the development of each guideline. This reliability check entails the independent review of a randomly selected sample of articles by at least two methodologists (i.e., experts in research

Practice Guidelines for Chronic Pain Management: Reviewer Reliability Form[1]
American Society of Anesthesiologists

Please review your assigned literature and complete one form for each study:

1. Name of task force member_____

2. Name of first author of article and date_____

3. What type of experimental design was used in this study? ***(Circle the one best answer)***
   - A. None (*e.g.*, editorial, case report)
   - B. Observational design (*e.g.*, medical records review, closed-claims)
   - C. Prospective nonrandomized comparative (*e.g.*, quasi-experimental, cohort)
   - D. Randomized controlled trial (*e.g.*, randomized clinical trial)

4. What type of data analysis was used in this study? ***(Circle the one best answer)***
   - A. None (*e.g.*, editorial, case report, multiple case descriptions with no data)
   - B. Descriptive statistics (*e.g.*, percentages, frequencies)
   - C. Associative statistics (*e.g.*, correlations, regression analysis)
   - D. Comparative statistics (*e.g.*, t-test, Mann-Whitney U, Kruskall-Wallace W)

5. Which evidence linkage does this article best represent? ***(Circle the one best answer)***

1. None	12. TENS
2. History, PE & psychological evaluation	13. Epidural steroids
3. Interventional diagnostic procedures	14. Intrathecal drug therapies
4. Multidisciplinary programs	15. Anticonvulsants
5. Thermal intradiscal procedures	16. Antidepressants
6. Radiofrequency ablation	17. NMDA receptor antagonists
7. Acupuncture	18. Opioid therapy
8. Joint blocks	19. Topical agents
9. Nerve or nerve root blocks	20. Physical therapy
10. Botulinum toxin injections	21. Psychological treatment or counseling
11. Neuromodulation with electrical stimulus	22. Trigger point injections

6. Do you have a second choice for a linkage representation? (indicate number from above)_____

7. Do you think this article should be included in the database? Yes_____ No_____

8. (Optional). If "No" in question #7 above was selected, briefly indicate below why you think the article should not be included (back of page can be used for additional space).

[1] Survey form used in the development of the American Society of Anesthesiologists "Practice Guidelines for Chronic Pain Management: an Updated Report," *Anesthesiology 2010*; 112:810-833

Figure 112-2. Example of a reviewer reliability form.

design and analysis) *and* task force members. To ascertain whether bias has been introduced into the review process, a formal reliability assessment is conducted using a predetermined reliability form (Fig. 112-2). The information collected on this form is then assessed using sensitivity analysis,[12-17] and the findings obtained from this reliability assessment are reported in the guideline.

REPORTING BIAS

Reporting bias can result when only findings from a selected pool of literature are reported in the guidelines. Sometimes referred to as reporting the "best available literature," this form of bias attributes greater importance to certain types of literature (e.g., randomized controlled trials [RCTs]) while disregarding other types of literature (e.g., observational studies or case reports). This wholesale removal from consideration of findings from entire categories of evidence risks the underreporting of certain outcomes (e.g., rare or severe adverse effects) and the potential misrepresentation of benefits or harms associated with an intervention. To attenuate the impact of this type of bias, the ASA search protocol is not restricted to any particular type of literature and, in fact, deliberately searches for published case reports to ensure that the range of outcomes associated with any intervention is adequately covered.

BIAS ASSOCIATED WITH STUDY DESIGN

Study bias is a primary concern in any process of inquiry, and deliberate actions are needed to constrain its impact. The design features of RCTs provide, in principal, for an unbiased evaluation of the impact of an intervention and exemplify the "gold standard" for causal inference. Moreover, the prospective feature of the RCT avoids the problem of sequence timing because it mandates that any exposure to an intervention must appropriately precede

in time any measurement of outcome. Random allocation helps ensure that the reported findings are relatively unaffected by unmeasured risk factors or subject (patient) characteristics.[18] Comparability across study groups is facilitated, and the implied similarity in composition of study groups controls for potential confounding factors, whether measured or not.[19] The validity of findings obtained from RCTs is thus based on the extent to which the random assignment of patients to the different study groups equalizes the distribution of unmeasured patient risk factors or tendencies across study groups.

However, the gold standard status of RCTs assumes that they are conducted in full accordance and compliance with the formal design features of these studies. Problems can arise when compliance with the randomization protocol is not followed; moreover, inadequately concealed allocation or lack of blinding can produce assessment bias and overestimation of treatment effects. Additionally, it is important to assess whether important changes have occurred in the study population during the course of the study and to ensure that the study population adequately represents an important clinical population. Although many of these potential issues reside outside the domain of the task force, the last issue related to the clinical salience of study populations is directly addressed by the task force when precisely stipulating the focus of the guideline.

As previously noted, RCTs may underreport some important outcomes or may fail to identify rare outcomes. RCT findings may not be as specific or as thorough as those reported in non-RCT studies, which often provide more detailed lists of complications or adverse effects. Thus, exclusively focusing on RCTs may result in the underreporting or even nonreporting of important outcomes. RCTs can also be subject to nonrandom variability, which can arise from several sources, including the manner in which a study was conducted or early termination of a study.[19-21] At any point in the process (e.g., research design, identifying and measuring outcomes, analyzing the data, or reporting findings), nonrandom bias can misrepresent the effect size of an intervention, and the magnitude of this misrepresentation can vary by clinical topic.[22-28]

RCTs can provide evidence regarding the efficacy of an intervention, but they may be limited in their scope of inquiry.[6,9,29-31] Many important clinical questions are not or cannot be evaluated by RCTs, such as the incidence of a particular medical condition in the general population or patient subgroup characteristics associated with the risk of having a disorder. For many clinical issues, an RCT may not be conducted because of ethical concerns, legal restrictions, or feasibility constraints. To control for these problems, the ASA process incorporates the collection and evaluation of outcome data published in both RCT and non-RCT studies.

Although the absence of RCT evidence should not be regarded as the lack of evidence, findings associated with nonrandomized studies should be regarded with caution. Nonrandomized prospective studies, even those designed to minimize selection bias (e.g., quasiexperimental, cross-sectional, or cohort designs), risk the introduction of biases such as the overestimation of treatment effects or potential intragroup noncomparability.[32,33] Similar caution is needed when interpreting the findings of retrospective studies, (e.g., case-control studies) or, more generally, any study based on sampling by outcome. Nonetheless, when properly interpreted, observational studies can be of value in identifying potential covariates and in generating new testable hypotheses, but they do not provide direct causal evidence.

In an attempt to adjust or control for confounding features of observational studies, various statistical techniques, such as linear modeling with covariate adjustments and propensity score analysis, can be used.[34,35] These procedures tend to minimize nonrandom assignment bias by adjusting for potential influences of observed covariates, but they can never fully mitigate the bias introduced by unmeasured variables.[36,37] Statistical procedures are useful to show that the data may not support a valid estimate of causal effect; however, most observational studies lack the capability to evaluate the effect of confounding variables. As noted in the ASA "Practice Advisory for Preanesthetic Evaluation,"[38] multiple examples of confounding-based bias from observational data can be found in the preoperative diagnostic and testing literature, such as the absence or inability to blind the surgical team to the preoperative test findings, thereby potentially influencing the perioperative management of patients and confounding the association between preoperative testing and postoperative outcomes.

Thus, although RCTs represent the best available literature in terms of the accurate and valid assessment of effectiveness, the ASA search protocol includes other types of studies that may provide the best sources of evidence related to outcomes not evaluated by RCTs. To provide a comprehensive blend of evidence, the full range of outcomes must be reported regardless of study design.

BIAS ASSOCIATED WITH GRADING THE QUALITY OF RESEARCH

During the formulation of practice guidelines, formal systems for grading and weighting the quality of research studies are often used. Many different grading systems are available, some of which are based on earlier classification systems that graded RCTs on the basis of research design and data analysis criteria.[39-41] Although these grading systems are commonly used, they nevertheless can be subject to biases that limit their ability to determine the quality of the reported literature accurately.[42]

An accurate grade relies on full disclosure in the published studies of information pertinent to study design and analysis criteria. When a portion of this information is lacking, the assigned grade can be directly affected. For example, a well-designed, double-blind study may omit information pertinent to concealment of allocation. Even if the study did, in fact, effectively conceal allocation, it would not be reflected in the assigned grade because this information was not reported in the published article. Realistically, little can be done to manage this type of bias other than focusing on the aggregated studies as a quality indicator.

In addition, attributing a single weight to an intervention risks the introduction of bias because interventions are typically associated with any number of qualitatively different outcomes. For example, a pain medication may

reduce the occurrence of pain but may also increase the likelihood of vomiting. A reviewer must then judge which of the outcomes is the more clinically important. In some cases, the importance of one outcome compared with others is obvious (e.g., mortality versus satisfaction). In many other instances, a hierarchy of clinical importance is not clear, and a reviewer's judgment in pooling relevant outcomes to make global determinations of efficacy would thus be required. Rather than expose the guideline to this potential source of bias, the ASA separately categorizes the evidence for an intervention on the basis of *each specific reported outcome*. Separate findings for each outcome found to be associated with an intervention are then reported in the document. This level of transparency is a hallmark of the ASA process.

Finally, bias in quality assessment may also be generated when the reviewer is influenced by factors extraneous to the merits of the study under review. For example, the reviewer may have an opinion regarding journal quality or may have personal knowledge about study authors that can subtly or unknowingly influence decisions regarding quality. In some cases, the reviewer may have information about a study that was not reported in the publication, thereby affecting the reviewer's judgment when determining the grade for a study. This is mitigated by the ASA process through the use of multiple reviewers. The recognition and containment of potential bias when grading literature are other concerns that must be addressed when attempting to control the impact of bias.

AGGREGATION AND CLASSIFICATION OF LITERATURE-BASED EVIDENCE

On completion of the literature review and recording of clinical outcome data, evidence obtained from the aggregated literature is reported in the guideline. The ASA uses a standardized classification system based on study design that permits the reader of a guideline to understand the source of literature-based evidence clearly. This evidence can range from meta-analytic findings obtained from RCTs to outcomes published in case reports.

Findings for the aggregated literature are classified by evidence category, level, and direction (i.e., benefit versus harm). Evidence categories refer specifically to the *research design* of the studies specific to each evidence linkage (i.e., intervention-outcome set). *Category A* evidence represents results obtained solely from RCTs, whereas *category B* evidence represents observational results obtained from nonrandomized study designs, RCTs without pertinent controls, or case reports. When available, category A evidence receives precedence over category B evidence in the reporting of results in a published guideline. Evidence categories are further divided into evidence levels. Evidence levels refer specifically to the strength and quality of the summarized study *findings* (i.e., statistical findings, the type of data, and the number of studies reporting or replicating the findings) within the two evidence categories. Finally, a designation of benefit, harm, or equivocality for each outcome is documented. This system thus provides a clear and concise categorization of literature-based evidence (Box 112-1).

BOX 112-1 ***American Society of Anesthesiologists Literature Classifications***

Category A: Randomized controlled trials (RCTs) report comparative findings between clinical interventions for specified outcomes. Statistically significant ($P < .01$) outcomes are designated as either beneficial (B) or harmful (H) for the patient; statistically nonsignificant findings are designated as equivocal (E).
- *Level 1:* The literature contains a sufficient number of RCTs to conduct meta-analysis,* and meta-analytic findings from these aggregated studies are reported as evidence.
- *Level 2:* The literature contains multiple RCTs, but the number of RCTs is not sufficient to conduct a viable meta-analysis for the purpose of these guidelines. Findings from these RCTs are reported as evidence.
- *Level 3:* The literature contains a single RCT, and findings from this study are reported as evidence.

Category B: Observational studies or RCTs without pertinent comparison groups may permit *inference* of beneficial or harmful relationships among clinical interventions and outcomes. Inferred findings are given a directional designation of beneficial (B), harmful (H), or equivocal (E). For studies that report statistical findings, the threshold for significance is $P < .01$.
- *Level 1:* The literature contains observational comparisons (e.g., cohort, case-control research designs) among clinical interventions for a specified outcome.
- *Level 2:* The literature contains observational studies with associative statistics (e.g., relative risk, correlation, sensitivity and specificity).
- *Level 3:* The literature contains noncomparative observational studies with descriptive statistics (e.g., frequencies, percentages).
- *Level 4:* The literature contains case reports.
- *Insufficient Literature:* The *lack* of sufficient scientific evidence in the literature may occur when the evidence is either unavailable (i.e., no pertinent studies found) or inadequate. Inadequate literature cannot be used to assess relationships among clinical interventions and outcomes because such literature does not permit a clear interpretation of findings as a result of methodologic concerns (e.g., confounding in study design or implementation) or does not meet the criteria for content as defined in the "Focus" of the guidelines.

*All meta-analyses are conducted by the American Society of Anesthesiologists methodology group. Meta-analyses from other sources are reviewed but are not considered a source of original evidence.

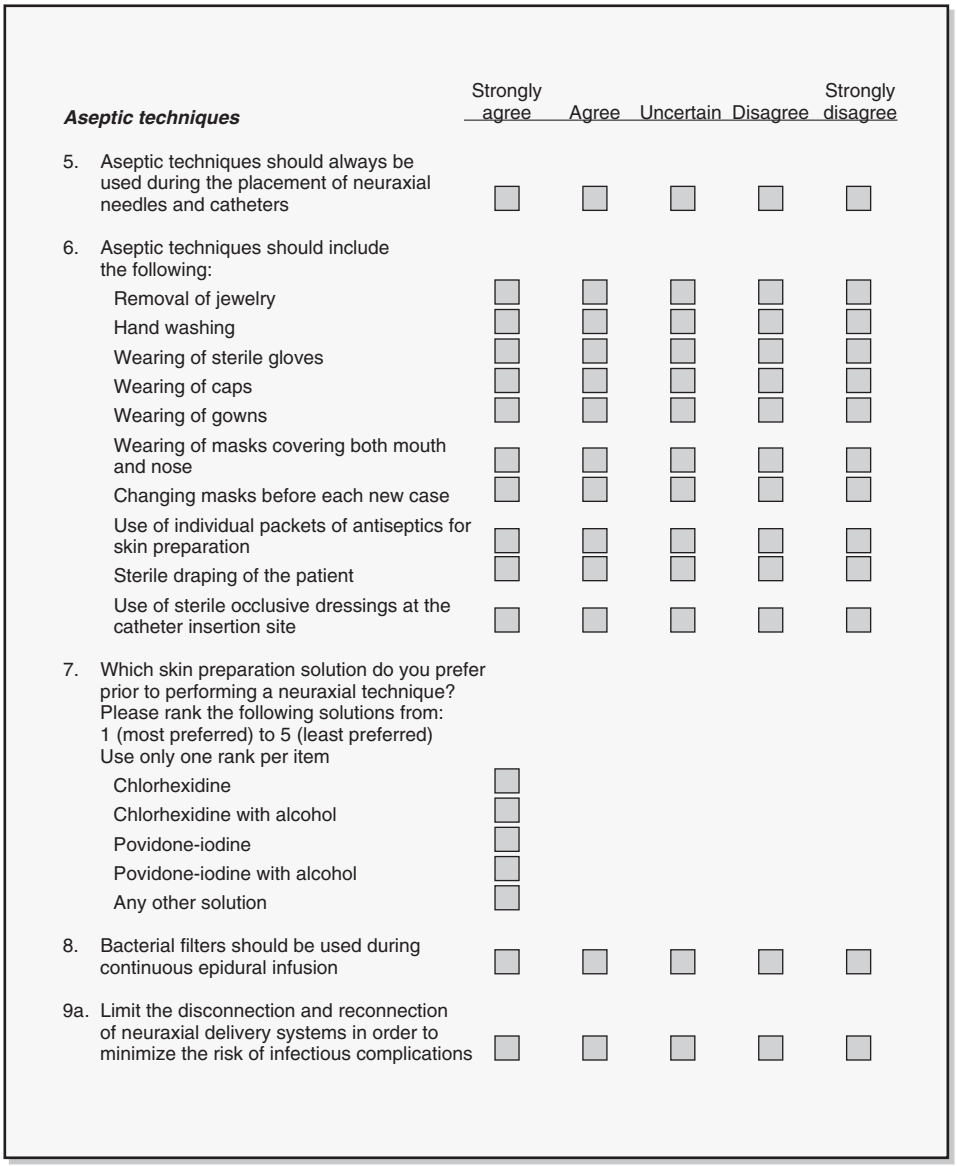
EVALUATION OF OPINION-BASED EVIDENCE

Although literature can provide compelling evidence regarding benefits or harms associated with an intervention, its value is often complemented by considering and synthesizing opinion-based evidence. These opinions often bear on issues that are critical to the acceptance and implementation of guidelines in clinical practice, such as resource utilization, cost, and workplace feasibility. During the development of guidelines by other organizations, this type of information is often overlooked, discounted, or given only brief consideration. Conversely, opinion-based evidence is systematically collected by the ASA to evaluate the extent to which the literature-based evidence and the specific recommendations formulated within a guideline are congruent with practitioners' experience and patient care.[43-45]

Practice Guidelines for the Prevention, Diagnosis and Management of Infectious Complications Associated with Neuraxial Techniques[1]
American Society of Anesthesiologists

Thank you for agreeing to serve as a consultant to the American Society of Anesthesiologists Task Force on Infectious Complications Associated with Neuraxial Techniques. Below are topics that are important in the development of our "Practice Advisory for the Prevention, Diagnosis and Management of Infectious Complications Associated with Neuraxial Techniques." Please respond by checking the items below which best represent your opinion.

I. Prevention of Infectious Complications Associated with Neuraxial Techniques:	Strongly agree	Agree	Uncertain	Disagree	Strongly disagree
1a. A history, physical examination, and review of relevant laboratory studies should be conducted prior to performing neuraxial techniques	☐	☐	☐	☐	☐
1b. A history, physical examination, and review of relevant laboratory studies is useful in identifying patients at increased risk of infectious complications prior to performing neuraxial techniques	☐	☐	☐	☐	☐
For patients determined to be at risk of infectious complications:					
2a. The decision to select a neuraxial technique should be made on a case-by-case basis	☐	☐	☐	☐	☐
2b. Alternatives to neuraxial techniques should be considered	☐	☐	☐	☐	☐
2c. Consider the evolving medical status of the patient when selecting a neuraxial technique	☐	☐	☐	☐	☐
3. When a neuraxial technique is selected in a known or suspected bacteremic patient, pre-procedure antibiotic therapy should be administered	☐	☐	☐	☐	☐
4. Lumbar puncture should be avoided in a patient with a known epidural abscess	☐	☐	☐	☐	☐



[1] Selected items from a consultant survey form used in the development of the American Society of Anesthesiologists "Practice Advisory for the Prevention, Diagnosis, and Management of Infectious Complications Associated with Neuraxial Techniques," *Anesthesiology 2010*; 112:530-545

Figure 112-3. Example of an expert consultant survey.

Continued

As with the literature, opinion-based evidence can be obtained from a variety of sources, and each source must be independently and thoroughly examined. Explicitly designed surveys are one means of systematically collecting opinion-based evidence.[46] For the ASA, the primary (but not exclusive) source of such information involves opinions obtained from surveys of experts and from a broad base of clinicians and other health care professionals.[43,44] The ASA guideline task force then identifies and critically reviews (1) the intended sampling frame, (2) the anticipated size of the response sample, (3) the expected response rate, (4) the specific wording of the questions, and (5) the manner in which the responses will be recorded. Formal standardized surveys are then sent to 75 to 150 "expert consultants" selected by members of the task force, as well as to a random sample of up to 5000 active members of the ASA.

Expert consultants are identified by the task force as individuals who are knowledgeable in the topics addressed by the guidelines and/or whose medical specialty or clinical practice is directly affected by the guidelines. The sampling frame for surveys sent to ASA members is the official registry of active members. A similar sampling frame is used for surveying members of subspecialty or other participating organizations. Identical surveys are sent to all groups, thereby permitting the clear recording of any "gap" or differences of opinion between them. Survey questions are *not* designed to assess the efficacy of an intervention. The questions directly address whether each intervention identified in a proposed guideline *should* be performed; the opinions of the respondents are measured in terms of their level of agreement or disagreement with the proposed recommendation (Fig. 112-3). Findings obtained from these surveys therefore provide a highly structured and pertinent source of evidence concerning the use of specific clinical interventions. These formal surveys generate a quantifiable source of opinion-based evidence that has

Aseptic techniques

	Strongly agree	Agree	Uncertain	Disagree	Strongly disagree
5. Aseptic techniques should always be used during the placement of neuraxial needles and catheters	☐	☐	☐	☐	☐
6. Aseptic techniques should include the following:					
Removal of jewelry	☐	☐	☐	☐	☐
Hand washing	☐	☐	☐	☐	☐
Wearing of sterile gloves	☐	☐	☐	☐	☐
Wearing of caps	☐	☐	☐	☐	☐
Wearing of gowns	☐	☐	☐	☐	☐
Wearing of masks covering both mouth and nose	☐	☐	☐	☐	☐
Changing masks before each new case	☐	☐	☐	☐	☐
Use of individual packets of antiseptics for skin preparation	☐	☐	☐	☐	☐
Sterile draping of the patient	☐	☐	☐	☐	☐
Use of sterile occlusive dressings at the catheter insertion site	☐	☐	☐	☐	☐
7. Which skin preparation solution do you prefer prior to performing a neuraxial technique? Please rank the following solutions from: 1 (most preferred) to 5 (least preferred) Use only one rank per item					
Chlorhexidine	☐				
Chlorhexidine with alcohol	☐				
Povidone-iodine	☐				
Povidone-iodine with alcohol	☐				
Any other solution	☐				
8. Bacterial filters should be used during continuous epidural infusion	☐	☐	☐	☐	☐
9a. Limit the disconnection and reconnection of neuraxial delivery systems in order to minimize the risk of infectious complications	☐	☐	☐	☐	☐

Figure 112-3, cont'd.

consistently proved to be invaluable in the development and finalization of guideline recommendations.

To attenuate potential biases that inherently reside in opinion-based information, the formal surveys developed by the task force are designed to measure opinions directly related to the same topics addressed during the literature evaluation. The set of intervention-outcome linkages identified in the evidence model and used during the search and evaluation of literature-based evidence is also used to formulate the individual items in the surveys. Therefore, to control for possible bias associated with how questions are worded, the ASA surveys use identical language to that used in the proposed recommendations. This survey design feature minimizes the chance of misunderstanding or misinterpreting the wording used in the final guideline recommendations.

In the text of the guidelines, a narrative summary of survey responses is provided and is expressed either in terms of percentage response for categoric questions or median values for the five-point response survey questions (Box 112-2). In addition, each practice guideline includes tables reporting the complete range of responses to each survey question recorded for the expert consultants, the broader sample of the randomly selected ASA membership and, when appropriate, members of other related organizations (Fig. 112-4). This opinion-based information elucidates and quantifies the opinions of professionals about the practicality and appropriateness of a proposed recommendation. Knowledge of the percentage of practitioners who do and who do not agree with a proposed recommendation is critical to the final articulation of a recommendation.

Besides information obtained from formal surveys, an informal source of opinion-based information is provided by the presentation and discussion of proposed recommendations at national meetings of physician organizations whose practice would be affected by the guidelines. Although the information collected is not quantifiable,

BOX 112-2 ***American Society of Anesthesiologists Survey Classifications***

Category A: Expert Opinion. Survey responses obtained from American Society of Anesthesiologists (ASA) task force–appointed expert consultants

Category B: Membership Opinion. Survey responses from a sample of members of the ASA and, when appropriate, responses from members of other organizations with expertise in the selected topics of interest

Survey responses may be dichotomous or are recorded using a five-point scale and summarized based on median values.*

Strongly Agree: Median score of 5 (at least 50% of the responses are 5)

Agree: Median score of 4 (at least 50% of the responses are 4 or 4 and 5)

Equivocal: Median score of 3 (at least 50% of the responses are 3, or no other response category or combination of similar categories contains at least 50% of the responses)

Disagree: Median score of 2 (at least 50% of responses are 2 or 1 and 2)

Strongly Disagree: Median score of 1 (at least 50% of responses are 1)

*When an equal number of responses is obtained, the median value is determined by calculating the arithmetic mean of the two middle values. Ties are determined by a predetermined formula.

Practice Guidelines for Management of the Difficult Airway: An Updated Report
American Society of Anesthesiologists

		Percent responding to each item[1]				
	N[2]	Strongly agree	Agree	Uncertain	Disagree	Strongly disagree
1. The likelihood and clinical impact of the following basic management problems should be assessed:						
Difficulty with patient cooperation or consent	66	60.6*	33.3	3.0	3.0	0.0
Difficult mask ventilation	66	93.9*	6.1	0.0	0.0	0.0
Difficult supraglottic placement	66	75.8*	21.2	1.5	1.5	0.0
Difficult laryngoscopy	66	84.8*	10.6	4.6	0.0	0.0
Difficult intubation	66	89.4*	9.1	1.5	0.0	0.0
Difficult surgical airway access	66	71.2*	24.2	4.6	0.0	0.0
2. Opportunities to deliver supplemental oxygen should be actively pursued throughout the process of difficult airway management.	66	86.4*	10.6	1.5	1.5	0.0
3. The relative merits and feasibility of the following basic management choices should be considered:						
Awake intubation vs. intubation after induction of general anesthesia.	66	78.8*	19.7	1.5	3.0	0.0
Non-invasive technique vs. invasive technique for initial approach to intubation.	66	54.5*	34.8	9.1	1.5	0.0
Preservation of spontaneous ventilation vs. ablation of spontaneous ventilation.	66	74.2*	21.2	1.5	1.5	1.5
Use of video-assisted laryngoscopy vs. rigid laryngoscopic blades as an initial approach to intubation.	66	48.5	25.8*	16.7	7.6	1.5
4. The following airway devices should be options for emergency non-invasive airway ventilation:						
Rigid bronchoscope	66	13.6	33.3	16.7*	30.3	6.1
Fiberoptic bronchoscope	66	69.7*	12.1	3.0	12.1	3.0
Supraglottic airway	66	92.4*	7.6	0.0	0.0	0.0
5. A videolaryngoscope should be included in the portable storage unit for difficult airway management.	66	71.2*	18.2	7.6	3.0	0.0
6. An airway history should be conducted, whenever feasible, prior to the initiation of anesthetic care and airway management in all patients.	66	90.9*	6.1	3.0	0.0	0.0

[1] An asterisk beside a percentage score indicates the median.
[2] N = number of consultants who responded to each item.

Figure 112-4. Example of survey findings from a table of consultant survey responses.

the input from individuals attending a presentation or "open forum" often identifies special problems arising from a proposed recommendation (e.g., the use of chlorhexidine as a skin disinfectant for neonates). To broaden the range of opinion-based sources of input further and to maximize input from as many sources as possible, copies of draft practice guidelines are posted on the public ASA website, along with accompanying documentation. Comments are invited from anyone reading the posted documents, and these unstructured comments are evaluated by the task force before finalizing a recommendation. In an effort to promote interdisciplinary collaboration and learning, comments and suggestions from other medical specialty organizations may be solicited.

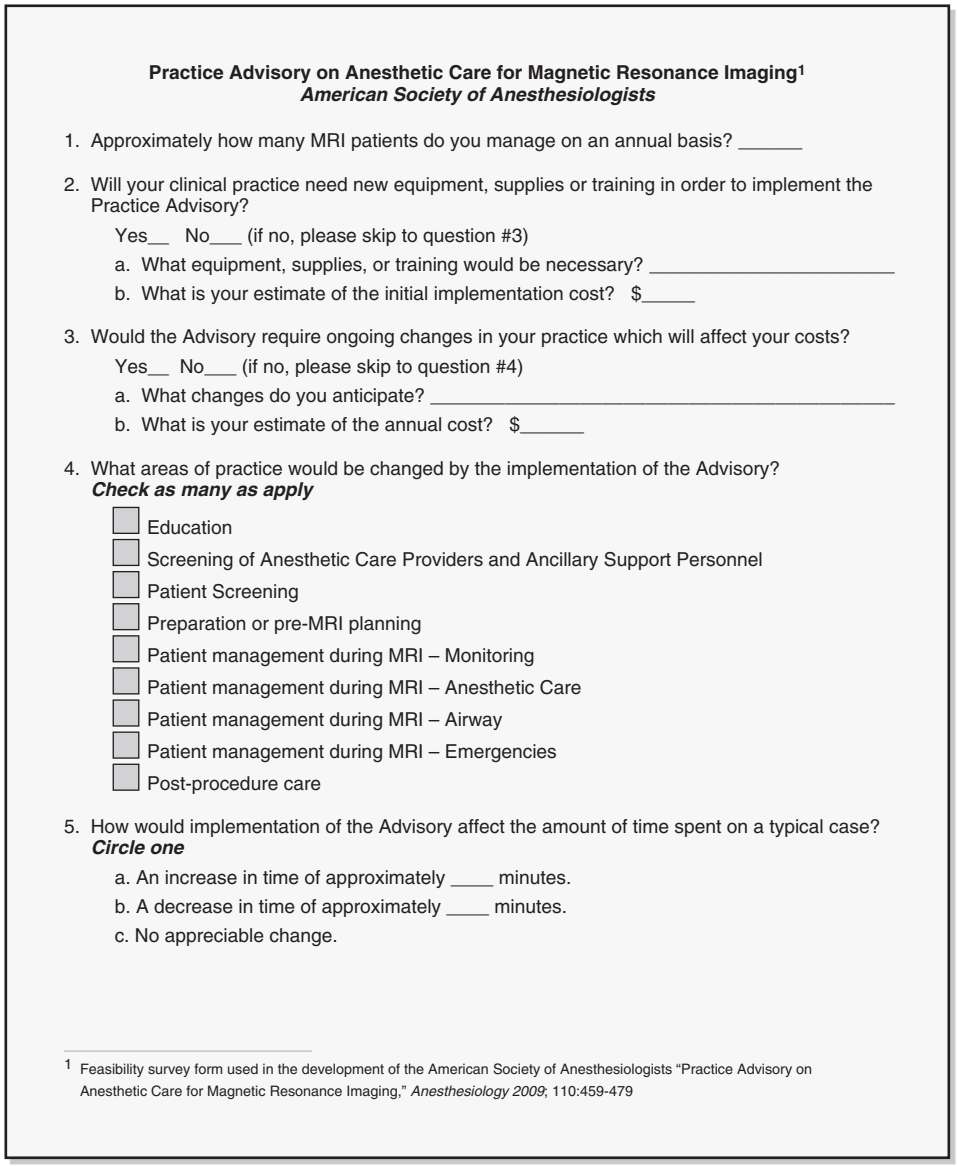
Each of these sources of opinion-based evidence is evaluated separately by the task force. If any disagreement is noted among these sources, additional information can be sought to attain consensus. The task force may then reevaluate all the assembled evidence before constructing a final recommendation. This reevaluation often results in mitigating or conditional statements accompanying a recommendation.

PROTOCOL FOR ORGANIZING AND INTEGRATING AGGREGATED EVIDENCE

When all information has been collected, organized, and evaluated, the task force determines where the literature and opinion-based evidence is complementary and where it is not. Strong literature-based evidence, particularly RCTs, in congruence with survey and other opinion-based evidence becomes the basis necessary for a strongly worded recommendation. When the literature-based evidence, even when strong, is not in congruence with opinion-based sources of evidence, the task force may consider terminology that is less pronounced or may offer alternatives to the routine application of a recommended intervention.

The intent of reviewing all categories of evidence collected during the development of a guideline is to ensure that the final recommendation has solid and broad-based evidence. Because the strength of a recommendation is based on congruence among the various categories of evidence, the final wording of a recommendation can reflect mitigating issues that may arise during the multiple vetting of the proposed recommendation. Rarely should a guideline recommendation be based solely on literature or opinion-based evidence. Other factors to consider include the readiness of practitioners to implement a recommended intervention and the regulatory requirements associated with an intervention. Therefore, a guideline task force must have the flexibility to make recommendations that are useful and applicable to a variety of clinical situations.

When recommendations have been written and a draft document has been created, a final survey is conducted addressing the feasibility and cost of implementing a guideline (Fig. 112-5). The ASA conducts these feasibility surveys by asking individuals with expertise in the affected area of practice questions such as the following:



1. Which areas of practice would change subsequent to the adaptation of a guideline?
2. What are the projected costs of implementing a guideline?
3. What is the projected increase or decrease in practitioner time associated with implementing a guideline?

These opinion-based feasibility estimates are critical to the final articulation of guideline recommendations.

The ASA methodology is designed to elicit patterns of evidence obtained from a broad set of sources, and it is applicable to the development of recommendations in any number of circumstances. Because the evidence for the ASA guidelines originates from two primary sources—published literature and practitioner opinion— this methodology is able to consider each source of evidence independently to identify patterns of evidence and the extent to which these patterns are consistent across the two primary sources. By examining these patterns, a guideline task force has the tools to assist them in the formulation of robust and useful recommendations.

To assist the reader in understanding these patterns, Figure 112-6 represents a color-coded visual depiction in which literature-based evidence is identified in the top rows, followed by formal survey evidence, and finally by informal opinion-based evidence. Evidence of benefit to the patient is noted in green or blue, whereas harm is noted in reds or oranges. Stronger categories of findings are noted in darker colors; no effect or "equivocal" evidence remains uncolored. Using this type of matrix, patterns emerge that can guide the working group in writing recommendations. For example, when darker colors (green/blue or red/orange) are consistently shown, the task force may be confident in making strong recommendations. A mix of colors may prompt the group to be more cautious with a recommendation or provide more detail regarding the implementation of a recommended intervention. Using these patterns, the task force can prepare fully transparent recommendations that adhere to their evidence-based justifications.

As the final step in the implementation of a guideline, a process of approval is initiated. Approval processes vary considerably across organizations, and they usually culminate in action by a governing body. For the ASA, the process begins with approval by the Committee on Standards and Practice Parameters (Committee) and ends with approval (by vote) in the House of Delegates. The Committee submits the document to the House of Delegates for one more vetting process by formal Reference Committee review. This review is conducted by holding hearings open to ASA members wishing to comment on the proposed guideline and its recommendations. The Reference Committee then submits a recommendation for approval or disapproval to the House of Delegates, and the House of Delegates, in turn, votes on approval or disapproval without any changes to the guideline document. Should the guideline fail to be approved, the House of Delegates may direct the Committee to address concerns that have arisen and submit a revised guideline the following year. This review process allows for a thorough vetting of the guideline before its final acceptance and endorsement on behalf of the members of ASA.

Practice Advisory on Anesthetic Care for Magnetic Resonance Imaging[1]
American Society of Anesthesiologists

1. Approximately how many MRI patients do you manage on an annual basis? _____

2. Will your clinical practice need new equipment, supplies or training in order to implement the Practice Advisory?
   Yes__ No___ (if no, please skip to question #3)
   a. What equipment, supplies, or training would be necessary? _____
   b. What is your estimate of the initial implementation cost? $_____

3. Would the Advisory require ongoing changes in your practice which will affect your costs?
   Yes__ No___ (if no, please skip to question #4)
   a. What changes do you anticipate? _____
   b. What is your estimate of the annual cost? $_____

4. What areas of practice would be changed by the implementation of the Advisory?
   Check as many as apply
   - ☐ Education
   - ☐ Screening of Anesthetic Care Providers and Ancillary Support Personnel
   - ☐ Patient Screening
   - ☐ Preparation or pre-MRI planning
   - ☐ Patient management during MRI – Monitoring
   - ☐ Patient management during MRI – Anesthetic Care
   - ☐ Patient management during MRI – Airway
   - ☐ Patient management during MRI – Emergencies
   - ☐ Post-procedure care

5. How would implementation of the Advisory affect the amount of time spent on a typical case?
   Circle one
   a. An increase in time of approximately ____ minutes.
   b. A decrease in time of approximately ____ minutes.
   c. No appreciable change.

[1] Feasibility survey form used in the development of the American Society of Anesthesiologists "Practice Advisory on Anesthetic Care for Magnetic Resonance Imaging," *Anesthesiology 2009*; 110:459-479

Figure 112-5. Example of a feasibility survey form.

SUMMARY AND CONCLUSIONS

Evidence-based guidelines are powerful instruments in the never-ending quest to improve patients' health and safety. These guidelines serve to educate clinicians and standardize practice in key areas of patient care. A complete and unbiased evaluation of scientific literature is essential and critical to this end. Literature-based sources of evidence include (1) RCTs for evidence of causation, (2) observational studies for evidence of association and description, and (3) case reports to identify rare or severe adverse events. However, scientific articles and observational literature should not be the sole sources of evidence for a guideline. Although literature is the primary source of scientific evidence for guidelines, other factors such as the feasibility, practicality, and professional acceptance of a recommendation also play a key role.

Supplementing scientific findings with opinion-based evidence allows for the creation of a broad base of evidentiary support, thereby mitigating the risk of narrow interpretations of findings. Data from properly conducted formal surveys offer important evidence associated with the appropriateness and practicality of a treatment, whereas informal opinions from open forums, the Internet, and other sources are useful for validation and feasibility of implementation. Moreover, other sources of information, such as large observational and administrative databases, may also be helpful.[47,48] Because these sources contain distinct varieties of informational types, some quantifiable and some not, each must be evaluated on its own merits as an element of the whole.

The increased use of concise and transparent evidence-based guidelines allows clinicians to be more confident in the quality of the evidence, given the comprehensiveness and rigor of the underlying methodology. The openly transparent process used by the ASA clearly displays to practitioners the means by which the evidence

Literature findings:
